

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

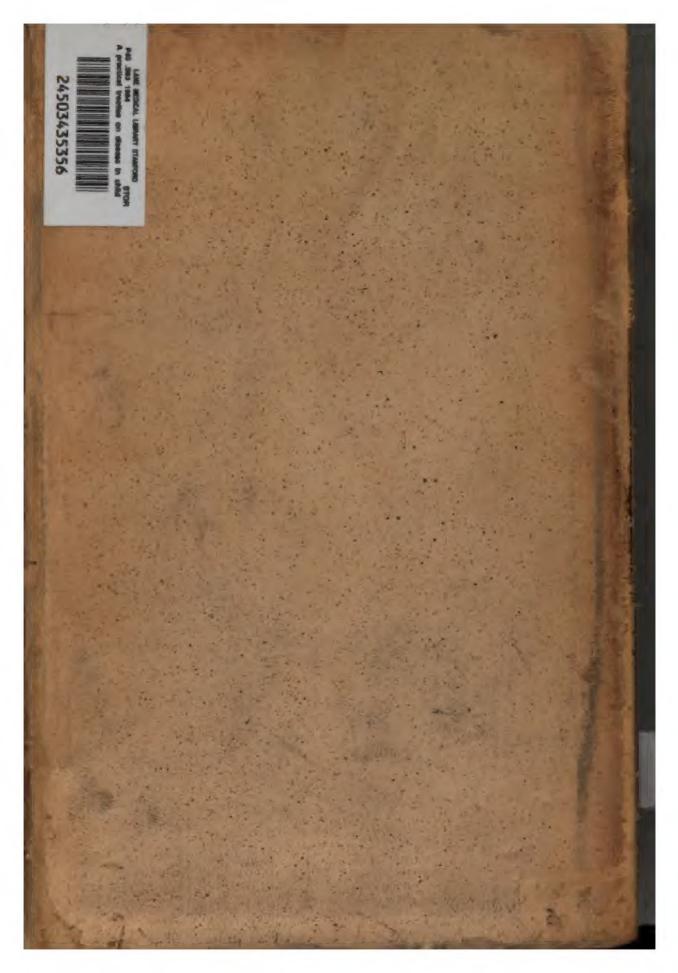

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + Make non-commercial use of the files We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + Refrain from automated querying Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + Maintain attribution The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + Keep it legal Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at http://books.google.com/

PREFACE.

It was not without hesitation that the author consented to the proposal made to him by Messrs. Wood & Company, of New York, that he should write for them a complete Treatise on the Diseases of Infancy and Childhood. The length of time which would be required for the completion of a task so considerable, and, especially, the knowledge that many manuals of varying merit were already in the field, indisposed him to attempt a work which must necessarily prove not only long but laborious. Encouraged, however, by the reflection that his opportunities for studying these complaints had been abundant; that in the course of more than twenty years he had acquired a mass of valuable material, and that of existing books few dealt with more than a part of the subject, he thought himself justified in believing that a treatise which undertook to discuss the whole subject of disease in early life, and to deal with the matter purely from a clinical stand-point, might not be without its uses.

The constitutional peculiarities of childhood, and the weakness due to immaturity, so shape the course and symptoms of disease that there are few complaints which do not assume special features when present in the young. Consequently the author has not hesitated to admit into his pages descriptions of every form of illness which is capable of being influenced in its manifestations by the early age of the patient. Those only have been purposely omitted which, like diabetes, present exactly the same characters in the child that they do in the adult.

Each subject has been treated as fully as the space would allow, but many faults of omission may, no doubt, be discovered. The author, however, has striven to satisfy all clinical requirements, and where much must be left out, that the book may be kept within reasonable limits, has been anxious to omit nothing of real value to the practitioner.

In the composition of the work the use of statistics has been generally avoided, for unless dealing with enormous numbers little that is

trustworthy can be obtained from this method of inquiry. In fact, there can be little doubt that very erroneous impressions have been sometimes derived from statistical calculation based upon an insufficient number of cases.

In order to increase the usefulness of the book, much care has been bestowed upon the sections relating to diagnosis and treatment. No attempt, however, has been made to include in the directions for treatment an enumeration of all the remedies which have been suggested for the cure of the several forms of illness. Such excess of detail not only fills the page with information often of doubtful value, but tends rather to confuse the reader than to instruct him. Moreover, it gives to this branch of therapeutics an importance which, in the case of children, it does not always possess. In the case of a young patient, judgment in feeding and care in sanitary arrangements not seldom constitute the sole necessary treatment of the illness. Quiet, rest, appropriate food, and plenty of fresh air will often restore the health without the aid of physic; or if physic seem called for, the remedies needed are simple and few. But whatever be the nature of the malady, and however elaborate may be the medication required, the details of nursing should always take precedence of those of drug giving. Keeping this truth in view, the author has been careful to give due prominence to the subjects of diet and hygiene; and in the matter of drugs has confined himself, for the most part, to recommending those only which experience has taught him to value, and upon which, therefore, he has himself been accustomed to rely.

For purposes of illustration a number of concisely narrated cases have been introduced into the text. Most of these have been selected from the author's case-books, but a few are taken from the practice of his hospital colleagues. To these colleagues, for their kindness in placing their cases at his disposal, the author desires to express his deep obligations.

GRORGE STREET, HANOVER SQUARE, June, 1884.

TABLE OF CONTENTS.

INTERODUCTORY CHAPTER	1
Physiological peculiarities of early life, 1; causes of sudden death, 5; convalescence, 5; definition of infancy and early childhood, 5; clinical examination of infants, 6; inspection of the face, 6; attitude, 8; cry, 8; absence of cry, 9; the pulse, 9; the respirations, 10; the temperature, 10; pyrexia from rapid growth, 11; movements of the chest and belly in breathing, 12; inspection of the mouth and throat, 18; treatment, 14; forced feeding, 14; reducing temperature, 15; baths, 16; internal remedies, 18; abuse of sperients, 19.	
Part 1.	
THE ACUTE INFECTIOUS DISEASES.	
CHAPTER I,	
MEASURS.	21
The contagious principle, 21; morbid anatomy, 22; symptoms, 22; pre-oruptive period, 22; the rash, 23; catarrh, 23; asthenic messles, 24; relapses, 24; complications, 25; sequelse, 26; diagnosis, 26; prognosis, 27; treatment, 28.	
CHAPTER 11.	
EPIDENIC ROSEOLA.	30
Symptoms, 30; diagnosis, 31; treatment, 31.	
CHAPTER III.	
SCARLET PEVER.	33
Canastion, 32; morbid anatomy, 33; symptoms, 33; invasion, 34; eruptive stage, 34; the rash, 34; temperature, 35; the desquamative stage, 36; malignant scarlet fever, 36; complications and sequelæ, 37; scariatinous rheumatism, 38; albuminuria and uræmic symptoms, 39; latent scarlet fever, 40; diagnosis, 41; prognosis, 42; illustrative case, 42; treatment, 43.	
CHAPTER IV.	
CRICKES-POS	48
Symptoms, 48; temperature, 48; gangrenous varioella, 49; treatment, 50.	

CHAPTER V. Symptoms and course, 5t, protective value of vaccination, 52; method of vaccinating, 58; occasional sequele, 54. CHAPTER VI. Morbid anatomy, 55, symptoms, 56, incubation, 56, invasion, 56; complications, 59, varieties, 60; diagnosis, 61; prognosis, 62, treatment, 62, CHAPTER VII. Morbid anatomy, 65, symptoms, 65; incubation, 65; temperature, 65; metastasis, 66 , deafness, 66 , diagnosis, 67 , treatment, 67, CHAPTER VIIL CREERIRO-SPINAL FEVER, 68 Causation, 68; morbid anatomy, 68; symptoms, 69; rash, 69; nervous symptoms, 60; temperature, 70; paralysis, 70; convulsions, 70; varieties, 71; form in Infancy, 71; diagnosis, 72; prognosis, 78; treatment, 78. CHAPTER IX. Cantation, 74; morbid anatomy, 75; symptoms, 76; first week, 76; second week, 77; third week, 77; digestive organs 79; the urine, 78; special senses, 70; temperature, 79; duration, 80; case, 80; mode of death, 81; relapses, 82; secondary pyrexia, 83; convalescence, 82; diagnosis, 83; prognosis, 84; treatment, 85. CHAPTER I. DIPRITHERIA Diphtheria and croup, 88; causation, 90; morbid anatomy, 91; symptoms, 93; mild form, 93; severe form, 94; albuminumia, 95; larynscal diphtheria, 95, despuces, 96, malignant form 97, case, 97, secondary diphtheria, 97; complications, 97, nasal diphtheria, 98; cutaneous diphtheria. 98. inflammatory complications, 98; thrombesis of heart, 98; cardiao dyspuca, 98; apucas from laryngeal obstruction, 99; sudden death, 99; paralysis, 99; diagnosis, 100, prognosis, 102; treatment, general, 103; local, 104; trachectomy, 105. CHAPTER XI. Causation, 100; morbid anatomy, 110, symptoms, 111; rash, 111; fever, 111; complications, 111, diagnosis, 112; prognosis, 112; treatment, 118 CHAPTER XII. WHOOPING-COUGH..... Causation, 114; duration of infection, 114; pathology, 114; nature of the disease, 115; symptoms, 115, the cough, 110, the whoop, 116; hemorrhages, 116, complications, 117, ulceration of tengue, 117; bleeding from ears, etc., 118; digestive troubles, 118; nervous accidents, 118; pulmonary lesions, 119; sequelæ, 120; diagnosis, 122; prognosis, 123; treatment, 124; of complications, 127.

Part 2.

GENERAL DISEASES NOT INFECTIOUS.

CHAPTER I.	PAGE
Bic 1021	159
Causation, 129; bad feeding, 120; bad air, 130; relation to syphilis, 131; relation to tuberculosis 131; nature, 131, morbid anatomy, 132; ossification of bone, 152; softening of bones, 133; changes in internal organs, 133; the urine, 134; effects of bone changes, 134; on the contents of the chest cavity, 134; relation to osteo malacia, 135; "congenital rickets," 135; symptoms, 136; distortion of bones, 137; chest, 139; spino, 139; long bones, 140; general nutrition, 140; complications, 142, diagnosis, 143, prognosis, 143, treatment, 144.	
CHAPTER II.	
AGCR	147
Cansation, 147; morbid anatomy, 147; symptoms, 148; the cold stage, 149; the hot stage, 145, the aweating stage, 148, stages often ill developed, 148; temperature, 149; urine, 149; malignant form, 149; ausemia, 149; hematuria, 149; diagnosis, 149; prognosis, 150; treatment, 151; hypodarmic injection of quinine, 151.	
CHAPTER III.	
ACUTE RHEUNATISM	153
Frequency in children, 158; causation, 153; morbid anatomy, 154; symp-	
tums, 154, inflammation of joints, 155; pericarditis, 155, fewness of its averptoms, 155; identified case, 155; occasional severity of symptoms, 155, pericardial fraction, 156, effusion, 156, elevation of hearits apex, 157; dinstrative case, 157; supportative pericarditis, 157; endocarditis, 158; interrative case, 158; pneumonia, 159; hyper-pyretia, 159; rheumatism of ableminal wall, 159; fibroid nodules, 160; duration, 160; relapses, 160; chronic rheumatic pams, 161; diagnosis, 151; of pericarditis, 161; endocarditis, 162; ulcocative endocarditis, 162; prognosis, 162; occasional disappearance of cardia, marmins, 163; treatment, 163; salicylate of soda, 164; importance of rest, 165.	
CHAPTER IV.	
Pathology, 166, morbid anatomy, 167; symptoms, 167; disseminated form, 168; illustrative cases, 169, gangrene of extremities, 169, dry and mont varieties, 189, of vulva, 170, diagnosis, 170; prognosis, 171; treatment, 171.	166
Part 3.	
THE DIATHETIC DISEASES.	
CHAPTER I.	
Canastion, 173; hereditary tendency, 173; exciting causes, 174; morbid anatomy, 174; casestion of glands 175; symptoms, 175; variety of the lexions, 176; cutaneous absences, 177; disease of hones and joints, 178; of the spine 178; casestion of glands, 179; of bronchiae glands, 180; its consequences, 181; asthmatic attacks, 182; alternion in physical signs, 182 of missenteric clands, 183, its consequences, 184; diagnosis, 185; prognosis, 186; treatment, 187.	

CHAPTER 11. ACITE TURERCULOSIS...... Three forms, 190; causation, 190; hereditary tendency, 190; acute specific diseases, 191; the tubercle bacilina, 191; morbid anatomy, 191; the gray granulation, 192; the giant cell, 192; lung changes, 193; lesions of intestines, 193, of the spleen, 193; of the bladder, 193; nature of cheesy matter, 194; symptoms, 194; gradual onset, 194; temperature, 195; ordern of legs, 195; local symptoms, 195; in brain, 195; in lung, 196; illustrative case, 196, in bladder, 197; in other organs, 197, duration, 198, diagnosis, 198; from gastric catarrh, 198; from infantile strophy. 199; of pulmonary complication, 199; of tubercle of bladder, 199; prognosis, 200 , treatment, 200. CHAPTER III. INFANTILE SYPHILIS..... Causation, 202; influence of the father and mother, 202; Colles's law, 202; sation, 202; manence of the inter and motion, 203; editers have, 202; acquired syphilis, 203; merbid anatoms, 203; affection of mucous membranes, 204, of solid organs, 204, of bones, 206, two varieties, 206; Parrot's views, 206, dactyfitis, 207, affection of hones of skull, 207; cranio-tabes, 208; symptoms, 208; snuffling, 209; rash, 209, complexion, 209, affection of hair and mails, 210; the cry, 210; thekening of the bones, 210, pseudo-paralysis, 210, true paralysis, 210; general nutrition, 210; relapses, 211, sequelæ, 211; diagnosis, 211; prognosis, 213, treatment, 212. ment, 213. Part 4. DISEASES OF THE DUCTLESS GLANDS AND BLOOD. CHAPTER L. LHUOOCYTHEMIA..... Causation, 216; morbid anatomy, 216; symptoms, 217; enlargement of spicen, 217, anamia, 217; temperature, 218; hemorrhages, 218; enlargement of glands, 218; diagnosis, 218; from enterio fever, 218, from lymphadenoma, 210; prognosis, 219; treatment, 219. CHAPTER IL LTMTHADENOMA Cauxation, 220; morbid anatomy, 220; changes in lymphatic glands, 221; in spheen, 221; in liver, 222; kidneys, 222; adenoid new growths, 222; blood, 222; symptoms, 222; regular, 223; illustrative case, 223; glandular satellings, 224; temperature, 224; cashectic stage, 224; anamia, 224; early local symptoms, 225; illustrative case, 225; accidental symptoms, 226; pressure signs, 226; paralysis, 226; illustrative case, 226; diagnosis, 227; prognesis, 227; treatment, 227. CHAPTER III. Frequency of impoverishment of the blood in children, 229; reasons for this, 229; use of the blood in antention, 230; causation, 230; two classes, 230; morbid anatomy, 231, idopathie ansemla 232; symptoms, 232, complexion, 232 breathlessness, 232, anomic murmurs, 233, epistaxis, 233, headache, 233, symptoms of idiopathic anamia, 233; diaznosis, 233; prognesis, 234; treatment, 234; diet, 234; attention to general hygiene, 234, iron, 235; arsenie, 235; cold-water packing and massage, 236.

CHAPTER IV. Consation of spienic enlargement, 237, aimple hyperplasia, 238; morbid anatomy, 238, symptoms, 238, anemia, 358; actiona, 238, the blood, 239; cases, 239, gastro-intestinal troubles, 239; diagnosis, 240; prognosis, 240; treatment, 240, abuse of mercurial frictions, 241. CHAPTER Y. Canastion, 242; morbid anatomy, 243; symptoms, 243; three grades, 243; hismorrhages 243, joint attestion, 244, diagnosis, 245, prognosis, 245, treatment, 245. CHAPTER VL Two varieties, 247; causation, 247; morbid anatomy, 247; pathology, 248; a) inpitems, 248; emption, 248; illustrative case, 249; pains in bushs, 249; homographic purpura, 249; various homographics, 249; purpura rheumat. a, 249; anæmia, 250; temperature, 250; illustrative case, 250; celema, 250; cerebral hemographics, 251; convulsions, 251; course, 251; diagnosis, 251; prognesis, 251; treatment, 251. CHAPTER VIL SCURVY..... Camation, 253 , morbid anatomy, 254; periosteal extravasation, 254 , pathology 255, symptoms, 255, tenderness, 256, swelling, 256 petechie, 256; separation of epiphyses, 256, the gums, 256; cachexis, 256; temperature, 257, course, 257, diagnosis, 257; prognosis, 258; treatment, 258. Part 5. DISEASES OF THE NERVOUS SYSTEM. CHAPTER I. Excitability of the nervous system in early life, 200; value of various symptoms, 261; squart, 261, nystagmus, 261; state of the pupils, 261, dehrum, 262; drowsnies, 262; loss of consciousness, 262; changes of temper, 262, tremours, 263, spanns 263; paralysis, 263; aphasis, 263; maid, v. 264, retraction of head, 264, vomiting, 264; the breathous, 264, the pulse, 265, cerebral flush, 265; the urino, 265; hysterical symptoms, 365. CHAPTER II. LARYRGISHUR STRIDULUS..... Causation, 267. association with rickets, 267. pathology, 268; exciting causes, 269; illustrative case, 268, symptoms, 269, description of the science, 269; duration of attacks, 269, illustrative case, 269, spasm limited to glotts, 270, characters of the spasm in new-born Infants, 270, mode of death, 270, incarceration of epiglotts, 271, duamosis, 271; prognosis, 272, treatment, 272, ammonia, 272, cold bathing, 272; freeh air, 272; antispasmodics, 273, tonics, 273.

CHAPTER III.	PaGE
TONIC CONTRACTION OF THE EXTREMITIES	274
Usually associated with largengismus stridulus and reflex convulsions, 274; not uncommon in the subjects of rickets, 274; symptoms, 274; pain, 274; contraction of muscle, 274, usual seat, 274, indicate of manipulation, 275; is usually bilateral, 275. If severe, persists during sleep, 275; sensation unaffected, 275; diagnosis, 275; prognosis, 276; treatment, 276.	
CHAPTER IV.	
CONVULSIONS	
Common during the first two years of life, 277; causation, 278; symptoms, 279; description of paroxysm, 279; drowsiness 280; temporary paralysis, 280; congestion of brain, 280; illustrative case, 280, diagnosis, 281; from cerebral convulsions, 281; from epilepsy, 282; progness, 283, influence on brain development, 283; treatment, 284; warm bath, 284; chloral, 284; nitrite of amyl, 285; stimulants, 285; tonics, 285.	
CHAPTER V.	
EPREPSY	286
Causation, 286; hereditary tendency, 286; injuries, 286; a fit of convulsions, 286; illustrative case, 286; pathology, 287; syruptions, 288; epilepsia gravior, 288, epilepsia mittor, 288, a fit of epileptic vertigo, 288, illustrative case, 289; frequency of attacks, 289, association with chorea, 290; diagnosis, 290; from syncope, 290; from hysterical fits, 290; prognosis, 294; treatment, 291; general attention to health, 291; dist, 292; the brounides, 292; strychnia, 292; nitrite of amyl, 293	
CHAPTER VI.	
MEGRIX,	294
Causation, 294; pathology, 294; symptoms, 295; headache, 295; impairment of sight, 295; of other senses, 295; illustrative case, 296; illustrative case, 296; diagnosis, 296; treatment, 297; strychnia and ergot, 297.	
CHAPTER VII.	
CHOREA	290
Causation, 290; association with rheumatism, 290; pathology, 300; various theories, 300; symptoms 301; disordered movements, 301; inco-ordination of voluntary movement, 302; sheeplesoness, 302 sensory disturbances, 302; hemichores, 302; the urine, 303; mental state, 303; temperature, 303; weakness of muscle, 303; heart murnurs, 304; course and duration, 304; diagnosis, 304; prognosis, 304; treatment, 305; hygiene, 305; moral treatment, 305; drugs, 305; massage, 306	
CHAPTER VIII.	
IDIOPATRIC TETARUS	808
In infants, rare in England, 308; causation, 308; influence of general unsanitary conditions, 309; morbed anatomy, 309; symptems, 310; difficulty of swallowing, 310; stiffness of jaws, 310; temperature, 310; attacks of spasm, 310; tonic ricidity, 310; illustrative case, 310; duration, 311; tetanus in older clubbran, 311; illustrative case, 311; diagnosis, 312; from strychnia poisoning, 312; prognosis, 312; treatment, 313; forced feeding, 313; Calabar bean, 313; chlorat, 313; illustrative case, 314.	

CONTENTS.

CHAPTER IX.	
	316
Circulation of blood in the brain, 316; causation, 316; two forms, 316; relation to denution, 316; and convulsions, 317; must embolisms 317; morehold anatomy, 317; symptoms, 318; irritative stage not clinically recognizable, 318; the common form, 318; illustrative case, 318; thrombons of cerebral sinuses, 319; diagnosis, 319; prognosis, 320; treatment, 321.	
CHAPTER X.	200
Only common in still-born children, 322; causation, 322; sometimes the result of ancurism of a cerebral artery, 322; morbid anatomy, 322; mening al homorrhage, 323; cerebral homorrhage, 323; cause of ancurism, 324; symptoms, 324; of maningeal homorrhage, 324; low temperature, 324; stupor and convulsions, 324; resemblance to simple meningules, 325; silustrative case, 325; cerebral homorrhage, 326; illustrative case, 326; homorrhage from rupture of ancurism, 327; illustrative case, 327; diagnosis, 328; prognosis, 329; treatment, 329.	322
CHAPTER XI.	
CREBRAL TUNOUR	330
Cerebral growth usually tubercular, 330; morbid anatomy, 330; varieties of growths, 331; symptems, 331; headache, 332; convulsions, 332; loss of special sense, 332; ophthalmoscopic appearances, 332; illustrative case, 333; priemstous tumour, 333; tubercular growth, 330; illustrative case, 335; two stages often seen, 336; illustrative case, 339; co-shellar tumour, 337; characteristic symptoms, 337; other seats, 337; diagnosis, 337; prognosis, 339; treatment, 339.	
CHAPTER XII.	
CHRONIC HYDROCEPHALUB	340
Causation, 340; morbid anatomy, 341; effect of pressure on the brain and akull, 341; symptoms, 342; distention of skull, 342; imperfect nutrition, 343; intelligence, 343; nervous symptoms, 343; illustrative case, 343; the acquired form, 344; spontaneous evacuation of fluid, 344; diagnosis, 343; prognosis, 345; treatment, 345.	
CHAPTER XILL	
DTITIS AND ITS CONSEQUENCES	346
Extension of inflammation from the tympanum to the skull cavity, 346; causation, 340, morbid anatomy, 347, symptoms, 348, extension of inflammation to the meninges, 348; purulent meningitis, 349, temperature, 349, convulsions, 349, illinetrative case, 349, phrenito form, 350; delimin, 350; temperature, 350; thrombests of the cerebral sinuses, 351; encephalitis, 351; convulsions, 351, suppor, 351; paralysis, 351, illinetrative case, 352; diagnosis, 852; prognosis, 354; treatment, 354.	
CHAPTER XIV.	
Presectlar Mentnertis	355
Common at all ages of childhood, 355; causation, 355; morbid anatomy, 336; symptoms, 357, premonitory, 357, two forms, 357, premary meaningitis, 357, three stages, 358; first stage, 358; second stage, 359; third stage, 360; duration of tilmess, 361, secondary meningitis, 361; common in infants 362, anomalous cases, 362, diagnosis, 362; illustrative case, 363, prognosis, 365, treatment, 365.	

CHAPTER XV.	
Paralysis of the Portio Dura	367
Course of the facial nerve in the Fallopian canal, 367; causation of the paralysis, 367; symptoms, 368; illustrative case, 368; diagnosis and prognosis, 369, treatment, 370.	
CHAPTER XVI.	
ACUTE INPANTILE SPINAL PARALYSIS,	371
Causation, 371; morbid anatomy, 378; symptoms, 373; onset, 378; completeness of the paralysis, 374; rapid limitation of the paralysed area, 374; wasting of manseles, 375; stage of contraction, 375; mechanism of the deformatics, 375; diagnosis, 377; prognosis, 377; treatment, 378.	
CHAPTER XVIL	
Sparmodic Spinal Paralybis	350
Morbid austomy, 380; symptoms, 380; rigidity of joints, 381; diagnosis, 382; prognosis, 382; treatment, 382.	
CHAPTER XVIII,	
Parudo-hyprhtrophic Paralysis	384
Causation, 384; morbid anatomy, 384; symptoms, 385; enlargement of mus- cles, 385; progressive weakness, 385; occasional atrophy of moscle, 386; contractions, 386; course, 587; diagnosis, 387; prognosis, 388; treat- ment, 388.	
CHAPTER XIX.	
Causation, 389; morbid anatomy, 390; classification, 391; symptoms, 391; cretinism, 392; illustrative cases, 393; degrees of mental development, 394; diagnosis, 395; development of the senses in the healthy infant, 395; prognosts, 396; treatment, 397.	
Part 6.	
DISEASES OF THE ORGANS OF RESPIRATION.	
CHAPTER I.	000
Position of the patient during examination, 399; inspection, 399; shape of the chest, 400; movements in respiration, 400; retraction of the chest, 400; enlargement, 401; palpation, 401; vocal fremitus, 401; friction fremitus, 401, site of apex-best of heart, 401, causenof its displacement, 402, level of the liver and spheen, 402, percussion, 402; degree of resistance, 403; auscultation, 403; conduction of sounds, 444.	
CHAPTER II.	400
	406
Simple laryngitis, 406; causation, 406; morbid anatomy, 406, mild form, 407; severe form, 407; illustrative case, 408, chronic larynmin, 408; diagnosis, 408 case of hysterical aphonia, 409; prognosis, 410, treatment, 410; stradulous laryngitis, 411, causation, 411, morbid anatomy, 411, symptoms, 412, despines, 412; croupy cough, 412, temperature, 412; illustrative case, 412, carpo-pedal contrastions, 413; diagnosis, 413, prognosis, 414, treatment, 414, tubercular laryngitis, 415, causation, 415, avantoms, 416; illustrative case, 416, diagnosis, 417, case of warty growths on larynx, 417; prognosis, 418; treatment, 418.	

CHAPTER III.	
	419
Causation, 419; morbid anatomy, 419; symptoms, 419; orthopnes, 419; suppressed voice, 420; diagnosis, 420; prognosis, 421; treatment, 421.	210
CHAPTER IV.	
(autrous Preumonia	422
Camation, 422; nature of the disease, 422, sometimes secondary, 423, morbula anatomy, 423, symptoms, 424, onset, 424, temperature, 424, cough, 424, moseular weakness, 425, nervous symptoms, 426; illustrative case, 426; breathing, 426, pulse-respiration ratio, 426; digestive organs, 426; urine, 426, pyrsuia, 426, occasional dyspura, 427; physical signs, 427; their seat, 428; terminations, 428; resolution, 428; abscess of the lung, 429, latent form of pneumonia, 429; complications, 430; plastic pleures, 450; precartitis, 430; jaundice, 430; diagnosis, 430; prognosis, 431; treatment, 432; diet, 632, reduction of pyrexia, 432; tepid bathing, 432; quinine, 432; value of bleeding, 433; stimulants, 433.	
CHAPTER V.	
GIARRAL PREUMONIA	434
tausation, 434; morbid anatomy, 434; symptoms, 436, always secondary to pulmouncy catarrh, 436; temperature, 436; pulse-respiration ratio, 437; breathing 437, cough, 447, physical signs 437, terminations, 438, subscate course, 438, complications, 439; diagnosis, 439, from croupous purumonia, 440; excuston of tuberculosis, 440; acute dilutation of brough, 441; progness, 441; treatment, 441; tapid bathing, 441; counter-irritation of chest, 442; stimulants, 442; diet, 442; emetics, 442, fron, 443.	
CHAPTER VI.	
PLECTRIST	444
Causation, 444; morbid anatomy, 444; characters of effusion, 446; symptoms, 445; onset, 445; pyrexia, 446; pain, 446; complexion, 446; empyema, 447; physical signs, 447; inspection, 447; percussion, 448; auscultation, 449; fruitionssound, 449; oscassional symptoms, 449; appointments evacuation, 450; perforation of bronchus, 450; illustrative case, 451; varieties, 451; plastic pleurisy, 452; localated form, 452; tuberculous form, 452; complications, 453; discrosss, 453; from croupous pacumonis, 453; from estaterial pucumonia, 454; from collapse of lung, 454; of emporan, 455 of hydrothorax, 455; prognosis, 455; treatment, 456; iodide of potassium, 456; appration, 457; illustrative case, 457; causes of auddendeath, 458; use of the drainage tube, 459; resection of rib, 460; diet, 460.	
CHAPTER VIL	
DELAPSE OF THE LUNG	461
Two varieties, 461; congenital stelectaris, 461; morbid anatomy, 461, symptoms 462; prostration, 462; lividity, 462; temperature, 462; feeble respiration, 462; trifling physical signs, 462; drowsiness, 462; signs of recovery sometimes deceptive, 463, diagnosis, 463, prognosis, 463; treatment, 463, artificial respiration, 464, hot both, 464, counter-irritation, 464, stimulants, 464; post-natal at lectasis 465, causation, 465, morbid anatomy 466, symptoms, 467, lividity, 467; feeble, rapid breathing, 467, bemperature, subnormal, 467, perverted pulse-respiration ratio, 467; physical signs, 467; comptoms during second year, 468, illustrative case 468, diagnosis, 468, prognosis, 471; treatment, 471; warmth,	

CHAPTER VIII.

	-
FIBROID INDURATION OF THE LUNG	47
Pathology, 473; merbid anatomy, 474; amyloid degenerations, 475, symptoms 475; early stage, 475, physical signs of established desease, 476; symptoms, 476, cough, 476; offensive sputum, 477, nutrition, 477; temperature, 477, hypertrophy of right ventricle of heart, 477; contraction of side, 477; shroid phthisis, 477, diagnosis, 478; from pleurisy with retraction, 478; from phthisis, 478; prognosis, 479; trestment, 479; diet, 479; tonics, 480.	
CHAPTER IX.	
Broncettis	48
Causation, 481; morbid anatomy, 482; ayunptoms, 482; of bronchial catarrh, 483; the mild form, 483; the severe form, 483; capillary bronchitis, 483; temperature, 483; dyspnæs, 483; pulse, 484; physical signs, 484; signs of asphyxia, 484; chronic bronchitis, 484; symptoms, 485; lituatrative case, 485; diagnosis, 485; prognosis, 486; treatment, 486; counterirritation, 486; diaphoreties, 487; stimulant expectorants injurious at the first, 487; after-treatment, 488; treatment of chronic broughtle, 489.	
CHAPTER X.	
Емричеема	49
Causation, 491; morbid anatomy, 492; two varieties, 492; inter-lobular and vesicular, 493, symptoms, only present in the vesicular form, 493; physical rigns, 493; illustrative cases, 494; diagnosis, 494; prognosis, 494; treatment, 495.	
CHAPTER XL	
GANGRENE OF THE LUNG	49
Rarity in childhood, 496; causation, 496; morbid anatomy, 497; symptoms, 497; onset, gradual or sudden, 498; prostration and restlessness, 498; pulse, 498; respection, 498; temperature 498, fetial breath and expectoration, 498; disputes, 498; hamoptysis, 490; physical signs, 499; illustrative case, 499; diagnosis, 490; prognosis, 500; treatment, 500; anticeptic inhalations, 500; stimulants, 501; diet, 501.	
CHAPTER XII.	40
PULMONART PHTHISIS	
Varieties, 502; causation, 502; communicability of the disease, 503; morbid anatomy, 504, acute pithuss, 505, symptoms, 505, dyspaca, 506, temperature, 506; physical signs, 506; illustrative case, 506; mode of death, 502; duration, 507, prognosis, 507; chronic pneumonic pithuss, 508; mode of beginning, 500; stage of softsning, 500; cough, 508; hasmoptysis, 510; temperature, 510; physical signs, 510; utceration of boxels, 510; secondary catarrhal pneumonia, 510; mode of death, 511; chronic tubercular pithisis, 511; wasting, 511; temperature, 512; illustrative case, 512; occasional obscurity of physical signs, 513; diagnosis, 513, of dilated brench, 514; from empyema, 514; prognosis, 515; treatment, 516; preventive treatment, 516; treatment of acute pithisis, 516; reduction of temperature, 516; regular feeding, 517; treatment of chronic pithisis, 517, dist, 517; change of sir, 517, antiseptic inhalations, 518; sedatives and expectorants, 518; necessity of attention to the digestive organs, 518.	

CONTENTS.

CHAPTER XIII,	P4GB
to the same of the	519
Definition of dysphera, 519; causes which produce it, 519; obstruction of wind pipe, 519; of pulmorary artery, 519; disease of heart, 519; external pressure upon land, 519; by fluid in planta, 519; by the atmosphere in rukets, 519; disease of lung, 519; causes of paroxysmal dysphere. 520; bronchial asthma, 520; its causes, 520 its symptoms, 521; its physical signs, 521; diagnosis, 521; of enlarged bronchial asthma, 522; of foreign body in the air tubes, 52d; of bronchial asthma, 523; prognosis, 524, treatment, 524.	
CHAPTER XIV.	
FORRIGN BODIES IN THE AIR-TUBES	526
Morbit anatomy, 526; symptoms, 527; dyspaces, 527; spasmodic cough, 527; pain in the chest, 528; physical signs, 528; spontaneous expulsion, 529; cangrene of lung, 529; illustrative case, 529; seat of the foreign body, 530; in the larynx, 530; in the traches, 531; in the troncleus, 531; diagnosis, 531; from spasmodic laryngitis, 532; from membranous croup, 533; prognosis, 533; treatment, 533.	
part 7.	
DISEASES OF THE HEART.	
CHAPTER L	
CONGENITAL HEART DISEASE	585
Normal development of the heart, 535; arrest of development, 536; varieties of malformation 536; morbid anatomy, 537; symptoms, 538; oyanosis, 538; stape of cheef, 538; temperature, 538; dyspuese, 538; edema, 538; nine, 539; disease, 539; the commonest form of malformation, 539; nutrition, 539; disease of the petrous bone, 540; convulse us, 540; duration of life, 540; mode of death, 540; diagnosis, 540; prognesis, 542; treatment, 543.	
CHAPTER IL	
CHRONIC VALVULAR DISEASE OF THE HEART	544
Causation, 544; rheumatism, 544; chorea 544; syphilis, 545; morbid anatomy, 545; valvular leasons, 545; edhesion of pericardium, 546; Parrot's hiematomata, 546; hypertrophy and dilatation of walls, 546; symptoms, 547; dyspides, 547; pulpitation, 547; hiemorrhages, 547; editables, 547, of brain, 548; illustrative case, 548; symptoms due to the rheumatic disposition, 549; impairment of nutrition, 549; relative frequency of the various forms, 549, terminations, 550; cardiac droppy, 550; citting of blood in the heart, 550; illustrative cases, 550; diagnose, 550; occasional disappearance of murmur, 551, prognosis, 552; treatment, 552; digitalis, 553, aperients, 553; diet, 558; diuretics, 553.	
Part 8.	
DISEASES OF THE MOUTH AND THROAT.	
CHAPTER I.	
THE DEBANGEMENTS OF TRETHING	555
Teathing not a morbid process, 555; cruption of the milk-teeth, 556; natural order, 557; irregularities, 557; symptoms of teething, 558; temperature,	

	2.65
558; complications, 558; stomatitis, 559; digestive froubles, 559; pulmonary externh, 559; office, 560; skin diseases, 560; nervous disorders, 560; the second dentition, 560; order of eruption, 560, diagnosis, 561; treatment, 561; value of lancing the gums, 562; treatment of "night terrors," 562.	
CHAPTER IL	
STOMATITIS	51
Aphthous stomatitis, 563; symptoms, 563; diagnosis, 564; prognosis, 564; treatment, 564. Utcerative stomatitis, 564; causation, 564; symptoms, 565, diagnosis, 566; prognosis, 566; treatment, 566, value of chlorate of potash, 566.	
CHAPTER III.	
Gangrenous Stomatitis	5
Causation, 567; morbid anatomy, 567; symptoms, 568; duration, 569; prognosis, 560; treatment, 569; diet and stimulants, 569; caustics, 570; quining and iron, 570.	
CHAPTER IV.	
Тивуя,	5
Causation, 571; morbid anatomy, 572; the oidium albicans, 572; its meat, 572; symptoms, 573; in mild cases, 573; in severe cases, 573; local symptoms, 573; general symptoms, 573; diagnosis, 574; prognosis, 574; treatment, 574.	
CHAPTER V.	
Pharyngitis	5
Simple pharyngeal catarrh, 576, causation, 576; symptoms, 576, scald of throat, 577; diagnosis, 577; treatment, 577; of scald, 578. Followiar placyngits, 578, causation, 578, morbid anatomy, 578; symptoms, 579; deathess, 579, appearance of fances, 579, diagnosis, 579; prognosis, 579; treatment, 579, local applications, 580, causaties, 580. Herpes of the pharynx, 580, causation, 580; symptoms, 580, diagnosis, 580; treatment, 581. Tubercular pharyngits, 581; morbid anatomy, 581; symptoms, 581; appearance of fances, 581; nlectation of threat, 582 often extensive, 582; temperature, 582; pain in swallowing, 582; implication of lungs, 582; diagnosis, 583; from syphilitic ulceration, 583; prognosis, 583; treatment, 583.	
CHAPTER VL	
QUINBY	51
Nature of the disease, 584; causation, 584; merbid anatomy, 585; symptoms, 585; pain, 585; temperature, 585; formation of abscess, 586, duration, 586; the non-suppurative form, 586; chronic enlargement of tousis, 586; their influence on the general health, 587; alteration of features, 587; deformity of chest, 587; cough, 588; diagnosis, 588; prognosis, 588; treatment, 588; acouste, 588; salleylate of soda, 588; local applications, 589; dist, 589; treatment of chronic outargement, 589; excision, 590; causatics, 590.	
CHAPTER VII.	
RETRO-PHARYMORAL ABSCISSE	5
Causation, 591; morbid anatomy, 591; symptoms, 592; dysphagia, 592; dyspnosa, 592; congh, 592 acute form, 593; chronic form 593; illustrative case, 581; terminations, 591; diagnosis 594; from membranous croup, 594; from ordems of glottis, 594; prognosis, 595; treatment, 595.	

Part 9.

DISEASES OF THE DIGESTIVE ORGANS.

CHAPTER L

	596
Canstion, 506; due to insufficient nourishment, 506; cow's milk often indigentials, 507; reason of thus, 597; analysis of various milks, 597; difficulty of digesting states in early infancy, 508, hability to catarch in early life, 598; occasional indigestibility of breast-milk, 509; illustrative case, 509; morbid anatomy of atroj by, 600; symptoms, 600; wasting, 600; signs of indigestion, 500; cruptions on the skin, 501; cole, 601; construction, 501; vomiting, 501; diarrhea, 502; diagnosis, 502; from infantive yphilia, 502; from acute tuberculosis, 502; prognosis, 503; treatment, 503; rules for the hand-feeding of infants, 504; proparation of cow's milk, 506; pancreatised milk, 505; artificial human milk, 506; treatment of obstinate vomiting, 507; illustrative cases, 507; necessity of rigilance, 508.	
CHAPTER II.	
CAPRIC CATABRIL	600
(Sassiton, 600; morbid anatomy, 610, symptoms, 610; acute febrile form, 610; temperature, 610; signs of general catarrh, 610; recurring attacks, 611; their influence upon general nutrition, 611; the non-febrile variety, 611; asllow complexion, 611; languor, 611; fatulence, 611; nervous movements, 611 headache, 611, urn achl and urates in urine, 611; tengue, 612; fainting fits, 612; diagnosis, 612; illustrative cases, 613; treatment, 615, diet, 615; tonics, 615; warmth to the bedy, 616, baths, 616.	
CHAPTER III.	
OFFICE TO THE TOTAL PROPERTY OF THE TOTAL PR	617
Causation, 617, symptoms, 619; in infants, 619; in older children, 619; impaction of faces, 619, may prove fatal 620, diagnosis, 620, treatment, 621; in infants, 621; aperlents, 621; pepsin, 622, enemata, 622, treatment of colic, 622; in older children, 623; treatment of impaction of faces, 623.	
CHAPTER IV.	
	Mar A
Varieties, 624; causation of simple diarrhoa, 624; morbid anatomy, 625; symptoms, 625; character of the stools, 626; lienteric diarrhoa, 626; treatment, 626; of henteric diarrhoa, 626.	024
CHAPTER V.	
PLANMATORY DIARRICA	0:20
Causation, 629; morbid anatomy, 630; symptoms, 630; in infants, 630; character of stools, 630, frequency of motions, 631; their microscopic appearances, 631; general symptoms, 631; temperature, 631; illustrative cases, 631; catarrh of colon, 631; tonesmus, 632; blood in stools, 632; completations, 632; parenchymatous nephritis, 632; spurious hydrocephalus, 632; in children after infancy, 632; general symptoms, 632; temperature, 633; the urine, 633; early prestration, 633; the chronic form, 633; insidious beginning, 633; pacty atools, 633; gradual washing, 633; diarrhous, 634; diagnosis, 635; deat of catarrh, 634; diet 636; within 636; ventilation, 636; cold or tepid bathing, 637; illustrative case, 637; remelies, 637; value of astiments, 639; of spurious hydrocophatus, 639; of chronic diarrhous, 639; value of symmets, 639; of spurious hydrocophatus, 639; of chronic diarrhous, 649; value of symmets, 639.	

CHAPTER VI.	-461
	645
Causation, 642; morbid anatomy, 642, symptoms, 642; vomiting, 643, diarrhoza, 643, character of stools, 643; rapid wasting, 643, excessive thirst, 643, temperature, 643, exhaustion, 644, occasional recovery, 644, duration, 644; duranosas, 644; progness, 644; treatment, 644; abundant liquid, 644 food, 644, koumiss, 644, white wine whey, 645, drugs, 645, bypodermic injection of morphia, 645, illustrative case, 646.	
CHAPTER VII.	
DYSENTRAT	647
Causation, 647; morbid anatomy, 647; sloughing of mucous membrane, 648; abscesses in liver, 648, symptoms, 648; tenesmus, 648; mucus, 648; blood, 648; cohe, 649; character of stools, 640; their offensive odour, 649; temperature, 650; mode of death, 650; chronic form, 650; diagnosis, 650; prognosis, 651; treatment, 651; value of opium, 651; of special anha, 651; of mercury, 652; special treatment for infants, 652; astrugent injections, 653; dist, 658; treatment of the chronic form, 659; diet during convalescence, 653.	
CHAPTER VIII.	
GASTRO-INTESTINAL HAMORRHAGE	654
Spurious hæmatemesis, 656; its causes, 654; causes of the real hæmorrhage, 654 melæna neonatorum, 654, its causes, 655, hæmorrhage in older children, 655; causes, 655 general, 655 local, 655, polypus of rectum, 656, symptoms of gastro-intestinal hæmorrhage, 656; of inchena neonatorum, 656; of hæmorrhage in later childhood, 657; of polypus of rectum, 657; diagnosis, 657; prognosis, 656; treatment, 659.	
CHAPTER 1X.	
Ulceration of the Bowels	660
Varieties of ulcer, 660; morbid anatomy, 660; symptoms, 661; often obscure, 661; pain in abdomen, 661; tenderness, 661; tension of parietes, 661; the stools, 642; harmorrhage, 662; state of nutrition, 662; complications, 663; illustrative case, 663, diagnosis, 664; of nature of ulceration, 665; prognosis, 665 treatment, 666; diet, 666; value of raw mest, 666; of malted bread, 666; milk madmissible, 666; stimulants, 667; drugs, 667; nitrate of silver, 667; opium, 667; astringent injections, 667; pepsin, 667.	
CHAPTER X.	
INTESTINAL OBSTRUCTION (Intussusception)	608
Varieties of obstruction, 668; intussusception, 668; causation, 669; morbid anatomy, 668; symptoms, 670, in infants, 670; pain, 670; straining, 670, discharge of blood, 670, constipation, 670; temperature, 670; collapse, 671; in older children, 671; distention of belly, 671; vomiting, 671, meiana not always present, 671, signs of prostration, 671; separation of gaugienous segment, 672, mode of death, 672; special symptoms, 672, swelling in the abdomen, 673, temperature, 673, duration, 673; diagnosis, 673; from simple colic, 674; from peritonitis, 674; from dysentery, 674; from impaction of fiscal matter, 675; prognosis, 675, treatment, 673; injections of water, 676, insuffiction of air, 676; taxis, 676; surgical interference, 677.	

CHAPTER XI.	
TYPILITIS AND PERITYPHLITIS	HOR HOW
Canation, 678. symptoms, 679, of typhlitis, 679; of perityphlitis, 679; perferation of bowel, 679; extravasation into peritoneum, 679; suppuration behind encum, 680; simulation of hip joint disease, 680, post-excal absens, 680. flustrative case, 681, perforation of vermiform appendix, 682, diagnosis, 682, of typhlitis, 682, of perityphlitis, 688, of perforation of the vermiform process. 684; prognosis, 683; treatment, 684; aperients huriful, 684; diet, 684.	015
CHAPTER XII.	
ACTE PERITONITES	685
Caustion 685: morbid anatomy, 686; symptoms, 686, of the primary form, 686; verniting, 687; pain and tenderness, 687, temperature, 687; districted of belly 687; fluctuation, 687; looseness of bowels, 687; the secondary form, 688, the latent form, 688; diagnosts, 689, from the tuberculous form 689, from colic, 689; from rheumatism of the abdominal wall, 689; visceral peritonitis, 690; illustrative case, 690; prognosis, 691, treatment, 691; opinin, 691; leades, 601; warmth to the belly, 691; diet, 691, treatment of tympanitis, 692.	
CHAPTER XIII,	
	693
Marbid anatomy, 693; symptoms, 694; of the chronic form, 694; insidious beginning 694, dissurance case, 694, tenderness of abdomen, 694; disters from 695; innequal resistance of belly, 695, obscure the trainion, 695; temperature, 695; rapid wasting, 696; occasional improvement, 696; the scate form, 696; illustrative case, 696, diagnosis, 697, of the chronic form, 698; of acute form, 698; prognosis, 698; treatment, 698; wasmith to belly, 698, opium, 698, of the distribute, 699; thet, 699.	
CHAPTER XIV.	
ATTED,	700
Causation, 700; symptoms, 700; distention of belly, 700; fluctuation, 701; percussion duliness in flanks, 701, occasional dyspices, 701, other symptoms according to cause, 701; diagnosis, 702; illustrative case, 702; from hydronephrusis, 703; prognosis, 703; treatment, 704; paracentesis, 704.	
CHAPTER XV.	
INTERTINAL WORMS	705
Varieties, 765; description, 706; mode of entrance into body, 707; symptoms, general, 708; special, of thread-worms, 700; of lumbrici, 706; necturnal diarrhoes, 710; their migrations, 710, of tape-worm, 711; diagnesis, 711; treatment, 711; of thread-worms, 711; of lumbrici, 712; of tape-worm, 712, various vermifuges, 712.	
Part 10.	
DISEASES OF THE LIVER.	
CHAPTER L	
In infants (iclerus neonatorum), 714 , true and false jaundice, 714 , symptoms of icterus, 715 ; causes, 716 , from congenital mulformation of bile- ducts, 716 , cirrhosis of liver, 717 ; harmorrhage from navel, 717 ; illus-	714

	2142
trative case, 718, from syphilitic inflammation of the liver, 718; from umbilical phisbitis (interus malignus, 718; jaundies in childhood, 719, causes, 719, diagnosis, 719; prognosis, 720; treatment, 720.	
CHAPTER IL	
Congretion of the Liver	740
Causation, 722; morbid anatomy, 722; symptoms, 723; sense of weight in side, 723; dyspeptic symptoms, 723; light-coloured stools, 723; diagnosis, 723; illustrative case, 724; prognosis, 724; treatment, 724; diet, 724.	
CHAPTER III.	_
CIRRHONIS OF THE LIVER	
Causation, 726; morbid anatomy, 726; two varieties, 726; symptoms, 727 of strophic cirrhosis, 727; indigestion, 727. accites, 728; earthy tint of skin, 728; hemorrhages, 728; of hypertrophic cirrhosis, 728; paundice, 728; enlargement of liver, 728; diagnosis, 729; prognosis, 729; treatment, 730; aperients, 730; paraceutesis, 730.	
CHAPTER IV.	
Amylom Liven	78
Causation, 731: morbid anatomy, 731: symptoms, 731: enlargement of liver, 731: absence of pain or tenderness, 732; digestive disturbance, 732: snæmis, 732; ucdems, 732: kidneys and spicen often implicated, 732: diagnosis, 732; prognosis, 733: occasional complete recovery, 733; treatment, 733: iodine, 733; iron, 733; liberal diet, 734; sea air, 734.	
CHAPTER V.	
FATTY LIVER	72
Causation, 735; two forms, 735; morbid anatomy, 735; symptoms of fatty infiltration, 735; enlargement, 735; occasional tenderness, 736; diagnosis, 786, prognosis, 736; treatment, 736.	
CHAPTER VI.	
Hydatid of the Liver	73
Causation, 787; morbid anatomy, 737; description of the tenia echinococus, 737; symptoms, 738; swelling in liver, 789; rarely jaundice or ascitea, 730; illustrative case, 739; termination if left alone, 740; diagnosis, 740; prognosis, 741; treatment, 741; paracontesis, 742; illustrative case, 742; treatment by electrolysis, 742.	
Part 11.	
DISEASES OF THE GENITO-URINARY ORGANS.	
CHAPTER I.	
THE URINE	74
Characters of the urine in health, 744, variations in its quantity, 744; their causes, 745; variations in the quantity of solid matters, 745; of ures, 745, causes of lithates, 745, albuminucia, 746, its causes, 746, hematuria, 746 its causes, 746; from irritation of the passages by the bilitaria hamatchia, 747; retention of urine, 748, its causes 748, nocturnal incontinence of urine, 748, its nature, 749; and treatment, 750.	

CONTENTS.

CHAPTER II.	
CHRONIC BRIGHT'S DISEASE	250 250
Cansation, 752, morbid anatomy, 753; the granular kidney, 753; the fatty kidney, 753, the anyloid kidney, 753, symptoms, 754; illustrative case, 754; anamia, headache and vomiting, 755, acute exacerbations, 755, illustrative case, 755; insidious progress of the granular kidney, 756, illustrative case, 756; the amyloid kidney, 758, renal inadequacy, 758, sometimes seen in young infants, 758, diagnosis of renal disease, 756; prognosis, 750; treatment, 750, diet, 750; aperients, 761; especially valuable in uramia, 761; diaphoretics, 761; iron, 761; treatment of chronic albuminuria, 762.	
CHAPTER III.	
	763
Sand in the urine common in children, 763; formation of nric acid in urine, 763; formation of exclusive of lime, 764; causation of extensis of kidney, 764; symptoms, 764; hæmaturia, 765; pain in loins, 765; illustrative case, 765; renal cohe, 766; impaction of stone in ureter, 766; stone in blad ler, 766; diagnosis of calculus of kidney, 767; illustrative case, 767; prognosis, 768; treatment, 768; diet, 708; alkalis, 768.	
CHAPTER IV.	
TUMOURS OF THE KIDNEY	770
Sarcoma of kidney, 770; morbid anatomy, 770; symptoms, 770; swelling of abdomen, 770; suens of pressure, 771; illustrative case, 771; duration, 772; hydronephrosis, 772; causation, 772; symptoms, 772; painless tumour, 772; finatication, 773; diagnosis of renal tumours, 773; treatment of hydronephrosis, 774.	
CHAPTER V.	
VCLVITIS	775
Two forms, 775; causation, 775; symptoms, 775; of catarrhal vulvitis, 776; diagnosis, 776; treatment, 776; of catarrhal vulvitis, 776; of aphthous vulvitis, 777.	
Part 12.	
DISEASES OF THE SKIN.	
CHAPTER I.	
DIREASES OF THE SKIN	778
The papular eruptions 778, prunigo, 778; strophulus, 779, vesioniar cruptions, 779, herpes, 779, pemphigus, 779, duration of the spots, 780; treatment, 789, pustular eruptions, 780; ecthyma, 780; scaly cruptions, 780, peoriasis 780; value of perchloride of moreury, 781; alopecia areais, 781; treatment, 781	
CHAPTER II.	-
THE ERVINEWATA	783
Erythema simplex, 782; its varieties, 782; erythema fugax, 782, erythema papulatum, 782; erythema intestrino, 782, the belladonna rash, 783; diamosis, 76 fimple erythema, 783; treatment, 781; symptoms, 784; illustrative case, 784, diagnosis, 784; treatment, 784, urticaria, 785, a sumptoms, 785, diagnosis, 786, treatment, 786, of the chronic form, 786; rescoia, 786, symptoms, 787; lliustrative case, 787; diagnosis, 787; treatment, 788.	

CONTENTS.

CHAPTER III.	
	789
Causation, 789; symptoms, 790; varieties, 790; eczema simplex, 790; eczema rubrum, 790; eczema capitis, 790; impetigo contagiosa, 791; eczema tarsi, 791; eczema infantile, 791; illustrative case, 791; diagnosis, 792; treatment, 792; diet, 798; local applications, 798; treatment of the varieties, 794; baths, 795.	
CHAPTER IV.	
MOLLUSCUR CONTAGIOSUR	796
Morbid anatomy, 796; symptoms, 796; diagnosis, 797; treatment, 797.	
CHAPTER V.	
THE PARASITIC DIREASES	798
Scables, 798; the acarus scablei, 798; the furrow, 798; symptoms, 798; intense itching, 798; various rashes, 799; diagnosis, 799; treatment, 799; tinea tonsurans, 799; pathology, 799; symptoms, 800; on the scalp, 800; on the body (tinea circinata), 800; diagnosis, 801; treatment, 801; in the infant, 802; in older children, 802; various applications, 808; tinea favosa, 804; symptoms, 804; diagnosis, 805; treatment, 805.	
CHAPTER VI.	
SCIRRENA	806
Two diseases often confounded together, 806; true sclerema, 806; morbid anatomy, 806; sclerema adiposa, 807; symptoms, 807; rigidity of skin, 807; low temperature, 807; rapid course, 807; cedema of new-born infants, 808; symptoms, 808; diagnosis between the two diseases, 808; treatment, 809.	

DISEASE IN CHILDREN.

INTRODUCTORY CHAPTER.

Tax difficulties connected with the investigation of disease as it occurs in early life may be easily exaggerated. The subject is no doubt a special one; but when the first strangeness has been overcome of dealing with patients who cannot describe their sensations, and who show their distress by cries and gestures which it requires experience to be able to interpret, the chief obstacle to progress has been surmounted. All necessary information as to the onset and early symptoms of the complaint can usually be obtained from the mother. Most women are good observers. Affection and anxiety increase their watchfulness, and make them fairly accurate recorders of every outward change. The stress laid by them upon particular phenomena is not, indeed, always a true measure of the real importance of the symptoms; but it is easy to correct any undue emphasis in the curretive by our own judgment and experience. Still, we must guard our selves from being mided by the very fulness of the report: facts may be accepted with confidence, but volunteered explanation of these facts must on no account he allowed to influence our conclusions,

When called to a sick child our first care should be to give an attentive bearing to the statement of the mother, supplying any gaps in the history by suitable questions. Having thus been enlightened as to the previous health of the child as I the nature of the earliest symptoms, we have next to collect what information we can from the appearance and manner of the pitient. To do this with success we must possess already a certain familiarity with the ways of infants and young children; but this is easily acquired with a little practice. Again, we have so to regulate our own bearing as not to alarm the child, who is already perhaps in a state of disquiet. It has been said that a natural fondness for children is indispensible to success in this branch of medicine; but this is an exaggeration. A quiet, genial manner with a pleasant smile and a gentle voice will soon dissipate the apprehensions of the patient and gain his confidence. Lastly, we proceed to a physical examination of the various organs. This, if done defiberately and without abruptness or hurry, can be effected in most cases without much trouble.

The main difficulty in the diagnosis of disease in early life arises, not from the absence of intelligent speech on the part of the patient, nor from any uncertainty in the recognition of visible signs of suffering. It springs from the perplexity we often feel in referring these symptoms to their true origin. Children are not merely little men and women in whose bodies

disease manifests itself by exactly the same tokens that are familiar to us in the case of the adult. They have special constitutional peculiarities which give to disease in early life a character it does not afterwards return, and invest the commonest forms of illness with strange features which may be a source of obscurity and confusion. The most striking peculiarity of childhood is a marked excitability of the nervous system-an excess of sensitiveness which any deviation from the Lealthy state brings at once into prominence. Consequently, a functional derangement which in the adult would give rise merely to slight local symptoms, in the child may be accompanied by signs of severe general distress, and the indications of local suffering may be thus overshadowed or completely concealed. A common example of this nervous excitability is seen in the disturbance which often results from swellowing some indigestible article of food The skin becomes burning hot, the child is in a state of extreme agitation, is perhaps convulsed, or lies in a state of stupor from which he can with difficulty be roused. In such a case the state of the stomach is apt to be overlooked; for even if the child vonit, which does not always happen, the symptom may pass almost unnoticed as one of the consequences of the general nervous perturbation. General symptoms of a like character may accompany the onset of any scute illness, and their severity bears no relation to the importance of the ailment of which they are a consequence. As profound a disturbance may be excited by the simplest functional derangement as by the severest organic malady; so that to the eye accustomed to the orderly progress of disease in the adult symptoms seem to have lost their value and to be calculated rather to unstead than to inform. This excitability of the nervous system in early life is a peculiarity which must be taken into account in every case of scute illness; and we must endeavour to separate the local symptoms - those which point to mischaef of a special organ from others which are merely the expression of the general distress. Such local symptoms are the cough, rapid breathing, and active nares which point to acute lung disease, the squinting and immobility of pupils which are so characteristic of cerebral affections, and the peculiar jerking movement of the legs which, combined with hardness of the abdominal muscles, betray the existence of colicky pain.

Local symptoms are not, however, to be discovered in every case, and even if present cannot always be relied upon to furnish trustworthy indications. Owing to the exaggerated impressibility of the nervous system a peculiar sympathy exists between the various organs. Consequently, symptoms induced by irritation in any part of the body are seldom limited to the part actually affected. Signs of distress arise at the same time from other and distant organs; indeed, the organ from which the more definite symptoms appear to arise is often not the organ which is the actual scat of disease. These deceptive munifestations are most frequently notreed in the case of the stomach and the brain. In the case of the stomach the response excited in this organ by irritation in distant parts of the body persists more or less through life. The vomiting of pregnancy and disordered uterine function in the female, and of cerebral and renal disease in both sexes, is a matter of common observation. In the child, however, this sympathy is still more frequently manifested. Vomiting is a common symptom at the beginning of most forms of acute illness and in many children may be excited by any casual disturbance. The brain again shows a marked sympathy with irritation of the more important organs. Headache, vertigo, delirium, and stupor are phenomena by no means confined to cases of intra-cranial suffering. Any serious inflammatory disease

in the child may be accompanied by such symptoms; indeed, the expression of cerebral sympathy may be so decided as completely to divert attention from the part which is really affected. The onset of pneumonia is sometimes complicated by such deceptive symptoms, and the same cause for mis-apprehension may be found in cases of perioarditis and inflammation of the peritoneum. So, also, the violent nocturnal delirium—the so-called "night terrors"—of children who suffer from worms or other form of gas-

tro-intestinal derangement must be within the experience of all.

One of the best illustrations of the excitability of the nervous system in early childhood is seen in the case of convulsions. An eclamptic attack as a symptom which, in the majority of cases, has a far less grave significance in the young child than it has in the adult. In the latter it is usually the evidence of some serious cerebral lesion, and its occurrence excites the greatest alarm. In the child, on the contrary, "a fit" is a common expression of disturbance in the nervous system. It may be induced in some of didner by a trilling uritant; and in cases of acute illness is often seen at the beginning of the attack, taking the place of the rigor which is so I valuer a symptom at the onset of the februle disease in the adult. Conunbarns, however, are not always, in the child, of this innocent character. In earlier as in later life, they may occur as a consequence of cerebral disers, but in such a case they are repeated frequently, and are succeeded by coma, ngichty, paralysis, and other signs of centric irritation. As a rule, single fits, or convulsions unaccompanied by other indication of ner, e-lesson, occurring in an apparently healthy child, are purely reflex, and have no gravity whatever.

Extreme excitability of the nervous system is, therefore, in early childhood, a untural physiological condition which exercises an important influonce in disturbing the orderly evolution of symptoms. Into an otherwise simple case it introduces a number of redundant features which confuse the observer, and may possibly divert his attention from the actual seat of This normal nervous irritability is subject to variations. Thus, it may be temporarily intensified by causes which produce sudden depression of strength, such as severe acute diarrhors, or rapid loss of blood. In rickets, again, a peculiar feature of the disease is the extraordinary excitability of the nervous system. As a rule, however, in chronic disease, when the interference with nutrition is slow and long-continued, an exactly opposite effect is produced. A young child, especially an infant, if exposed for a coust lerable time to injurious influences so as to suffer both in flesh and strength, gradually loses his susceptibility to reflex irritation, and the excitability of his nervous system becomes less and less obvious until it finally disappears almost entirely. In a child so enfeebled, the system, instead of reacting violently against any intercurrent irritation, appears almost insensible to nervous impressions. If an attack of acute illness occur, we look in vain for the usual signs of general disquiet. Even the ordinary symptoms of local suffering may be dimmished or suppressed; and were it not for the increase of weakness, and perhaps for a rise of temperature, the complication might be altogether overlooked.

This obtuseness of the nervous system is only seen as a consequence of long-continued and profound malnutrition. In all such cases, therefore, we should watch very narrowly for inflammatory complications, remembering that such intercurrent diseases may give rise to but few symptoms, and

may easily escape notice.

Another psycharity of early life which attracts attention, is the large share taken in infantale disorders by more disturbance of function, and the

serious consequences which may arise from derangement as distinguished from disease. Infants quickly part with their heat and are easily chilled. They are, therefore, peculiarly prone to catarrhal disorders, and these, if severs, may produce material interference with the functions of the organ affected. No doubt the excitability of the nervous system helps to increase the gravity of these derangements. The commotion into which the whole system is thrown by the attack, tends to exhaust the patient and greatly to enhance the enfeebling influence of the complaint. In infancy, death is a not uncommon consequence of these disorders; and it is for this reason that post mortem examinations in the infant are so often unsatisfactory. It constantly happens that a young child is seized with alarming symptoms of illness and quickly dies, yet on opening the body no sufficient morbid

appearances are discovered to explain the fatal issue of the case.

Children differ from adults in yet another respect. Disthetic tendencies are especially active in early life. They exert a remarkable influence upon the growing body, shaping the figure, moulding the features, and so ordering the structure of organs that any interference with the nutritive processes, such as may be produced by ordinary insanitary agencies, is followed by widely distributed mischief. Sir William Jenner has drawn attention to the number of organs affected at the same time in cases of distance in the child. In a bad case of inherited syphilis, few tissues or organs escape; in scrofula the lesions may be almost universal; and in acute tuberculosis all the cavities of the body may be simultaneously affected. Thus, according to the constitutional character of the patient and the nature of his ailment, a child may die from mere arrest of function, with tissues sound, organs healthy, and no morbid appearances left to declare the nature of the complaint; or may succumb to a profound and general disease which visits every part of the body and leaves scarcely

any organ unaffected.

It is sometimes said that in a healthy child acute disease naturally tends to recovery, but this statement must not be taken without qualification. There are some diseases, such as typhoid fever, measles, and perhaps croupous pneumona, which commonly run a milder course in earlier than they do in later life; but there are others, especially acute affections of the gastro-intestinal tract, which weigh with peculiar severity upon the young. In infancy the patient is so dependent upon a frequent supply of nourishment that an abrupt interference with the nutritive processes, such as occurs in some forms of bowel complaint, is an event of the utmost gravity. Often it is followed by so much exhaustion that the infant rapidly sinks and dies. It is this sudden and complete cutting off of the nutritive supply which constitutes the chief danger of scute disease in the child; and in early life illness is often serious in exact proportion to the degree in which the alimentary canal takes part in the derangement. When digestion is not arrested and the system still continues to receive nourishment, the child, if in favourable conditions and of healthy constitution, will probably recover. The recuperative power of nature is very great, especially in the young; but that it may be free to operate it is essential that no unfavourable condition be present to impede the natural course of the illness. Over and above grave implication of the digestive organs, other untoward elements may enter into a case, and each of these has an influence in weakening the natural tendency to mend. The age is a matter of great importance. A new-born infant has but a feeble hold upon life and quickly succumbs to an attack of acute illness. Later, the child may be burdened with a disthetic taint which has already impaired

his nutrition and lowered his vital energies. Moreover, he may be hampered by unhealthy surroundings which intensify the weakening influence of the original disease, and, indeed, by themselves are often powerful enough to prevent recovery.

Therefore it is only in children of healthy constitution who are placed under favourable conditions that illness can be said naturally to tend to recovery, and in them only after the period of earliest infancy has passed by, and in cases where, nutrition not being completely airested, a limited sup-

pry of nour shment continues to be introduced into the system.

Sad len death in early childhood, is due, as a rule, to laryngismus, to syncope, or to collapse of the lung; and occasionally it is seen as a consequenes of convulsions. Spasm of the larynx is the common cause of death in children who are apparently healthy. Those who die suddenly in the coarse of an acute illness or during convalescence, do so usually from syncope, or in rarer cases from thrombosis in the pulmomity artery. In wasted infinits sudden death is more commonly the consequence of pulmonary collapse. When a disease is about to end fatally the extremity of the danger is shown by a marked alteration in the temperature. In some cases we notice a ripid fall, the thermometer registering only 96 or 97 in the rectum. In others there is a sudden increase in the bodily heat, and the temperature rises quickly to 108" or 109". The ante-mortem cooling is usually noticed in chronic ailments and in bronchitis with collapse of the lung. The rapid increase in heat is common in cerebral affections and in cases of acute gastro-intestinal derangements. Other unfavourable signs are lividity of face, refusal of food, thrush, rapidity and feebleness of the pulse, heaviness and stupor.

In acute disease when recovery takes place, convalescence is usually repri. In an uncomplicated case the strength appears to be recovered almost as quickly as it was lost. Directly the temperature falls, digestion as i nutrition resume their course and in a surprisingly short time the child is well. If convalescence is delayed in such a case it is almost invariably the consequence of a complication, and it must be remembered that this need lent is far from uncommon in the child. In all forms of catarrhal derangement—a variety of disease to which childhood, as has been said, is peculiarly prone—a gastro-intestinal complication may increase the gravity of the illness and delay the process of repair. Sometimes the depurative of the illness and delay the process of repair. Sometimes an unabsorbed patch of consolidation in the lung interferes with the return of strength. In all cases, therefore, where convalescence from acute disease is delived, or having begun, appears to falter, we should make careful examination of the various organs so as to discover the muschief and apply a

remedy.

In cases of chronic illness convalescence is usually tardy. The delay, no doubt, is partly owing to the fact that this class of discuse is common in children of a scrofulous habit of body; and the strumous cachexia is in itself a bur to rapid improvement. It is, however, also often due to the nature of the illness. In early life, especially in infancy, chronic udments commonly affect the alimentary canal, either primarily or secondarily, and the progress of such complaints to recovery as invariably slow.

In the following pages the term "infancy" is confined to the two first years of life, or to the period which ends with the completion of the first tentition. "early childhood " to the period between the close of the second and the close of the fourth year. The period of childhood ends at paberty. This important change occurs at various ages, especially in girls;

and some young people remain children both in mind and body to a much later date than others.

In the examination of an infant or young child every care should be taken to avoid abruptness or hurry. We must remember that we have to do with beings who act not from reason, but from instinct; that any sudden movement frightens them, a little pressure hurts them, and in either case a cry and a struggle bring the examination abruptly to a close. Again, young children, as a rule, dislike the sight of a strange face, and if old enough to understand the object of the visit, are already prepared to look with distrust upon the "doctor." Still, it is a mistake to suppose that children always make unmanageable patients. They are no doubt quick to take fright; but it should be the constant care of the practitioner to avoid any look or gesture which may arouse their suspicions. If he look, speak, and move gently, and do not hurry, most young children will let

themselves be examined thoroughly without great difficulty.

On entering the room it is well to accustom them to our presence before we even appear to notice them at all. This interval can be usefully
occupied by questioning the mother as to the onset of the illness, and the
character of the early symptoms. We can also take this opportunity of
inspecting the motions or vomited matters. In searching into the history
of the case it is especially desirable to obtain some starting-point for our
investigations. The question "When did the indisposition begin?" often
receives only a vagno reply; while an inquiry as to the time which has
elapsed since the cluld was last in good health may elicit an account of
more or less interference with nutration and indefinite malaise extending
over a considerable interval. Some tact is often required in obtaining a
definite account of the beginning and early progress of the illness. It is
important to avoid suggesting a reply by the character of the question,
while it is often necessary to be minute in our inquiries in order to stimulate a flagging memory.

In infants and young children much may be learned from mere inspection of the face. It is an advantage in these cases to find the patient asleep. We can then study at leisure the colour and general expression of the face, the form of the features, the presence or absence of lines or wrinkles, and remark if the nares act in respiration or the cyclids close incompletely. We can besides notice the attitude of the child, can count the pulse and respiration, and can observe their degree of regularity or any deviation from the healthy state. Even if the child be awake, many of these points can be noticed if we approach quietly and do not speak to or offer to touch the patient. Any movements he may make at this time in his cot must receive due attention, for they often convey very valuable

information.

These points having been noticed, the temperature should be taken. In doing this, if the patient be an infant, it is desirable to introduce the bulb of the thermometer into the rectum, for at this early age the difference between the internal and external temperature of the body is often considerable. The child should next be completely stripped of his clothes. The state of his skin can then be ascertained, noting the presence or absence of cruption; and a careful examination must be made of the abdomen and chest. If the child lose his temper at this time, the quality and strength of his cry should be remarked. At the end of the visit the gums, mouth, and throat should be inspected, and if any of the child's water can be procured, it should be examined for albumen, and its density and degree of acidity ascertained.

After this rapid sketch of the method upon which the clinical examination of the infant and young child should be conducted, the chief points to which attention must be directed may be considered more in detail.

In the new-born infant the tent of the face immediately after birth is a dull red. The redness, however, soon begins to subside; in a day or two the complexion assumes a slight yellow tint, and then passes into its normal coloring. The yellow tint and its diagnosis from infantile jaundice

are referred to obsewhere (see Jaumhee).

The clear fresh complexion of a healthy baby or young child is familiar to every one. A loss of its purity and clearness is one of the first indicatrous of digestive derangement. The face becomes muddy looking and the upper lip whitsh or bimsh. Blueness of the upper lip in early life is a common sign of Liboured digestion. In some children difficult digestion is shown by an earthy tint of the face which spreads to the forehead. It appears a short time after the meal and may last several hours. In chrome bowel complaints the earthy tint is constant. It is common in cases of chrome duarrages in the mant, and if at the same time there is much emporation, the derangement is likely to prove obstinate. In syphilis the prominent parts of the face—the nose, cheeks, chin, and forehead assume a swarthy five. In lardrecous disease the complexion is peculiarly pallid and bloodless; in rickety children whose spleens are greatly enlarged it has a greenish or faint olive cast; and in cyanosis the face has a characteristic leaden tint, the conjunctive are congested, and the cyclids and hps thick and purple. Lividity of the skin round the mouth and nose with a purple tint of the eyelids is common as a result of deficient accration of the blood. In severe cases the checks at the same time have a dull white color, and the symptom is an unfavourable one. In the spasmodic stage of whooping-cough the face looks swollen as well as hvid, the hps and eyelids are purple and thick, and the conjunctive are congested and often bloodshot.

In addition to the actual tint of the face the general expression must receive attention. In a healthy babe the physiognomy denotes merely sleepy content, and no lines mark the smooth uniform surface. Pain is indicated by a contraction of the brows which wrinkles the skin of the forehead. This is especially noticeable if the head is the seat of suffering. If the pain be in the abdomen the nose often looks sharp, the nostrils are distresd, and the child draws up the corners of the mouth with a peculiar expression of distress. In every case of serious disease the face, even in reposit, has a haggard look, which must not be disregarded. If this be accompanied by a hollowness of the cheeks and eyes the result is a ghastly expression which cannot escape attention; but a distressed look may be seen in the face although there is no loss of roundness of feature. If this be the case, even in the absence of striking symptoms, we may confidently predict the onset of serious disease.

Often an inspection of the face will help us to a knowledge of the part of the body affected. Many years ago M. Jadelot pointed out certain lines or furrows in the face of an ailing infant which by their position indicate

the west of the derangement, thus:

The exente-zygomatic line begins at the inner canthus of the eye, passes thence downwards and outwards beneath the lower lid and is lost on the check a little below the projection of the malar bone. This line points to discuss or derangement of the brain and nervous system.

The mosal line rises at the upper part of the ala of the nose and passes downwards curling round the corner of the mouth. This line is a constant

feature of abdominal mischief, and is never absent in cases of gastrointestinal derangement.

The label hue begins at the angle of the mouth and runs outwards to be lost in the lower part of the face. This is more shallow than the preceding. It is a fairly trustworthy sign of disease in the lungs and air-

passages

These lines have a distinct practical value and should be always attended to. We should also notice if the cyclids close completely, for imperfect closure of the lids during sleep is a common sign of weakness. Moreover, it must not be forgotten to ascertain the condition of the pupils and the presence or absence of squint. The value of these symptoms, and of others connected with the eye, is referred to elsewhere (see page 261). The nares must not be forgotten. If they set in respiration the movement is a common accompaniment of laboured breathing and often indicates an impediment to the respiratory function. It may, however, be present in cases where there is no conscious dysphosa, and is sometimes seen in simple pyrexis. Even the shape of the features must be attended to. An clougated head with square forchead and small lower jaw are characteristic of inchest; a broad flat bridge to the nose, especially if conjoined with prominence of the forchead and absence of eyebrows, suggests syphilis; and a big globular head surmounting a small face and little pointed chin

indicates unmistakably chronic hydrocephalus. The attitude of the child as he lies in his cot is not to be overlooked. Sometimes it is characteristic. A healthy infant or young child, even if lying on his back, inclines to one side and turns his head so as to bring the cheek in contact with the pillow. If a baby be found lying motionless on his back, with closed eyes and face directed straight upwards to the ceiling above him, he is probably the subject of serious disease. This position may be seen when the child is unconscious, as from tubercular meningitis; or is profoundly depressed, as in acute inflammatory diarrhaa. If the child lie on his side with his head greatly retracted on his shoulders, it is a suspicious sign of intra-cranial disease. If in such a position the breathing is audible and hourse, the case is probably one of laryngitis, or there is some impediment to the passage of air through the glottis. If the patient be found in his cot resting on his cloows and knees with his forehead buried in the pillow, or if he sleep lying on his belly, there is no doubt abdominal discomfort. These positions are common with rickety children. If the child press his eyelids against the pillow, turning partially on his chest, we may suspect intolerance of light.

Healthy infants and children sleep perfectly quietly. Frequent turning of the body or twitching of the muscles generally indicates feverishness or digestive derangement. If the child move his head constantly from side to side on the pillow, he is probably annoyed with pain in the head or ear. Frequent carrying of the hand to the forehead or side of the head has usually the same significance. If the child repeatedly flex the thighs on the abdomen, and cry violently in sudden paroxysms, he is probably

suffering from colic.

The cry of the child is a symptom of considerable importance. It is usually elicited by hunger or uneasiness, and from the manner of crying we can often gather considerable information. A hungry infant in most cases elenches his hands and flexes his limbs—both arms and legs—as he utters his complaints; and will often continue to do so until his desires are satisfied. Thirst may also be a cause of crying, and may be suspected if the child sucks his hips repeatedly, has a dry mouth, or has been suffer-

ing from purging. If he be tortured by colicky pain, the cry is violent and paroxysmal, and is accompanied by uneasy movements of the body and jerking of the lower limbs. The belly is also full and hard, and there is often a blue fint round the month. A shrill scream uttered at intervals, the child bring in a drowsy state with closed eyes, is suggestive of tubercular meninguis. A constant unappeasable screaming is often the consequence of earsiche. This panful affection is very common in infants, and should be always suspected if the lumentations continue without intermismental breast. The pain of pleurisy will also cause violent crying. In this case pressure upon the sides of the chest, as in lifting the child up, causes an evident increase in his suffering. Any alteration in the quality of the cry must be noted. It may be hourse in a young infant from inherited syphilis; in an older child from laryngitis or enlargement of the bronching glands.

In a healthy infant a cry is excited at once by anything which causes him discomfort or inconvenience; therefore the absence of crying is a sumptom which should always receive due attention, as it may betoken serious disease. In inflammatory affections of the lungs, in pulmonary collapse, and in advanced rickets where the bones are softened, a child will hear emisterable discomfort without loud complaint, for he has a pressure want for air and dare not hold his breath to cry. So, also, in severe distributes or any other illness which causes great reduction of strength, the child on account of his weakness, cries little if at all. In cases of profound weakness he will often be noticed to draw up the corners of his mouth and wrinkle his brows as if to cry without making any sound.

In the act of crying tears are copiously secreted after the age of three or four months. In serious disease, however, the lachrymal secretion often fails. Therefore the absence of tears must be taken to indicate con-

asierable danger.

The pulse in the infant can seldom be counted, except during sleep; as I even if its rapility can be ascertained the information thus derived is of little value. The rapidity of the pulse in infancy is constantly varying. The least movement excites the heart's action, and mental emotions, such as fright or anger, almost double the rapidity of the cardiac contractions; so that, according as to whether the infant is awake or asleep, is perfectly quest or has just moved, the pulse may vary from between 80 and 90 to 161) or 180) As a test of physical vigour in babies the pulse is worthless. In this respect the fontanelle is of far greater value. In infants under twelve months old a sinking of the fontanelle is a sure sign of reduction of the street th; and in touching a child of this age our first care should be to pass the unger over the top of the head and ascertain the condition of this part of the skull. In wasted babies the fontanelle often forms a cupshaped depression; and if the loss of flesh is very rapid, as when a prota-drain occurs from the bowels, the cranial bones may often be felt to meriap slightly at the sutures. Excess of fluid in the skull-cavity or a hyp remic state of the brain causes bulging and tenseness of the fontanelle. Indeed very distended the membrane is not motionless. It can be seen to more with respiration and to sink appreciably as air is drawn into the lumes

After the period of infancy has passed, the pulse becomes a far more tru-tworthy gorde. During sleep it is fifteen or twenty beats slower than during the waking state, and may then be occasionally irregular in rhythm or even completely remittent. When the child wakes the pulsations in-

crease in frequency and usually rise above 100. If at this age the pulse is found to fall as low as 60 or 70 in a child who is not asleep, and to intermit completely, the sign may be significant of tubercular meningitis. This

matter is elsewhere referred to (see page 359).

The respirations should be always counted. In new-horn infants their number is about 40 or perhaps more in the minute. But the breathing soon becomes less rapid, although for a long time the movements are more frequent than in the adult, and even after the second year are usually over 20 in the minute. The normal average is difficult to ascertain, for like the pulsations of the heart the breathing varies greatly in rapidity. It is rather slower during sleep than when the child is awake, but is apt to become more hurried from slight causes. More important than the actual rapidity of either the breathing or the pulse is the ratio the two bear to one another. If the breathing become rapid out of proportion to the pulse, the discrepancy should be carefully noted. The normal ratio is 1 to 3, or 3.5. If this proportion becomes greatly perverted and we find one respiratory movement to every two beats of the pulse, we should suspect the presence of pneumonia or of pulmonary collapse. The regularity of the respiration is also to be noticed. A slight irregularity, especially in force, is common in mants; but if the breathing become markedly irregular, the symptom may be an important one. Frequent heavy sighs and long pauses, during which the chest is perfectly motionless, are very suspicious of tubercular meningitis.

The temperature of the child ought always to be ascertained. It must be taken with care. In a healthy infant the temperature of the rectum is about 99, and is fairly constant throughout the day. It rises half a degree or so towards the end of digestion, but a marked difference between the morning and evening temperature is not noticed in a healthy baby who receives proper attention. According to Dr. Squire, if the boddy heat is found to vary considerably at different times in the day, the symptom should suggest neglect on the part of the nurse or delicacy of constitution on the part of the child. If the infant he kept too long without food the temperature falls, and will then rise again considerably after the meal. It also appears from Dr. Souire's interesting observations upon young babies, that the temperature is rather lower during sleep than when the child is awake. Even after the age of infancy the temperature is subject to frequent variations from slight causes; and in young children mental emotion will often induce a degree of fever which may be a source of perplexity. In children's hospitals it is a common observation that the bodily have the the evening of admission is high even when the disease is not one usually

attended with fever.

On account of the excitability of the nervous system in early life—a peculiarity of childhood which has been before referred to—children are very subject to what has been called "irritative fever," i.e., to a form of pyrexia which results from fretting of the system by various sources of irritation. Dentition, as is explained elsewhere, is a frequent promoter of this form of febrile excitement, and a pyrexia induced by this means is apt to complicate derangements ordinarily non-febrile and be a cause of confusion. So, also, irritation of the bowels by scybala, indigestible food, or parasitic worms, is a common cause of elevation of temperature in the young. The febrile movement resulting from the presence of a local irritant, like other forms of pyrexia in childhood, is generally remittent; but the remissions are not always found at the same period of the twenty-four hours. There is not always fail of temperature in the morning and a rise

at hight. One of the peculiarities of this form of febrile disturbance is the irregularity of the fever. In a young child a temperature higher in the morning than at hight should always suggest some reflex cause for the

pyrexin.

It is very important not to neglect the use of the thermometer in judging of the heat of the body, for not only is the hand very deceptive as a guide, but the skin of the patient may appear to be cool although the internal temperature is several degrees above the normal level. It is not uncommon in cases of inflammatory diarrhoea to find the extremities so cold as to require the application of a hot bottle, while a thermometer placed in the rectum registers 104 or 105. Sometimes in young children the pyrexia will reach a very high level. At the end of an attack of tubercular menugities the temperature is often 100° or 110°; and the same degree of febrile heat is occasionally seen in eases of acute gastro intestinal inflammation. In either case the symptom betokens extreme danger; although it must not be concluded that the illness will inevitably prove fatal. I have known a baby of a few weeks old recover after its rectal temperature had risen to the alarming height of 109.

Sometimes instead of an elevation the thermometer may show a lowering of temperature. In infants any reduction in the bodily heat is usually a sign of deficient nourishment. In a baby exhausted by chronic vonnting or purging the temperature in the rectum may be no higher than 97°. This is of course an extreme case; but a lesser depression is often found a infants insufficiently nourished, either from watery breast-milk or an unsuitable dietary. Again, in convalescence from acute disease the temperature usually remains for some days or even weeks at a lower level than that of health. This phenomenon may be often noticed after typhoid and

the other eraptive fevers.

Before leaving the subject of temperature, reference may be made to the pyrexia which sometimes attends rapid growth. Several cases have come under my notice in which growing girls were exciting great anxiety by a persistent evening temperature of over 100°. In one such case, a girl of twelve had been kept in bed for five weeks and treated for typhoid fever, the girl all the time begging to get up and declaring herself to be perfectly well. The patient was brought to me from the country for an opinion, as the temperature for six weeks had varied every night between 33 and 100 6. I examined the club carefully and could find nowhere any sign of disease. She looked healthy and was said to be growing rapidly. I accordingly a lyised that she should be no longer treated as an invalid, but should be allowed to get up, be put upon ordinary diet, and be sent as much as possible into the open air. This was done, and at the end of a fortugant the temperature became normal and did not afterwards rise.

Hiving obtained all the information we can without unnecessarily disturbing the patient, we should next, in the case of an infant or young child, have the clothes completely removed so as to be able to make a thorough extratation of the surface of the body. We can thus notice the condition of the skin as to texture and elasticity, and remark the presence or abstract of cruptions or signs of inflammatory swelling. In a healthy young child, the skin is delicate and soft, and of a beautiful pinkish-white tint. If it feel dry and have an earthy bue, the change is suspicious of chronic bowel complaint. If the skin is wanting in elasticity, we should suspect tubercutions or renal disease; and if the kidneys be performing their functions in operfectly, the skin may be often seen to lie in wrinkled folds upon the abtorners. Dryness, with a dingy hue of the skin, is also common in some

forms of hepatic disease, and occasionally in chronic tubercular peritonitis. At this part of the examination, any sign of tenderness either general or local should receive attention. The sharper cry of pain is usually to be readily distinguished from the cry of irritability or anger. In rickets there is general tenderness which unkes all pressure painful. In pleurisy pressure upon the sides of the chest, as in lifting the child up, is a cause of acute suffering. Sometimes signs of local tenderness can be discovered, such as may accompany the formation of matter beneath the surface; or again, slight tenderness of a joint may be the only indication of rheuma-

tism in the child.

The attention should next be directed to the respiratory movements. In healthy young children respiration is chiefly diaphragmatic. Foreible movement of the thoracic walls is a sign of laboured breathing, and is a constant symptom of broncho-pneumonia. Great recession of the lower parts of the chest suggests an impediment to the entrance of air into the lungs. If at each inspiration there is great recession of the epigastrum, the lower part of the sternum being forced inwards so as to produce a deep hollow in the centre of the body, the obstruction is probably in the throat or larynx. Such a depression is seen in the case of retro-pharyngeal abscess, in stridulous laryngitis, and diphtheritic croup. If the class fall in laterally so as to produce a deep groove, running downwards and outwards at each side of the chest, while at the same time a Lorizontal furrow form at the junction of the chest with the abdomen, the impediment is due to softening of the ribs. This is characteristic of rickets. Sometimes in children who suffer from enlarged tonsils a cup-shaped depression is seen at the lower part of the sternum. It is right, however, to say that this deformity is not confined to children with enlarged tousils. I have seen it well marked in patients in whom the pharvnx was perfectly normal, and in whom no impediment appeared to exist to the entrance of air into the lungs. If the clest move more freely on one side than on the other, we should suspect grave mischief on the side on which the movement is hampered. Still, in the child serious disease of the chest may be present without our being able to detect any such difference. Even in cases of copious pleuritic effusion, no impairment of movement in the intercostal spaces of the affected side may be visible. Marked contraction of one side of the thorax with curving of the spine is suggestive of a late stage of pleursy, or of an indurated lung.

In the healthy child the abdomen moves freely in respiration. If it be motionless, therefore, an inflammatory lesion of the belly should be suspected. If the superficial veins of the abdomen are unnaturally visible, the symptom is suggestive of some impediment of the abdominal circulation, such as would be produced by enlarged mesenteric glands or hepatic disease. In young children the belly is always disproportionately large. Its size is due to shallowness of the pelvis, to flatness of the draphragm, and to laxness of the muscular walls, which yield before the pressure of the flatus in the bowels. In some healthy infants the abdomen is much larger than it is in others. The difference is probably due in most cases to an exaggerated amount of flatus formed in the bowels during digestion. The size of the belly from this cause sometimes alarms parents, and it is not uncommon to be consulted with regard to this point in the case of young children who are in every respect perfectly healthy. Often, however, the enlargement is due to increase in size of the liver and spleen, to the presence of a growth, or to accumulation of fluid in the peritoneum. The size of the liver and spleen may be ascertained by placing the hand flat upon the abdomen, the fingers pointing to the chest, and pressing gently with the finger tips. In this way with a little practice the edges of these organs curred his be felt. At the same time, if the child be not crying, we can ascertain the degree of tension of the abdominal wall and the presence or absence of fluctuation. Abnormal tension of the parietes, especially if it is more marked on one side than on the other, is suggestive of peritonitis or ulceration of the bowels. For the means of diagnosis of the s-veral conditions which give rise to abdominal enlargement the reader is referred to the chapters trouting of these subjects.

If, instead of being distended, the belly is markedly retracted we have reason to suspect the presence of tubercular meningitis. To examine the abdominal organs at all satisfactorily the child must lie on his back with his head and shoulders raised by a pillow. The mother or nurse should sit up in the bed by his side, and the practitioner should take care that the hand he applies to the belly is warm and does not press too abruptly so as to give pain. This part of the examination is usually submitted to without

opposition if the child be humoured and cheerfully talked to.

Even an examination of the chest can generally be undertaken without fear of failure. Infants, as a rule, seldon, give much trouble; and if there is any scrious disease present in the lung, they are too much occupied by the needs of respiration to spare time to cry. In early childhood there is many reason to fear opposition, but with patience the examination can usually be carried to a successful issue. A stethoscope is seldom objected to fit be first placed in the child's hand and called a trumpet. For further canarks upon this subject and the peculiarities of the physical signs in childhood the reader is referred to the special chapter on examination of the chest in children.

Inspection of the month and throat should be always deferred to the call of the visit, is this part of the examination invariably produces every month tation of displeasure. An infant will often protrude his tongue when gentle pressure is made upon his clain, and a finger can be usually passed over his gains without sign of opposition; but to look at the throat we are forced to depress the tongue. If any symptoms are noticed requiring the operation, every precaution should be taken to render it successful. The nurse sitting in a low chair facing the window or a good lamp, holds the child struight upon her lap with his back resting against her chest. She then with her arm thrown round his body prevents the patient from changing his position or raising his hands to his mouth. At the same time an attendant standing behind her with a hand on each sude of the child's face holds his head in a convenient position. Matters being thus arranged it is the practitioners own fault if he do not obtain a good view of the faces. Firmle see is absolutely necessary at this point. Any other plan is equally aumoving to the patient, and is almost certain to end in failure. Before inspecting the throat, the sides of the neck should be examined for evidence of swollen cervical glands.

In some cases it is important to ascertain if the child takes the breast, sacks the bottle, or drinks from a cup with ease. In infantile tetanus the next fact that the patient is able to swallow enables us to speak less unfavourably of his chances of recovery. In cases, too, of apparent stuper, if the child still continue to take his food the sign is a favourable one. If a child be suffering from acute lung disease, he sucks by short suitches, supring at frequent intervals to draw his breath. A syphilitic child with occursion of the mines sucks with great difficulty, as his nose is useless for respiratory purposes and all air has to pass through his mouth. An infant

with bad thrush has much pain in drawing the milk from soreness of his mouth and tongue, and may refuse his bottle altogether. If the throat be sore the child swallows noisily, and often relinquishes the nipple to congl.

Lastly, the practitioner should be careful to inspect the vomited matters and discharges from the bowels, as the description of their appearance given by the best nurses is rarely to be trusted. The varieties of loose stool are elsewhere considered. Food vomited sour from the stomach indicates a catarrhal state of the gastric nursus membrane. Much mucus mixed with the ejected matters is also a sign of the same condition. Vomiting is not, however, always a symptom of distress. An infant who has swallowed too large a quantity of milk, or has taken his bottle too hastily, will often eject a part of the meal; but in such a case there is nothing offensive about the matters thrown up and the child himself shows no sign of distress.

In the treatment of disease in early life the actual administration of physic is of less importance than a careful regulation of the diet and attentive nursing. It is the duty of the practitioner to see that no impediment is thrown in the way of the proper working of the various functions; that the stomach is supplied with food it can digest, that the skin, the kidneys, and the bowels are encouraged to carry on their duties as enunctories, that the air of the room is kept pure and frequently renewed, and is

moreover maintained at a suitable temperature.

Febrile attacks are very common in childhood, and if the temperature is high (i.e., above 100°), which it may be from very slight and transient causes, the child should be confined to his bed and kept there as long as the pyrexia continues. In all forms of fever the child should occupy a large, well-ventilated room. This should be kept at the temperature as nearly as possible of 65°, and every care should be taken to maintain the air of the room fresh and pure. Still, no draught must be allowed. If the window is open the patient must be scrupulously protected from all currents of air. No discharges from the body, soiled linen, dirty plates or dishes should be allowed to remain in the sick-room a moment longer than is necessary; and in the case of the infectious fevers the exercta must be disinfected at once, and the soiled sheets and other linen steeped after removal in a tub of water containing carbolic acid or other disinfectant.

All noise and bustle must be prohibited; and few persons must be allowed at the same time in the room. If the child require amusement, he must be allowed only such unexciting diversions as books, pictures, and quiet games can afford. His food should be of a light, unstimulating kind, such as thin broth, milk, light puddings, and jelly. His thirst may be assuaged at frequent intervals, care being taken, however, that only small quantities of fluid are allowed on each occasion. Too birge quantities of liquid distend the stomach, impair the digestion, and help to promote diarrhera. This is a fact of some moment in the treatment of diseases where purging is a common symptom, as measles and typhoid fever. It is advisable to make use of a small glass holding about two ounces, for the child will be usually satisfied if allowed to drain this to the bottom. As the patient grows weaker and requires more decided support, he may be given pounded underdone mutton, strong boof-essence, yolks of egg, and, if stimulants are required, the brandy-and-egg mixture of the British Pharmacopacia.

In cases where deglutition is difficult or impossible, as in infantile tetanus or the paralysis which follows diphthema, and in all cases where from wilfulness or incapacity an adequate supply of food is not taken, it may he necessary to feed the child through a tube introduced into the stomach. The operation is last performed by passing an elastic cubater through the new and down the gullet. The instrument is more conveniently intraduced through the nose than through the mouth. Less opposition is aroused by this method, and little or no irritation appears to be set up in the most processes. The tube ' properly oiled must be directed along the door of the need cavity into the pharyna, and can be then reachly pushed down the gullet into the stomach. If it catch against the top of the laryna, a spasingdic cough is excited. The instrument must be then withdrawn sughtly and again pushed forwards. There is little difficulty about the operation if the child's head be directed well backwards. By this means liquid food can be administered regularly; and in certain diseases especially infuntile tetanus, where nourishment is urgently needed and is indispensable to success in the treatment-feeding through the nose

becomes a valuable addition to our resources.

If the power of swallowing be ununpaired, a simpler method may be viopted. In such a case it is only necessary to carry the food into the faures. If other means are not at hand, fluid nourishment may be poured directly into the nestral as the child has in his cot. The liquid at once countries to the back of the throat and is swallowed as it reaches the parent. If preferred, the fluid may be injected through a short cabuttheir tube passed through the nose to the upper part of the gullet. In most of these cases, however, the simple and ingenious method devised by We Seett Battains, and introduced by him into the East London Childr. i's Hospital, may be resorted to. In the case of weakly or collapsed minute this method is invaluable; but children of all ages, if postrated by sliness, can take nouralment more conveniently by this means than by any other. The apparatus is of the simplest kind, and consists merely of an ordinary gives syringe with a piece of India-rubber tuling, four inches long, slipped over the nozzle. The syringe is filled in the ordinary way by drawing up fluid through the tubing. The tube is then passed between the childs hips towards the back of the tongue and the contents of the syringe are slowly discharged into the mouth.

These different methods of feeding are all useful. The stomach-tube presel through the nose should be employed in all cases where deglutition is impaired, from whatever cause -either from inflammatory conditions of the throat, from loss of excitability of the pharynx owing to cerebral disor parente poisoning, or from paralysis, as after diphtheria. The arrange-freder just described may be used in cases of great weakness and prostration, and in all cases where the power of swallowing is not inter-

The question of reducing temperature when this rises to a dangerous height is an important one. Children often bear a high temperature well, an 1 it is not always easy to say what degree of heat constitutes hyperpyrexia in a child. When the fever is due to a septic cause it is perhaps less well berns than when it is the consequence merely of a local inflammation. In my case if the temperature rise above 106, or if the patient seem to be listressed by a less degree of heat, it is advisable to sponge the surface of the Lody with tapid water. If the fever be not reduced by this means, the

Il a last tube to use is a ruleanised india-rubber catheter sufficiently stiff not to

Mr Battam's paper on the Forced Peeding of Children, in the Lancet of June 1961 23, "Sei in which the various methods of feeding are described, is full of interest and instruction.

child should be placed in a bath of the temperature of 75°, and be kept there until the pyrexia undergoes a sensible diminution. Usually sponging the surface will reduce the bodily heat by several degrees, to the immediate relief of the patient. In cases of inflammatory diarrhora, even in babies of a few months old, the temperature often rises to 109 or 110°, and the child passes into a state of profound depression. When this happens death is inevitable unless the pyrexia can be quickly reduced, and tepid bathing is often successful in greatly retarding if it do not actually prevent a fatal issue to the illness.

In all forms of fever the comfort of the patient is greatly promoted by the use of two cots—one for the day, the other for the night. In cases of pericarditis with copious effusion, in the later period of typhoid fever, and in other instances where the debility is extreme or the action of the heart hampered and feeble, the change from one cot to the other must be made with every precaution to spare the child all spontaneous movement,

and to keep him in a recumbent posture.

In the treatment of disease in early life the remedies at our command are the same as are useful for similar conditions in the adult. On account however, of the impressible nervous system in the young subject external applications are of greater importance in childhood than they become in after years. Amongst the remedies of the greatest value baths form a class of no little importance. According to the temperature of the water employed the bath becomes a sedative, a stimulant, or a tonic, as may be required; and in these different shapes is often resorted to with great advantage. The usefulness of tepid bathing in reducing fever has already been referred to.

The warm bath (80° to 85° Fah.) is very useful in cases of convulsions or great irritability of the nervous system, shown by agitation, restlessness, spasm or disturbed sleep. It calms the excitement, allays spasm, promotes the action of the skin, and induces sleep. On account of its disphoretic effect warm bathing is of great service in cases of Bright's disease. In infants the warm bath has a sensible influence in promoting the action of the bowels, and in cases of constipation is often a valuable addition to purgative medicines. The child should remain from ten to twenty minutes in

the warm water.

The not both (95° to 100° Fah.) is of great value as a stimulant where there is sudden and severe prostration, such as occurs in cases of profuse durrhoea, urgent vomiting, shock, or other cause which induces a temporary depression of the vital energies. When employed in this way as a stimulant the child must not remain too long in the water or the stimulant effect will pass off and be succeeded by depression. For an infant three, and for an older child five minutes will be sufficient immersion. The patient can then be removed, wiped rapidly dry, and laid between blankets with a hot bottle to his feet. This bath may be made more stimulating by the addition of mustard. Flour of mustard, in the proportion of one cunce to each gallon of water, is mixed up with a little warm water into a thin paste and placed in a piece of muslin. This is squeezed in the hot water until the latter becomes strongly sinapised. So prepared, the mustard bath is an important remedy in cases of prostration and collapse. The child should be held in the bath until the arms of the attendant supporting him begin to tingle.

The rold dancke is a tonic of the utmost value. It must, however, be employed with discretion, for the patient if weakly seldom obtains a proper reaction unless special precautions be taken. If the child look blue or

feel chilly after the bath, the shock to the system has been too violent. For a weakly cluid the cold douche should always be given in the followme way: On rising from his bed the child is thoroughly shampooed all over the body, using steady frictions especially to the back and longs. His skin being thus stimulated and prepared to resist the shock of the cold water, the patient is made to sit in a few inches of water as hot as he can conveniently bear it, and then immediately a pitcher of cold water (55° to (21) is complied over his shoulders. He is then at once removed, and well rubbed with a rough towel to assist reaction. In winter the bath stould be placed before the fire, and every care should be taken to make the process a rapid one. The shampooing will occupy from ten to fifteen minutes, but the douche should be over in as many seconds. It is well to allow the child a drink of milk or a biscuit before beginning the process; and when dried the child may return to his bed for a short time if thought desirable; but after one or two repetitions of the bath this precaution will be unnecessary. So employed, the bath must be regarded purely as a the rapeutic agent, and not as a cleansing process. The body may be washed in the ordinary way at night before the child is put to bed.

The cold douche is of great service in all cases of weakness, whether this be due to acute or chronic illness, and is only madmissible if the lungs are actively diseased or there is fever. It is especially useful in cases of long-standing derangement and in the scrofulous cachexa, and may be recommended without hesitation for children of very fragile appearance. In william to its tonic effect the bath has another valuable quality in that it strangthens the reasting power of the body against changes of tempera-

ture, and lessens the susceptibility to cold.

The hot and nurstard boths may be considered in the light of counterirributs, which act through the surface generally and produce a powerful striguisting effect upon the flagging nervous system. A similar means of rousing the vital energies consists in the employment of stimulating liniments. Thus, in cases of atelectosis, energetic frictions with a strong irritatmy application will often enable the child to expand the collapsed portion of lang, and thus are him from immediate danger. In many varieties of Lead disease, counter-irritants are of extreme service. They may be used as the form of blisters, mustard poulties, and printing with the fincture or lumment of rodine. The kind of application best suited to each particular case will be described in the proper place. It may be here stated, however, that blisters must be used to children, especially to young infants, with great caution; and Bretonneau recommends that in every case a thin have of oiled paper should be interposed between the vesicating surface and the skin. A blister applied too long leads, as M. Archambiult has counted out, to a sore equivalent to a burn of the third degree, and heals nor slowly. Caution in the application of the more powerful countercritants is especially to be observed when the patient is very young, or is the subject of defective nutrition or of chronic disease. In such cases ob-"in ate ulcoration may be set up, or gangrene of the skin may be induced, got to mention the exhausting effect upon a weakly patient of the pain caused by the application of the irritant, and the effusion of a highly albu-If diphtheria be epidemic in the neighbourhood, blisters arraid never be employed, as the resulting sore may become covered with the diphtheritic exidation. For a young child a blister should be of small are and ought quickly to be removed. Under twelve months of age canthandrue applications should rarely be resorted to. If used during the second year, the blaster may remain in contact with the skin for an hour and a half. For each additional year of life a further half hour may be added to the length of time the application may be employed; so that for a child of four years of age the blister may remain two hours and a half; for a child of five, three hours. If vesication has not been produced when the irritant is removed, a warm bread-and-water poultice will soon cause it to appear. The fluid can then be let out and cotton wadding applied.

No other dressing will be required.

Amongst internal remedies alcoholic stimulants take a high place. Children reduced by severe illness respond well to the action of alcohol, and a few timely doses of this medicine have often, in a doubtful case, turned the scale in favour of recovery. So, also, weakly children with poor appetites and feeble digestions often benefit greatly by an allowance of wine with their principal meal. Stimulants may be prescribed for the youngest infants, and in cases of great weakness may be repeated at frequent intervals. When the patient is very young and requires energetic stimulation, a small quantity of wine or brandy often repeated is to be preferred to a larger quantity given at more distant intervals. The remedy should not be continued too long. It must be remembered that a stimulant is not a tonic. It is given for an immediate purpose, and should be withdrawn

or greatly reduced in quantity when the object has been attained.

Tonics, such as quinine, iron, the mineral acids, and vegetable bitters, are also of great value in the treatment of disease in the chold. But they require to be given with judgment, and must not be administered indiscriminately because the patients look weak and pale. A feeble-looking, pailed child, is not always to be benefited by iron and other tonics. Such a condition is often dependent upon a chronic form of dyspepsia, the result of repeated catarrhs of the stomach. In such cases a proper selection of food, and alkalies given to diminish the secretion of mucus and neutralise acidity, will soon produce a marked improvement in cases where tomes have been given without good result. It is only when local derangement has been remedied that the tonic becomes useful. The same remarks apply to cod-liver oil. This valuable remedy is inappropriate so long as any digestive derangement remains uncorrected. When the alimentary canal has been brought into a healthy state, the oil is of enormous service, and may be given in suitable doses to the youngest infants. It must be remembered, however, that the power of digesting fats in early life is not great. Under twelve months of age ten drops will be a sufficient quantity to be given on each occasion; and if any oil is noticed undigested in the stools, even this small quantity must be reduced.

In cases where, although nourishment is urgently required, oil cannot be digested, the remedy may be rubbed into the skin. The external application of oil is of service in all cases of chronic weakness and wasting. It is useful not only as a means of introducing nourishment, but also as an agent in promoting the action of the skin, which in most forms of chronic derangement is apt to become inactive and dry. The application should be made at night. Any oil is useful for the purpose, and it is not indispensable that cod-liver oil be employed. The oil should be warned and then applied to the whole body with a piece of fine sponge. At the same time if there is any special weakness in the back or elsewhere, vigorous friction with the oil may be used to the part it is desired to strengthen. Afterwards the child should be put to bed in a flannel night-dress.

In the administration of drugs to young subjects, we must remember that the dose is not always to be calculated according to the age of the child, but that children have a curious tolerance for some remedies and as

curious a susceptibility to others. Opium, it is well known, should be given with caution. The remedy is, however, of extreme value, and if care be taken to begin with only a small quantity, and to postpone a second dose until the effect of the first has been ascertained, no ill effects can possibly be produced by the narcotic. Thus, for a child of twelve months old suffering from purging, if one drop of laudantin has not produced drowsiness, a second may be given in six hours' time; and the remedy will be well borne three times a day.

Bella lonna can be taken by most children in large quantities. Sometimes the characteristic rash is produced by a small dose, but a much larger quantity will be required to dilate the pupil, and a further considerable increase before we can produce dryness of the throat or other physiological effect of the drug. It is often necessary to push the dose so as to produce dilatation of the pupil. Many cases of nocturnal incontinence of urine show no sign of yielding until some symptoms are produced indicating that the system is responding to the action of the remedy. A child of twelve months old will usually take fifteen, twenty, or more drops of the uncture of belladonna three times a day; and often we can push the dose at this age far beyond this limit.

Besides belladonna children bear well quinine, digitalis, arsenic, lobelia, and many other remedies. Mercury rarely salivates a child, but has often a powerful effect in deteriorating the quality of the blood. A child is

usually left excessively pale at the end of a course of this drug.

On account of the frequency of digestive disturbances and the tendency to actility in early life, alkalies form a very valuable class of remedies. A disc of bearbonate of soda or potash neutralises acidity, checks hypersecretion of micros, and if given with a few drops of spirits of chloroform as I an aromatic, stops fermentation, dispels flatus, and reduces spasm. In all varieties of dyspepsia in the child, and in many forms of looseness of the bowels, this combination is of the utmost value.

One word may be said with reference to the abuse of aperient medicines which is so common in the nursery. Delicate children have often died from the effects of a drastic purge, and many a case of typhoid fever has received a fatal impulse by this means. An aperient is the common domestic remedy—the corrective to be administered at once upon the slight at appearance of illness; and prescribing chemists invariably recommend it as an antidote for every ill. But constipation is only one of many causes of malaise, and to irritate the bowels unnecessarily with a strong purgative powder may do serious injury to a weakly child.

THE ACUTE INFECTIOUS DISEASES.

CHAPTER I.

MEASLES

My oras (rubeola or morbili) is one of the commonest infectious fevers to which children are liable; and few persons arrive at adult years without having suffered from an attack. It affects children of all ages, and is far from uncommon in infants Scattered cases of measles may be found almost at any time in large towns, but at certain periods of the year the complaint becomes epidemic. These epidemics vary curiously in severity and in the predominance of particular symptoms. One may be signalized by a high percentage of mortality. In another vomiting may be a prominent and distressing feature. In a third the catairlad phenomena may be unusually slight; or again, they may be severe out of all proportion to the estructy of the rish. When fatal, measles is so generally through its compheatrons. It rarely kills by the intensity of the general disease. Still, in some cases we meet with epidemies in which the disease tends to assume an asthenic type. In these the mortality is high. The fatal cases are marked by early and extreme prostration. The patient seems overwhelmed by the violence of the attack, and dies before any complication has had time to manifest itself. As a rule, one attack protects against a second, but cases where the disease has occurred two and even three times are not un-

The contagious principle of measles is apparently communicated by means of the breath. It is said to be volatile, and to be capable of adhering to clothing. According to Meyer, it is easily removed, as the mere string of clothes is sufficient to disinfect them. Means, Braidwood and Vicker have examined the expired air of measles patients by making them breathe through glass tubes coated in the interior with glycerine. On examination afterwards with the microscope, the glycerine showed in every case numerous sparkling colourless bodies, some spherical, others more consisted with sharpened ends. They were most abundant during the less and second days of the cruption. As a negative test, the breath from healthy children, and children suffering from scarlatina and typhus, was also examined, but without any result.

Part 1.

THE ACUTE INFECTIOUS DISEASES.

CHAPTER L

MEASLES

Mr ars (rubeola or morbili) is one of the commonest infectious fevers to which children are liable; and few persons arrive at adult years without having suffered from an attack. It affects children of all ages, and is far from uncommon in infants. Scattered cases of measles may be found almost at any time in large towns, but at certain periods of the year the complaint becomes epidemic. These epidemics vary curiously in seventy and in the pre-lommance of particular symptoms. One may be signalized by a high percentage of mortality. In another vomiting may be a prominent and distressing feature. In a third the catarrhal phenomena may be unn-mally slight, or again, they may be severe out of all proportion to the mensity of the rush. When fatal, measles is so generally through its compheatons. It rarely kills by the intensity of the general disease. Still, in one cases we meet with epi lemics in which the disease tends to assume m astheme type. In these the mortality is high. The fatal cases are marked by early and extreme prostration. The patient seems overwhelmed by the violence of the attack, and dies before any complication has had time to manifest itself. As a rule, one attack protects against a second, but cases where the disease has occurred two and even three times are not uncommittee.

The contagious principle of measles is apparently communicated by means of the breath. It is said to be volatile, and to be capable of adhermant to clothing. According to Meyer, it is easily removed, as the more aring of clothes is sufficient to disinfect them. Messes Braidwood and Varber have examined the expired air of measles patients by making them breathe through glass tubes coated in the interior with glycerine. On examination afterwards with the microscope, the glycerine showed in every case numerous spurkling colourless bodies, some spherical, others more clourated with sharp need ends. They were most abundant during the first and second days of the cruption. As a negative test, the breath from heartly children, and children suffering from scarlatina and typhus, was also examined, but without any result.

The infection of measles begins at the very beginning of the catarrial stage, and lasts for some time after the rush has faded. Dr. Squire is of opinion that three weeks ought to clapse before the patient can be con-

sidered free from all chance of communicating the disease.

Morbid Anatomy.—The post-mortem appearances in cases of death from this complaint are those of the complication to which the fatal termination is owing. In cases where the child has died early from the severity of the disease, little is found except that the blood is dark coloured, deficient in fibrine, and coagulates imperfectly. There is also hypostatic congestion of the lungs and hypersemis of the mucous membranes and organs generally, with extravasation into their substance. The splcen and lymphatic glands are often swollen. Sections of the skin made on the sixth day of the cruption were examined by Messrs. Braidwood and Vacher. There was swelling of the corium, and thickening of the rete Malpighii from great proliferation of cells, which extended along the hair and sweat-ducts into the glands. Sparkling, colourless, spheroidal, and clongated bodies, similar to those discovered in the breath, were found in the portion of the true skin lying next to the rete, in the lungs, and in the liver. In all these situations these bodies were mixed with other bodies, spindle-shaped, staff-shaped, and

canoe-shaped. They appeared to be albuminoud in character.

Symptoms.- The incubation period of measles is ten or twelve days. The complaint then begins with the signs of catarrh. The patient is thought to have a cold: he sneezes, coughs, and his eyes look waters and red. With this there is fever; often headache; the appetite is poor; and the child generally feels ill and is languid. The catarrhal symptoms is crease; the nose may bleed; there is some soreness of throat, and the patient is often hoarse, and complains of soreness in the chest. If the fever is high, the child may wander at night and be very restless. Sometimes the attack is ushered in by a convulsive fit, and occasionally the convulsions recur later on, either before the rash has appeared or afterwards. The skin is generally moist, although the temperature rises to 102° or 103°, or even higher. In a case which came under my own notice at this stage, a boy was seized with charries on July 10th. His temperature on that evening was 102. The next morning it was 103, but the bowels acted five times in the course of the day, and in the evening it had fallen to 101.4. His pulse at that time was 160, and his respirations were 48. On the evening of the 12th the temperature was 102°, and on the morning of the 13th, when the rash appeared, the mercury marked 103°; pulse, 124; respirations, 48. Although pyrexia is the rule during the pre-cruptive stage, in exceptional cases the temperature may be normal. I have known this to be the case in two instances. In each of these young children the bodily heat, both morning and evening, for the four days before the appearance of the rash was between 98° and 99°; and when the cruption began the temperature only rose to 101. The rash was typical in character, and all the catarrhal symptoms were present.

The digestive organs are usually deranged, partly on account of the fever; partly on account of the mucous membrane of the stomach sympathizing with the general derangement. The tongue is thickly furred.

there is often vomiting; and the bowels may be relaxed.

The characteristic eruption appears as a rule on the fourth day, having been preceded by three clear days of catarrh and fever. In rare cases it is seen on the third day; or, again, it may be delayed until the fifth, or even longer; but these are exceptions. There is seldom any appreciable subsidence of the fever on the appearance of the rash. Indeed, the opposite

is usually the case. Both the fever and the entarrhal symptoms seem to be intensified when the rash comes out; and if charrhea have not been

present before, the bowels generally become loose.

The cruption is first seen about the clun, the temples, and the forehead, as slightly elevated spots of a yellowish red colour, which disappear under pressure. Small at first, they soon reach one and a half or two lines in diameter, and have irregular edges. From the face the rash soon spreads to the trunk and limbs, and in twenty-four hours is generally found to cover the whole surface of the body and extremities. As it spreads, the borders of neighbouring spots unite so as to form crescentic patches. Between these the skin is of normal colour, unless the cruption levely profuse, in which case, as we often see on the face, the junction of the closely set spots may produce a uniform blush over a considerable extent of surface.

As the rash becomes more completely developed, its colour grows of a deeper red; and if the skin be very most, vesicles with an inflamed base may be seen scattered over the surface. A child with the cruption fully out and the catarrhol symptoms well marked, presents a very characteristic appearance. His face is somewhat swollen, so that the features appear thick and course. A dull red flush occupies each check; and the forehead, mouth, and chin are speckled over with the crescentic patches. The eyes are red, the cycluds congested; and the upper hip is excorated by the copicus flow of thin mucus from the nose. Often crusts of dired blood are seen about the nostrils, for epistaxis is a very common symptom. The rash remains at its height for about twenty-four or forty-eight hours, and then begins to fade. The colour changes again to a yellowish red, and in a day or two his disappeared, leaving nothing on the skin but a faint redisan stain, which may hast for a few days longer before the normal colour of the integriment is completely restored.

There are varieties in the rash. Sometimes the spots when they first appear are hard, sentered, and prominent. These are the cases which are often mistaken for variola. Sometimes the eruption does not completely disappear under pressure, and we then often find little points of extravastion from rupture of small capillaries in the skin. This occurs in cases where there is great hypercomia of the cutaneous tissue. It is of no bad ancory. A further degree of the same phenomenon is sometimes seen in which the cruption grows darker and darker until it has acquired a deep purply that. This is also the consequence of rupture of distended cutaneous capillaries. Such a rash does not disappear with pressure, and remains visible for a much longer time than an ordinary cruption, fading very

dustr.

The fever and catarrh remain at their height until the rash begins to take. The severity of the catarrhal symptoms varies very much in different epidemics and with different patients. Sometimes all the mucous membranes seem to suffer; the threat is sore; the eyes are inflamed; there is deafness from closure of the Eustachian tube, and the inflammation may even spread to the middle ear; vomiting may be distressing, and parging severe; a mild laryngitis may become intensified and be accompared by spasm (stridulous laryngitis). All these symptoms are usually greatly relieved when the cruption begins to disappear; and if there be no complication sufficiently serious to maintain the pyrexia, the temperature fails at once to nearly its natural level, and the pulse loses much of its fromency.

The decippe trance of the rash is followed by a fine desquamation of

the skin. The peeling differs much from the shedding of the skin which is such a marked symptom in scarlatina. The epithelium falls in fine bran-like scales which are often almost invisible to the naked eye, so that this

stage not unfrequently passes quite unnoticed by the attendants.

In an uncomplicated case of measies the chest symptoms are usually mild. The cough is at first hard and hacking, and during the eruptive period is often paroxysmal, with a loud barking character. After the eruption has begun to fade, the cough becomes looser and less frequent; and if proper care be taken to avoid chills, it soon ceases to be heard. The physical signs about the chest are those of pulmonary catarrh. One consequence of the irritation in the lungs set up by the catarrh is seldem absent, especially in acrofulous children. This is enlargement of the bronchial glands. If there be much throat affection, there may be a similar swelling of the glands at the angle of the lower jaw and at the sides of the neck.

The urine during the fever is high colored, with abundant urates. It

may contain a trace of albumen.

In some epidemics cases are seen which present all the characters of the complaint with the one exception that the rash is absent. These are no doubt cases of irregular measles. Cases have been also described in which the rash is present, but the catarrhal symptoms are absent (morbilisine catarrho). It is very questionable if these latter are classed rightly

under the head of measles.

There is a form of measies which is distinguished by great prostration. Here the complaint assumes from the first an asthenic type. The pulse is small, feeble, and very frequent; the respirations are rapid: the tongue is dry, brown, and thickly furred; the temperature of the body is high, although the extremities feel cold to the touch; and the child is dull and seems stupefied. When the rash comes out, it is imperfectly developed and of a dark red or violet line. The skin is thickly spotted with petechise. Soon the pulse becomes so rapid that it can only be counted with difficulty; the muscles become tremulous: there is muttering delirum, and the patient dies comatose or convulsed. These cases, fortunately very rare, almost invariably prove fatal. They are generally accompanied by hemographics from the mucous membranes as well as into the skin. Epistaxis is often obstinate; hematuria may occur; and after death ecchymoses may be found in various internal organs.

In a healthy child an ordinary attack of measles is a mild disorder with little severity of the general symptoms. The sharpness of the illness appears to be determined to some extent by the constitutional tendencies of the patient. One of the pathological consequences of the specific fever being the active congestion of the nucous membranes, we might expect that a constitutional state in which there is already a predisposition to derangement of these membranes would determine more serious symptoms than are found in cases where there exists no such predisposition. Children who start in life weighted with a scrofulous diathesis are generally bad subjects for measles. It is in these patients that catarrhal symptoms assume such prominence, and that ophthalmia, offic, and the other troubles referred to above are so liable to be met with. Even in the mildest cases a certain depression follows the subsidence of the fever. The temperature sinks to a subnormal level, and the pulse is very slow

and intermittent.

Of all the emptive fevers measles is, next to typhoid fever, the one most liable to return. Many children have it a second time, often after

only a short interval: and in some cases the second attack may occur at so early a period after the first as to constitute a true relapse. Cases are met with from time to time in which a child sickens with measles, passes through a more or less severe attack, recovers, and after a biref interval of convolvemence sickens with it again—and all this within a month.

Complications.—The complications which may render an attack of meades troublesome or dangerous have been already in part referred to. As a rule, they are exaggerations of ordinary or extraordinary symptoms of the complaint, and are determined either by the character of the epidemic.

or by the constitutional peculiarities of the patient,

Convulsions have been already mentioned as occasionally marking the beginning of the disease. The fits may be repeated several times; but when hunted to the first day or two of the disorder, although alarming to the friends, are seldem dangerous. Should they be repeated, however, during the cruptive stage, they must be regarded with more anxiety, for they must then prove fatal.

Epistaxis, a common symptom and generally insignificant, may become profuse and exhausting. In severe epidemics, where the type of the disease is a low one, this may be of serious moment. In any case it must

tend appreciably to protract the period of convalescence.

Drift, to a is also, as a rule, a symptom of little consequence; but sometimes the mild intestinal catarrh to which it is owing may be converted into a real colitis. The stools are then bloody and glairy, and there is colic

with great tenesmus and pain in defecation.

Laryngitis is a marked symptom in some epidemics. There is generally a certain amount of houseness early in the disease from participation of the laryngeal mucous membrane in the general catarrh. If this get worse the mace becomes hisky and almost extinct, the cough house and "enough," and the breathing noisy and oppressed. Great alarm is naturally excited by this condition of the patient, but the danger is really slight. When the rash begins to fade, an improvement is noticed in the throat symptoms; and they often disappear quite suddenly when the temperature falls. It must not be torgotten that laryngitis with marked spasm may arise quite at the beginning of the attack, and be out of all proportion to the signs of general catarrh. In such cases the existence of measles may not be even suspected until the eruption comes out and discloses the nature of the discorder.

Ophthalmia and otitis are less common symptoms. When these occur, it is usually in children of marked scrofulous tendencies. The first may form an obstinate complication, and the second may lead to very serious

consequences (See Utitis.)

Extension of the bronchial catarrh to the smaller tubes is a very grave accident. It is common in babies and young children, and almost invariably proves fatal, for in early life collapse of the lung is easily provoked, and once established quickly terminates the illness. The first indication of danger in these cases is oppression of the breathing, which becomes very rapid. There is lividity of the face, and the countenance is haggard and charges ed. With the stethoscope we hear abundant fine subcrepitant rhonchus over both sides of the chest. When these symptoms are present, next active measures must be taken to avert a fatal issue to the complaint.

In children who have passed the age of twelve months catarrhal pneumonts is a more frequent complication than the preceding. If, in any case, on the fading of the rash the temperature undergoes little diminution, we may expect catarrhal inflammation of the lungs to be present. In such a case the child, instead of becoming better and more lively as the eruption disappears, seems to be weaker and less well than before. His face, the swelling having subsided, is seen to be pinched and haggard looking; there is lividity about the lips; the nares act in inspiration, and the breathing is quick and labored. A thermometer in the axilla marks about 102', seldom higher. The patient is thirsty, but will take little food. He shows no interest in his toys, but often lies picking at his lips and fingers, indifferent to everything but his own uncomfortable sensations. Examination of the chest reveals all the signs of acute catarrhal pneumonia.

This complication may also come on at an earlier stage, when the cruption is beginning to appear. The development of the rash is then retarded, or the exanthem may even retrocede with great aggravation of the general symptoms. Catarrhal pneumonia is fully described in another part of the volume, but it may be mentioned in this place that catarrhal inflammation complicating measles often runs a subscute course, and persists long after all signs of the primary complaint have disappeared. It may end in death, in complete recovery, or may become a chronic lesion forming one of the

varieties of pulmonary phthisis.

Sequelar.—The sequelæ of measles are constituted in part by the above-mentioned complications, which, like catarrhal pneumonia, may become chronic and give rise to trouble and anxiety. Chronic laryngitis' and bronchitis are common sequences. Enlarged bronchial glands often remain for a considerable time relies of the disease which has passed away. Also, it may again be repeated that in children of scrofulous tendencies an attack of measles may light up the cachexia, and give rise to any or all of the troubles which are characteristic of that constitutional state. Even children who are free from this unfortunate predisposition may not escape unburt from the attack. A condition of the system is often left which appears to favour the occurrence of secondary disease; and whooping-cough, croup, gangrene of the mouth and vulva may occur at such a short interval after the attack that they cannot but be looked upon as direct sequelæ of the illness.

Acute tuberculosis requires special mention as an undoubted and fatal consequence of measles. Measles, indeed, is followed by true tubercular discuse with such frequency that in every case where we are called to a child who has been left weak and feverish after a recent attack of the exanthematous disorder, we may expect him to be the subject either of

catarrhal pneumonia or of acute tuberculosis.

Diagnosis.—Before the stage of eruption measles is not easy to detect. A severe cold in the child is often accompanied by fever, and there is nothing in the catarrhal symptoms of measles which can be considered peculiar to that complaint. If such symptoms occur at a time when we know an epidemic to be raging, the probabilities are no doubt strongly in favour of an attack of this disorder; but in the opposite case, if we cannot ascertain that the child has been exposed to contagion, it is wise to wait before expressing an opinion. Still, we should never forget in any case of high temperature in a child with signs of general catarrh, that these are

^{&#}x27;In all cases of hourseness left after measles the vocal cords should, if possible, be inspected with the laryngoscope. The supposed larvingitia will be sometimes found to be mally anomated the larynx, due to general debility, combined with weakness of the adductor muscles, which fail to approximate the cords. This local condition may be present although the signs of general anomia are not pronounced. In such cases we should watch the child anxiously for any symptoms indicative of tuborculosis.

the carly symptoms of measles; and we should inquire as to the existence

of the disease in the neighbourhood.

The presence of the catarrhal phenomena will enable us to exclude scarlatina should the combination of sore throat and high temperature have led us to suspect the onset of that disorder. If laryngitis with stridor and speam be an early symptom, the persistence of high fever after the spasmodic attack is at an end will suggest that these manifestations may be symptomatic of some latent febrile disorder, and we shall remember that

measles is sometimes ushered in by laryngeal troubles.

When the rush appears we shall be less liable to fall into error. The crescentic, slightly elevated patches with the skin between them of a healthy tint, combined with coryza and cough, are very characteristic. If the eruption come out first as hardish isolated papules, small-pox may be suspected, and indeed this is a mistake which is often made. But the papules have not the hard shotty feeling peculiar to the variolous eruption; there is no history of pain in the back; and vomiting, if it have occurred, is much less severe than the vomiting of the pre-eruptive period of small-pox. Moreover, in variols the temperature falls notably on the appearance of the rash; while in measles, if any change occur at all in the fever, it is in the opposite direction; and the catarrhal symptoms become aggravated. Doubt is only permissible at the very beginning of the cruptive stage; for on the second day the rash of small-pox has completely changed its character on the face of the patient, the papules having become converted into vesicles.

The rash of roseola may bear a close resemblance to that of measles, but in the former complaint there is no catarrh, and the temperature is normal or only slightly elevated. Between epidemic roseola (or rotheln) and measles the difficulty of distinguishing is often very great. This subject is referred to in the chapter treating of the former disorder (see page 30). I have also known the early signs on the skin of an acute general eczema to present the closest possible resemblance to measles. But an exanthem should never be judged of by the rash alone. In every case we should search for confirmatory symptoms, and inquire as to the temperature and the initiatory phenomena of the illness. In measles we examine the eyes for injection, the throat for redness, and ask about cough, hoursentss, and catarrhal symptoms generally. If these are completely absent, and the temperature be below 100°, it is very unlikely that the disease is measles, however typical the rash may appear.

The stains left on the skin as the rubedous eruption dies away have been compared to the mottling of syphilitic roscola, but the history and course of the illness are so different in the two cases that hesitation is im-

aktraus

Prognosis.—The percentage of mortality in measles is small. Still, it is much higher in some epidemics than it is in others; and, therefore, in estimating the chances of a patient's recovery we must take into account the character of the epidemic. Another consideration is the previous state of health, especially the constitutional tendencies of the child. Unless the case be one of malignant measles, or the child have been previously in a state of great weakness, there is every hope of preserving life if ordinary care be exercised in nursing the patient through his illness. But it is less easy to avert injury to the health from the dangerous equals of the disease. In spite of all we can do, a child of strong scrotulous predisposition may be left greatly the worse for the attack; and if his lungs be already the seat of caseous consolidation, it will be difficult

indeed to prevent his phthisical tendencies from receiving a distinct

impulse.

In children under two or three years of age bronchitis is a common complication. Here the child's previous health is a point of very great importance. One danger in these cases is the occurrence of collapse of the lung, and this is predisposed to by the presence of rickets, or by general weakness of the patient. If the child be the subject of marked rickets, and bronchitis supervene, his chances of recovery are small. Another danger is the tendency of the bronchial inflammation to spread into the finer bronchial tubes and air-vesicles, and give rise to catairful pneumonia. The occurrence of this accident greatly increases the gravity of the case; but if the child be a healthy subject, and the epidemic be a mild one, the chances are in favour of recovery, for in measles catairful pneumonia tends to run a subscute course. If, however, the child be weakly, or the case occur in the midst of an epidemic of unusual severity, we should speak

very guardedly of his hopes of escape.

Treatment.—In the early stage of measles the treatment is that of a severe cold on the chest. The child must be kept in bed, put upon a diet of milk and broth with dry toast, and take for medicine a saline with some unstimulating expectorants. While the cough is hard and the chest tight, the stimulating expectorants, such as ammonia, squill, and senega, should on no account be made use of, as they increase the tightness of the chest and make secretion more difficult than before. If vomiting be distressing, an emetic may be given to relieve the stomach of unhealthy secretions. Mustard, or sulphate of copper (gr. 1 to gr. 4 every ten minutes), is to be preferred for this purpose, as ipecacuanha has a very irritating effect upon the bowels of some children. If there be diarrhora, a small dose of castoroil or of rhubarb and sods will be of service at the beginning of the attack; but the aperient should not be repeated, for in measles the bowels are very susceptible to the action of purgatives. If the diarrhosa continue, a mixture of aromatic chalk powder and rhubarb, five grains of each, may be given to a child three years of age every night for three nights; or he may take oxide of zine with glycerine (two grains three times a day), and either of these will usually arrest the purging. Still a moderate looseness should not be interfered with. It is better not to employ astringent remedies unless the stools are very watery, and threaten by their number to reduce

The general management of the child must be conducted according to the rules already laid down for the nursing of febrile complaints (see Introduction). In cases of measles special care should be taken to avoid draughts while insuring free ventilation of the room. A strong light hurts the reddened eyes, so care should be taken to keep the room in a half light, without making it actually dark. Due attention must be paid to cleanly meas. It is not necessary in cases of measles to keep the child dirty. The skin should be cleaned every morning: using tepid water, and being careful to wash and dry separately each part of the body, so that the whole surface may not be exposed at one time. The patient may be allowed to take fluid often, but he must be prevented from drinking large quantities at once. The best drink is pure filtered water, and if a small cup or glass be used, the child will be satisfied if allowed to drain it to the bottom.

The condition of the throat usually requires httle treatment. A strip of lint wrung out of cold water may be applied closely round the neck, and be covered with oiled silk and flannel. This can be re-wetted as often as is necessary. The same application is useful if there be much inflammation of the larynx; and if spasm occur with stridulous breathing, the threat may be fomented by applying below the chin a sponge dipped in

water bot, but not hot enough to scald.

A single convulsion does not require treatment; but if the fits are repeated, the child should be placed for a few minutes in a warm bath and then he returned to his bed. A hot bath is useful if capillary bronchitis or extarrhal pneumonia occur early, and interfere with the development of the rash. If they occur later during the subsidence of the eruption, the child's back should be dry-cupped, or be covered with a large poultice made of one part of mustard to five or six parts of hisseed meal. This can be kept in position for eight or ten hours, and afterwards the front of the chief can be poulticed in the same way. In cases where the danger is great, the dry cups are to be preferred to the more slowly acting poultice; and I believe life may be often saved by the timely use of this energetic

Stimulants are not required in ordinary cases of measles, but when the patient is of weakly habit of boly or of distinct scrofulous type, or when he is suffering from an unusually severe attack of the disease, it may be necessary to support the strength by alcohol. The brandy-and-egg mixture of the British Pharmacopieia is very useful for this purpose, and may be given in such doses as the child's age and condition require. Children—even very young children—who are weakly or prostrated by illness respond well to stimulants, and can take them in considerable quantities with great advantage. I have often seen an infant of eight or nine months of age greatly benefited by a tenspoonful of brandy-and-egg imixture given every hour. Of this quantity a third part is pure brandy. If without the occurrence of any severe complication the patient seems to be getting into a typhoid state, with dry tongue and small rapid pulse, stimulants are urgently needed. Also, the presence of bronchitis or pneumonia will demand a recourse to the same remedy, or the child may sink and die with startling suddenness.

Food must also be given with care and judgment, taking pains not to overload the stomach, but to proportion duly the nourishment, both in quartity and quality, to the age and strength of the child. In all cases of weakness the milk should be diluted with half or a third part of barley water, so so to insure a proper division of the curd. In addition, it may be guarded by tifteen or twenty drops of the saccharated solution of lime to prevent its turning sold upon the stomach. This must be given in small quantities at regular intervals. Strong beef-tea, or beef-essence made in the house, is also very useful when the strength is failing, but it must be given in very small doses at sufficient intervals. Brandy can be

wide it necessary.

When the rash begins to fade and the temperature falls, the child, if old enough, may take pounded meat, the yolk of an egg lightly boiled, and

a little light pudding.

The chronic sequels must be treated according to the rules laid down in such cases, and the reader is referred to the chapters treating of these subjects. It may only be added that quinine is invariably required at the ent of an attack of measles; and bracing sea-air is very beneficial in hastening the return of health and strength. This is of especial importance in the case of acrofulous children, who will also require cod-liver oil as soon as their stomaches can bear it.

CHAPTER II.

EPIDEMIC ROSEOLA.

Empenic roseola, often called rotheln or German measles, is a mild infectious complaint which bears so close a resemblance to measles that it is in all probability frequently confounded with it. The two diseases are, however, not the same, for rotheln does not protect against measles, and is itself often seen to occur in a child who has been lately the subject of that disorder. The complaint is almost always a mild one, and has no compli-

cations or sequelæ.

Symptoms. - The stage of incubation is said to last a week. When the disease begins, the child is seen to lie about and to look poorly. He is slightly feverish and, if old enough, complains of headache. With this there are the usual accompaniments of thirst and want of appetite; and sometimes a pain in the back has been complained of—violent in character like the back-ache of small-pox. The pre-eruptive stage often lasts only a few hours, or, indeed, may be even absent. Perhaps its average duration may be taken at twenty-four hours. The eruption then comes out on the cheeks, and sides of the nose, as dusky-red slightly elevated papules, the colour of which disappears on pressure The wrists and ankles are attacked almost as early as the face; and from these points the rash quickly spreads to the rest of the body and limbs. On the cheeks the rash is more papular than elsewhere. It differs from the cruption of measles in that the spots do not group themselves in crescentic patches; but resembles it in the tendency of the rash to become confluent in places. Thus a large patch of uniform redness is often seen on the cheeks; and sometimes we find the same confluence of rash on the wrists and forearms, the legs and the ankles. The eruption is attended with a good deal of irritation, and when it subsides, is followed by a slight fine desquamation.

The general symptoms during this stage are trifling. The fever may persist during the first day or two, but often subsides soon after the appearance of the rash. The conjunctive may be injected, but there is seklom coryza; and if cough be present, it is insignificant. One almost constant symptom is sore throat. This generally comes on with the rash, and, on inspection, the fauces are found to be the seat of diffused redness; and the tonsils may be inflamed and swollen. The soreness subsides in a day or two, but after a short interval is apt to return. The secondary sore throat is a characteristic symptom of rotheln. It occurs between the third and seventh day-usually, according to Dr. Tonge-Smith, on the fourth or fifth-and is accompanied by great pain and much swelling. In the severer cases the voice is altered, articulation and deglutition are distressing, and there is much secretion of sticky mucus. The temperature at this time may reach 103° or 104°; still, even when the throat symptoms are worst there is no prostration or even any feeling of general illness. Sometimes the glands of the neck are enlarged and tender, and in some cpidemics the post-cervical glands have been noticed to be swollen. The axillary, inguinal glands, etc., may be also affected. The duration of the

eruptive stage is three or four days.

An attack of rotheln is then, as a rule, a very insignificant matter. The difficulty is to distinguish it from measles, which it so much resembles The two chief points of distinction are the shorter period of the eruptive stage in rotheln, and the non-crescentic arrangement of the rash. The milder character of the catarrh will hardly serve as a distinguishing mark, for sometimes in measles the cough and coryza cause little inconvenience to the patient. Another point is the lower temperature. Sometimes in rothein there seems to be scarcely any fever at all; and when present, the pyrexia generally subsides on the second day. In spite of these points of contrist between the two complaints, we must often hesitate to express a pentive opinion upon a particular case. The absence of any increase of fever when the oruption comes out may afford a suspicion that the case is not one of true measles, but we can seldom speak with certainty upon the first day of the rush. On the second or third day, however, if we find the general symptoms still retain their trifling character, and if the fever subsales before the rush has begun to fade, we may conclude the case to be one of rotheln. In doubtful cases the more or less general glandular enlargement, especially the swelling of the cervical and suboccipital glands, is a very suspicious symptom; and the occurrence of secondary sore throat with no actual sense of illness is very suggestive of rothelu.

The disorder has been described as a mild one, but it is right to say that some authorities hold that it may assume a much more severe character. Dr. Cheadle, from careful observation of two epidemics, which presented all the characters of measies and occurred in succession in the same district within the same year, concluded that the second of these epidemics was retheln although the symptoms were severe, and the laryngeal phenomena especially well marked. He founded this opinion upon the shorter period of incubation during the second epidemic, and upon the fact that out of thirty cases in which absolutely trustworthy histories could be obtained, twenty-two had had measles before, and ten of these under his own immediate observation within the year. Still, we may remember with regard to this latter point that membes, although as a rule it protects the subject for the future against a similar attack, is perhaps of all the contagious fevers the one most hable to recur. A second or even a third attack in the same individual is far from uncommon, and sometimes

the interval between two such attacks is currously short

Treatment.—The patient must be confined to one room while the fever lasts, and care must be taken that he is not overfed. No medicine is required.

CHAPTER III.

SCARLET FEVER.

Scanner fever (or scarlatina) is, like measles, one of the commoner infectious fevers of childhood. It usually occurs in epidemics which vary greatly in severity. One attack, in the large majority of cases, protects against a second, for it is a disease which very rarely occurs twice in the same person. A second attack may, however, occur. Some time ago I saw a little girl, aged seven years, who had a significant history of fever followed by desquamation and dropsy, which had attacked her when she was in perfect health two years before. The child was a patient in the East London Children's Hospital, suffering from general amyloid disease dependent upon spinal caries which had followed the illness referred to. While she was in the hospital the girl again contracted scarlatina, and was sent away to the Fever Hospital, where she died.

Sometimes the disease appears in an abortive form in persons who are already protected by a previous attack. In every epidemic of scarlatina it is common to find cases of anomalous sore throat occurring in protected persons exposed to the infection. Such persons may communicate the

perfect disease to others who are not protected.

Causation.—The fever is of a highly infectious nature, and is readily communicable from one individual to another. Sporadic cases are sometimes met with, but the illness generally occurs in epidemics. The infectious principle is probably not at all volatile, for articles of clothing, flannel, etc., have been known to retain their poisonous properties for long periods of time. It is a debated question whether the disease ever has a spontaneous origin. Some authorities hold that it may be generated denovo by cesspools and ill-ventilated drains. Different epidemics have different degrees of severity; but apart from the special type of fever prevalent, the intensity of the disease is dependent more upon the constitutional state and sanitary surroundings of the recipient than upon the severity of the disease in the person from whom the infection is conveyed. Scrofulous children, and those who are ill cared for, or are exposed for long periods to an impure atmosphere, are likely to take the disease bally.

During the first few days of the illness the patient is less dangerous as a source of infection than he afterwards becomes. The time of desquamation is probably the period at which the complaint is most likely to be carried away, for the particles of epithelium thrown off must be highly contagious, and the patient's power of communicating the disease does not cease until the peeling of the skin is at an end.

Scarlatina is seen less frequently than measles during the first twelve months of life; but between the first and second years the disease is a common one, and, according to the researches of Dr. Murchson, 64 per cent, of the cases occur before the completion of the fifth year. After the

tenth year the disease again becomes less frequent, although it may occur

during adult life or even in extreme old age.

Morbid Anatomy,—After death from scarlatina we usually find evidence of the special complications which have determined the fatal issue. In addition the blood congulates imperfectly, as a rule, although pule

fibrinous clots may be found in the right ventricle.

The parts especially prone to suffer are the gastro-intestinal mucous membrane and the glandular system. In fatal cases inflammatory swelling is found in the lymphatic glands of the neck; also in the folicies at the base of the tongue, and in those of the pharynx, tonsils, and larynx. In the intestine the solitary glands and those of Peyer's patches are often enlarged, reddened, and softened. There may be also enlargement and softening of the spleen, liver and pancreas. In all these organs, according to Dr. Klein, there are changes in the small blood-vessels. A hyalmothickening is noticed in the arterioles, with a proliferation of the cells of the endothehum and of the nuclei in the muscular coat, together with an accumulation of lymphoid cells in the tissues around. In the gastro-intestinal mucous membrane there is hypernemia of the ambepithelial layers, and great proliferation of cells which distend and obstruct the gastric tubules. Sometimes casts of these tubules may be detected in the matters ejected from the stomach.

The cutaneous affection is not a mere hyperæmia. It is also an exudation into the rete mucosum. The cells in this situation are problerated and swellen, and the sweat-glands may be stuffed and distended by their increased cellular contents. Serous chusions with migration of leucocytes may also occur. The lymphatic glands, especially those of the neck, are enlarged; the lymphoid cells disappear, and in places large giant cells be-

come developed containing many nuclei.

The kidney presents the characters of acute Bright's disease. The whole organ is congested, and important changes are noticed in the glomerali, the small arteries, and the convoluted tubes. According to Dr. Klein, these changes take place very early, so that in the first week of the disease proliferation of the nuclei in the Malpighian tufts and in the muscular coat of the arteries can be detected, as well as hyaline degeneration of the intima. At the same time there is hyaline thickening of the walls of the Malpighian capillaries, and cloudy swelling of the epithelium in some of the convoluted tubes. At a later stage the cloudiness and swelling of the tubal epith hum increases, and fatty degeneration takes place; infiltration of lymphoid cells occurs into the interstitial tissue around the tubules; and the tubules themselves are filled with hyaline casts.

In cases of ure mia the blood is sometimes found to contain an enormous excess of urea. In a case reported by M. D'Espine of Geneva, in which venesection was employed, the blood was found to contain 3.3 parts of urea per thousand, or about twelve times the normal quantity. The potash salts, also, were increased to three times the natural proportion, and of this two-thirds was contained in the serum, and not, as in healthy blood, in the red corpuscles. From the experiments of Feltz and Ritter, and others, it appears probable that the symptoms of uremic poisoning are due not to the retained urea, but to the excess of potash salts in the blood.

Symptoms. After exposure to infection a period of incubation precedes the actual outbreak of the fever. This stage is of very variable duration. It may last only twenty-four hours, or be prolonged to a week or more. Probably six days may be taken as the ordinary duration of this period.

Different cases of scarlatina vary so much in severity and in the violence of special symptoms that it will be convenient to divide the disease into two chief forms. The common mild form and the malignant form.

Afterwards the complications and sequela will be described.

In the common form the invasion of the disease is abrupt. It begins with a chill; the child complains of sore throat, and generally vomits. Sometimes there are nervous symptoms, and in exceptional cases the disease may be introduced by a convulsion or a state resembling coma. The tongue is generally furred at the back, red at the tip and edges; the appetite is lost, and there is thirst. The skin is hot, and the pulse rises to 130', 140 , or even higher. The rash sometimes appears within a few hours of these early symptoms: occasionally it is itself one of the early phenomena; and again in rare cases it may be delayed for three or four days, or, it is said, even for a week. As a rule it is noticed within twenty-four hours of the beginning of the disease. The temperature rises progresssively through the invasion stage until the rash appears. The pyrexia is not, however, excessive. In the case of the little girl, before referred to, who was taken with scarlatina while in the hospital, her temperature had always been normal, but one evening it was noticed to be 100.2. The next morning it was 101.2°, and the child vomited several times. Toward the evening the rash appeared, and the mercury reached 103. In another case a little boy aged eight months, who was teething the temperature for several days had been 100°. One morning it rose to 102.2°; he vomited, and in a few hours the rash appeared. To the hand, perhaps, the skin gives the impression of being hotter than it actually is, for the heat is often accompanied by a peculiar dryness, which gives a burning character to it like that of pucumonia. Tested by the thermometer, the temperature will be rarely found to exceed 105.

With the appearance of the rash the invasion stage comes to an end and the eruptive stage begins. The rash first appears as scarlet points, not elevated above the surface. These are closely set, and then borders, which are paler than the centre, unite so as to produce, when fully developed, the appearance of a uniform pink ground dotted thickly over with scarlet points. The rash rarely affects the face to the same degree that it does the rest of the body, and differs in this respect from the cruption of measles. Usually the region about the mouth is comparatively free, and contrasts by its paleness with the deep red tint of neighbouring parts. The colour of the rash disappears on pressure of the finger When the eruption is confluent, as it is in a typical case, no intervening healthy skin can be seen. Often, however, the eruption is not confluent. The puncta are then more or less isolated, and may be separated by spaces in which the skin has the normal colour. The rash may be confluent in some places, not in others. On the cheeks, neck, chest, abdomen, and inner aspect of the arms and thighs, coalescence of the neighbouring puncta is usually complete. In other parts the spots may be more or less isolated. Sometimes the eruption is everywhere discrete. The puncta are then usually larger; and if at the same time the temperature is only slightly elevated and the sore throat insignificant, great doubt may be entertained as to the nature of the disease; especially as when thus discrete the spots are often

a little elevated. These cases have been mistaken for measles.

Again, the colour of the rash may vary. It may be very pale, so as to be only discovered by careful examination; or it may be dusky and purple. Often it is more pink than scarlet. Sometimes it is limited to certain parts of the body, such as the sides of the neck, the chest, or abdomen.

and cannot be detected upon the limbs. It is usually said to begin about the root and sides of the neck and on the chest; but if so, these parts precede the rest of the body by a very short interval, and the rish becomes general very quickly. It is at its height on the third or fourth day of the illness. There is then often a good deal of irritation of the skin, and some subcutaneous ædema is present, which makes the fingers stiff and clumsy-looking. The rash may be accompanied by miliaria about the neck and chest; the skin is often rough from enlargement of the subcutaneous papilla (cutis anserins); and petechia are not unfrequently present. These small hæmorrhagic spota do not necessarily indicate any special severity in the attack. Sometimes also vesicles or even papules may be noticed. When the cruption is at its height, a line drawn upon the real-lened surface by the finger-nul remains visible as a white streak for about a ninute. This sign has been considered to be pathognomomic. The rash begins to fade on or after the fifth day of the illness, and has

usually completely desuppeared by the tenth.

During the cruptive stage the symptoms of the invasion period increase in intensity. The tongue cleans and becomes deep red with swollen papills, so as to present the well-known strawberry appearance. The child is very thirsty, but in the miller cases has a fair appetite. Vomiting is seldom repeated after the first day; but in exceptional cases this symptom is an obstinate and distressing one, adding greatly to the gravity of the case. If severe, it may reduce the temperature. The soreness of throat usually increases during the cruptive stage; and examination of the Luces shows a bright redness of the soft palate, uvula, tonsils, pillars of the fauces, and often of the back of the pharynx. Sometimes these parts are also swollen from cedema, so that the uvula is broad and the tonsils nearly meet in the middle line. There is also in most cases exers of tonsillitic secretion, and yellow pulpy matter may be seen collected at the mouths of the follicular recesses, or even coating the surface in a uniform layer. If the matter do not escape, it may form an abscess in the tonsil, as in common quinsy. In the more severe cases the tongue loses its moist appearance and the mucous membrane of the mouth, and throat generally, looks dry and shining. Unless in the worst cases, ulceration does not occur until the disease is subsiding. Sometimes at an early period the disease is complicated with diphtheria. If the throat affection is severe, there is much pain and tenderness in swallowing; the voice is nasal in quality; and the glands of the neck become enlarged and tender. The inflammation may extend from them into the connective tissue around, and and eventually in suppuration. In an ordinary case the throat improves as the crustion fades; but the tonsils and the lymphatic glands may remain enlarged, although painless, for some time after the inflammation has

The degree of pyrexia as a rule is moderate. The temperature seldom rises above 195°, although in exceptional cases it may reach a higher elevation. Unless it be maintained by the presence of a febrile complication, the temperature tends to subside when the rash begins to fade; and a crisis then usually occurs, the heat of the body being normal for twenty-four hours. Should this crisis not occur, the pyrexia may be prolonged for several days. Even in a mild uncomplicated case I have known the temperature to remain elevated two degrees above the normal level for twelve days. As long as the fever continues, the pulse is as frequent as at the beginning, and slackens when the temperature falls. It often reaches 160, and this frequency is not to be taken as a sign of danger. So, too, deli-

Different cases of scarlatina vary so much in severity and in the violence of special symptoms that it will be convenient to divide the disease into two chief forms: The common mild form and the malignant form.

Afterwards the complications and sequelæ will be described.

In the common form the invasion of the disease is abrapt. It begins with a chill; the child complains of sore throat, and generally vomits. Sometimes there are nervous symptoms, and in exceptional cases the disease may be introduced by a convulsion or a state resembling coma. The tongue is generally furred at the back, red at the tip and edges; the appetite is lost, and there is thirst. The skin is hot, and the pulse rises to 130°, 140, or even higher. The rash sometimes appears within a few hours of these early symptoms: occasionally it is itself one of the early phenomena; and again in rare cases it may be delayed for three or four days, or, it is said, even for a week. As a rule it is noticed within twenty-four hours of the beginning of the disease. The temperature rises progresssively through the invasion stage until the rash appears. The pyrexia is not, however, excessive. In the case of the little gurl, before referred to, who was taken with acarlatina while in the hospital, her temperature had always been normal, but one evening it was noticed to be 100.2. The next morning it was 101.2°, and the child vomited several times. Toward the evening the rash appeared, and the mercury reached 103". In another case a little boy aged eight months, who was teething the temperature for several days had been 100'. One morning it rose to 102.2; he vomited, and in a few hours the rash appeared. To the hand, perhaps, the skin gives the impression of being hotter than it actually is, for the beat is often accompanied by a peculiar dryness, which gives a burning character to it like that of pneumonia. Tested by the thermometer, the temperature will be rarely found to exceed 105.

With the appearance of the rush the measion stage comes to an end and the crupture stage begins. The rash first appears as scarlet points, not elevated above the surface. These are closely set, and their borders, which are paler than the centre, unite so as to produce, when fully developed, the appearance of a uniform pink ground dotted thickly over with scarlet points. The rash rarely affects the face to the same degree that it does the rest of the body, and differs in this respect from the eruption of measles. Usually the region about the mouth is comparatively free, and contrasts by its paleness with the deep red tint of neighbouring parts. The colour of the rash disappears on pressure of the finger. When the eruption is confluent, as it is in a typical case, no intervening healthy skin can be seen. Often, however, the eruption is not confluent. The puncts are then more or less isolated, and may be separated by spaces in which the skin has the normal colour. The rash may be confluent in some places, not in others. On the checks, neck, chest, abdomen, and inner aspect of the arms and thighs, coalescence of the neighbouring puncta is usually complete. In other parts the spots may be more or less isolated. Sometimes the cruption is everywhere discrete. The puncta are then usually larger; and if at the same time the temperature is only slightly elevated and the sore throat insignificant, great doubt may be entertained us to the nature of the disease; especially as when thus discrete the spots are often

a little elevated. These cases have been mistaken for measles.

Again, the colour of the rash may vary. It may be very pale, so as to be only discovered by careful examination; or it may be dusky and purple. Often it is more pink than scarlet. Sometimes it is limited to certain parts of the body, such as the sides of the neck, the chest, or abdomen,

and cannot be detected upon the limbs. It is usually said to begin about the root and sides of the neck and on the chest; but if so, these parts precede the rest of the body by a very short interval, and the rash becomes general very quickly. It is at its height on the third or fourth day of the illness. There is then often a good deal of irritation of the skin, and come subcutaneous cidema is present, which makes the fingers stiff and clumsy-looking. The rash may be accompanied by miliaria about the neck and chest; the skin is often rough from enlargement of the subcutaneous papillar (cutis anserma); and petechiæ are not unfrequently present. These small harmorrhagic spots do not necessarily indicate any special severity in the attack. Sometimes also vesieles or even papiles may be noticed. When the eruption is at its height, a line drawn upon the reddened surface by the linger-mul remains visible as a white streak for about a minute. This sign has been considered to be pathognomonic. The rush begins to fade on or after the fifth day of the illness, and has

usually completely disappeared by the tenth.

During the emptive stage the symptoms of the invasion period increase in intensity. The tongue cleans and becomes deep red with swollen papillie, so as to present the well-known strawberry appearance. The child is very thirsty, but in the milder cases has a fair appetite. Vomiting is will im repeated after the first day; but in exceptional cases this symptom is an obstanate and distressing one, adding greatly to the gravity of the case. If severe, it may reduce the temperature. The soreness of throat asually increases during the eruptive stage; and examination of the faures shows a bright redness of the soft pulate, uvula, tonsils, pillars of the fances, and often of the back of the pharynx. Sometimes these parts are also swollen from cedema, so that the uvula is broad and the tousils nearly meet in the middle line. There is also in most cases excess of tonallitic secretion, and vellow pulpy matter may be seen collected at the mouths of the follicular recesses, or even conting the surface in a uniform layer. If the matter do not escape, it may form an abscess in the tonsil, as in common quinsy. In the more severe cases the tongue loses its moist appearance and the mucous membrane of the mouth, and throat generally looks dry and shining. Unless in the worst cases, idecration does not occur until the disease is subsiding. Sometimes at an early period the discass is complicated with diphtheria. If the throat affection is severe, there is much pain and tenderness in swallowing; the voice is nasid in quality; and the glands of the neck become enlarged and tender. The atturnation may extend from them into the connective tissue around, and end eventually in suppuration. In an ordinary case the throat improves so the eruption facles; but the tonsils and the lymphatic glands may reman enlarged, although painless, for some time after the inflammation has subsaled.

The degree of pyrexia as a rule is moderate. The temperature soldom ross above 105°, although in exceptional cases it may reach a higher elevation. Unless it be maintained by the presence of a febrile complication, the temperature tends to subside when the rash begins to fade; and a crisis then usually occurs, the heat of the looky being normal for twenty-four hours. Should this crisis not occur, the pyrexia may be prolonged for several days. Even in a mild uncomplicated case I have known the temperature to remain elevated two degrees above the normal level for twelve days. As long as the fever continues, the pulse is as frequent as at the beamning, and slackens when the temperature falls. It often reaches 160, and this frequency is not to be taken as a sign of danger. So, too, deli-

rium may be present, and if slight and occurring only at night, is not of serious import. The child often complains of headache and of aching pan about the limbs.

The urme is scanty and high coloured. It may contain excess of bile pigment, and there is often a sediment of lithates or of free urne acid. According to Dr Gee, the chlorides are sensibly reduced in quantity, and the phosphoric acid undergoes a decided reduction. The urea is not neces-

sarily increased.

The desquamative stage begins a few days after the rash has faded. The exact period at which it can be first noticed is very variable. The first sign of peeling may be seen while the akin is still tinted with the remains of the eruption and before the pyrexia has subsided; or it may be delayed for some days or even weeks after the rash has disappeared. It usually occurs early in proportion to the intensity of the eruption, and if miliaria has been present, is often early and profuse. In the slighter cases it may be long delayed, and Dr. Page states that after a mild attack he has known desquamation to be postponed for five weeks. The epithelium at first looks dry and may be finely wrinkled. Then, on the neck, upper part of the chest, and front of the shoulders, the skin begins to fall in fine bran-like scales. Over those parts where the cuticle is thin and deli-cate the desquamation is very fine. Where the skin is thicker the particles thrown off are larger, and in some places, such as the hands and feet, large areas of epithelium may be cast off unbroken. On close inspection of the peeling surface the cuticle will be seen to be raised in the form of an empty vesicle. The crown of this elevation falls, leaving a minute circle, which gradually extends itself, until its circumference meets other circles widening in the same way. If the crown of the vesicle does not break off. the separation of the epithelium may go on, at the periphery until, by the coalescence of neighbouring centres of desquamation, large tracts of skin are thrown off.

The process may be over in ten days or a fortnight, or may be prolonged for weeks. It often lingers long about the fingers and toes. A secondary desquamation is even said to occur in some cases, and the peeling undergoes a species of relapse. Until the last flake of epithchum has been cast off the patient cannot be said to be completely free from infection.

In this stage the pulse is at first often slower than natural, and may interior. The temperature, also, after the cessation of the pyrexis, remains

subnormal for some days.

In malignant scar'a and the severity of the disease is shown either by violence of nervous phenomena which prove rapully fatal; or by the early appearance and intensity of the throat affection, which causes death in the

first or second week of the illness.

In the first form the disease from the beginning may show the utmost violence. The vomiting is repeated and distressing; the child is agutated and delirious or convulsed; the temperature ruses to 107° or 105; the breathing is quick and shallow; the pulse is rapid. After some hours or days, according to the violence of the symptoms, the patient sinks into a stupefied condition with haggard, dusky face, cold extremities, a feeble, rapid pulse, and a moist skin. He vomits frequently or may be violently purged, and dies comatose or in convulsions. In the worst cases the patient seems literally overwhelmed by the intensity of the fever poison, and dies before the rash appears or the sore throat has assumed any special pronumence. Thus, a child may be found a few hours after his first attack

collapsed or unconscious, vomiting incessantly, and passing frequent, thin, watery stools. The throat presents a dusky redness; the pulse is very rapid and feeble; and the thermometer in the rectum marks 102 or 103. In a few hours the temperature rises to 105 or 106°; convulsions come on, and the child dies. In other cases he lingers longer, and may appear to pally for a time; but the depression continues, the stupor returns, and with occurs by the end of the week.

When the disease assumes a unlignant form from exaggeration of the throat affection, the course of the disease for the first few days prescuts nothing abnormal, but on the fifth or sixth day the fauces become excesavely tender, and deglutation is very difficult and painful. The lymphatic giands at the angle of the jaw and the connective tissue around them are influenced and swollen. On examination of the throat the mucous memwhy gray exudation matter are dotted over the surface of the soft palate. urula, such tomab. In the had cases ulceration takes place in these spots, and, spreading, causes wide destruction of tissue. The face is often livid an I haggard; the pulse is quick, feeble, and fluttering; there are sordes on the teeth and lips; the tongue is dry and brown; the fetor of the breath sextreme; and an offensive purulent discharge escapes from the nose. At the same time the neck swells and feels brawny to the touch; the akin melts away in places; and thun, purulent matter, with shreds and lumps of draghy connective tissue, are discharged through the openings. deagling of the subcutaneous tissue of the neck is often accompanied hy other serious symptoms. Hemorrhage may take place from the large readly, codema of the glottis may occur; the patient may fall into a typhori state or die from pysemia. In one way or another such cases usually terminate fatally.

When the throat affection assumes a malignant form the prostration is generally marked, and the patient lies in a drowsy state, although he seems intelligent enough when roused. The temperature is not excessively clavated, sellom roung above 103; but the pulse is very rapid and feeble. It is unportant to know that the swelling of the cervical glands is not always in proportion to the severity of the throat complication, and furnishes no ground upon which to establish a prognosis. Deep-scated sloughing and fatal hamorrhage may occur in cases where the external glands are only mosterately enlarged. If the throat affection is severe from the first, the appearance of the rash may be delayed for several days; and it may come out in a patchy manner, being most marked in parts where the skin is especially thin and delicate, as in the folds of the arm-pits and groms.

Sometimes we find the above two forms of unlignant fever combined. The nervous symptoms are in excess, and there is also serious ulceration of the fauces and destruction of tissue. Convulsions occurring from any cause during the cruptive period are of very serious import, and generally

and fatarry whether the throat symptoms are mild or severe.

Comparations and Sequelas. The intercurrent disorders which are liable to occur during or after an attack of scarlet fever may be looked upon as examplications or sequele, according as to whether or not the disease is considered at an end when the temperature returns to a normal level. Most of them arise during the second week of the illness, although some may occur earlier. They will be described in the order of their occurremove

During the first muck the fever may be complicated by diphtheria, diarthere and coryza. The ulcerative throat affection, which by many writers is considered as a complication, has been described as a phase of the malicnant form of the fever.

Diphtheria may be an early complication of scarlet fever, and may spread to the nose and larvnx. It often comes on during the first week of the illness, but may occur later and at a time when the patient is supposed to be rapidly approaching convalescence. It generally proves fatal.

Coryza of a mild character occurring in the course of the first week is not a symptom of unfavourable omen; but if it persist into the second week, it becomes more serious. In such cases the catarrh may spread along the Eustachian tube into the tympanum and set up otitis. If in any case the nasal discharge becomes fetid, it suggests the presence of diphthema.

Diarrhora is sometimes an early complication. It usually crases after a day or two, but may prove so severe as to endanger the life of the patient. According to Henoch it is preceded by swelling of the Pverian and solitary glands. Sometimes as the rash fades the diarrhoa, which had at first appeared of little importance, passes into a true entero-colitis. The temperature which had fallen rises again; there is nausea and often vomiting; the belly is swollen and perhaps tender; and the child complains much of abdominal pain. The tongue, dry and hot, is furred on the dorsum, The bowels are loose, and the stools contain red at the tip and edges. much food partially digested, mixed up with mucus and sometimes with blood. The child looks excessively ill and rapidly loses flesh. He may die from the acute attack, or the complication may pass into a chronic stage.

In the second week bronchitis and pneumonia, rheumatism, and scrous

inflammations may be seen.

Bronchitis and pneumonia, which are common in measles, are comparatively rare complications of scarlatina. It is much more frequent to find inflammations of the serous membranes, especially of the pleura and perscardium; and these are often associated with symptoms indistinguishable

from those of rheumatism.

Scarlatinous rheumatism may occur during the second week or beginning of the third, and is often met with as a complication or sequel of the fever. Whether the disease is to be looked upon as a true rheumatism quite independent of the scarlatina, or as an arthritis resulting from septica mis, or as a further manifestation of the scarlet fever poison which may fasten upon the joints as it may fasten upon the kidneys or the throat, is still a matter of discussion. The rheumatic attack certainly follows the ordinary course of that disease; it frequently affects the serous membranes in and around the heart; and the joint inflammation subsides, as a rule, after a day or two, although in exceptional cases it thay end in suppuration. This, may, however, occur in cases where there is no suspicion of scarlet fever. Endocarditis is as common as pericarditis, and heart disease in the child often dates from an attack of scarlatina. Pleurisy and pericarditis sometimes come on in the third week instead of the second, and may occur in cases where joint pains are not complained of. They may then be a symptom of Bright's disease; but pericarditis from this cause is not very common in the child as a sequel of scarlet fever. If pleurisy occur the effusion very rapilly becomes purilent.

In the third work the patient is especially liable to kidner mischief. At this time, too, or shortly afterwards, otitis may occur, and gangrene

and abscesses may make their appearance.

The urine should be examined daily throughout the illness for albumen. This may be found at any time from the second to the twenty-first day. It is however, in the course of the third week that it is especially liable to be next with.

All-unimum does not bear any relation to severity of attack. It may be present in muld cases and absent in severe ones. By itself it does not indicate serious renal mischief, and if small in quantity does not affect the

programais

If the albummuria is due to anything more than a simple congestion of the kelneys, which is of little consequence, the urine soon shows signs of the presence of nephritis. Its quantity is reduced: its colour is smoky from the presence of blood, or even deep red if the hemorrhage is co-pass: boiling throws down a copious precipitate of albumen; and renal quithchum, blood-disks, and casts, granular and epithelial, are discovered by the microscope. At the same time or shortly afterwards the face is pale or puffy-booking; the cyclids are stiff and swellen; and more or less

adema is noticed about the legs and ankles.

The beginning of the kidney complication is generally announced by romiting, heads he, loss of appetite, a dry skin, a pallid complexion, an irregular pulse, and a rise in the temperature. The temperature is not very high, sellom exceeding 101"; and the vomiting is not often repeated, although cometimes it becomes a distressing symptom. The orderna varies in amount. Sometimes it is little more than a putliness of the skin. In other cases the swelling may be general and severe, so as completely to alter the natural expression of the face, and greatly distend the limbs and lower part of the back. At the same time effusion may take place into the serous cavities, the lungs, and even the glottis. If these effusions are rapid and concerns, great hyulity and dyspacea may ensue, and death may take place with startling rapidity. The most violent attacks of dysphera may be in luced by interstitial ordena of the lungs. The patient is found gasping for breath, with a haggard, livid face. His eves are staring and congrested, his has blue, and his nails purple. His pulse is weak and raped and has heart's action feeble and fluttering. On examination of the class few physical signs are to be discovered. The rhouchi are seanty and scattered, for very little fluid, if any, exudes into the air-passages and al-HOST

In a certain proportion of cases uramic symptoms may occur. The child is perhaps, violently convulsed several times, and may lapse into a state of coma, or he may be seized with headache of a very distressing character. Fortunately these symptoms usually pass off under the influence of judicious treatment. It is exceptional for a child to die of scarlamous nephritis. The occurrence of the renal complication appears to be dependent in a great measure upon the character of the epidemic; for stale in some it is a common symptom, in others it is almost entirely absent. The popular impression that it is always the consequence of a child has been disproved over and over again. There is no doubt that if albuminous nephritis be present, a child may hasten the occurrence of dropsy; but that slight exposure, such as occurs during convalescence from scarlet force, can determine the occurrence of the nephritis is now very generally disbelieved.

In the earlier stage of the nephritis the amount of urine is diminished and its specific gravity is rused. After a time the secretion becomes more explains and at the same time its density falls. Usually the pyrexia subseless when the quantity of urine increases. Dropsy is not un-invariable symptom. It may be completely absent, although the other phenomena are well marked. As a rule the nephritis is rapidly recovered from, and

the albuminuria and ursemic symptoms quickly disappear; but sometimes, although improvement takes place in other respects, the water still continues to throw down a deposit on boiling; for a long time a certain amount of albumen may be present, and under the microscope the sediment may continue to exhibit casts of tubes. In exceptional cases a permanent albuminuria may be left. In other instances, and these are probably more common than is usually supposed, the urine ceases to contain albumen and casts, and, indeed, with the exception of a low specific gravity, may present all the characters of health. Still the restoration of the kidneys is not complete, and slight causes, such as a passing chill, may determine a return of all the acute symptoms which have been described.

Dropsy without albuminuria is occasionally met with, and this not a mere amenic dropsy. In some of these cases albuminuria has been present, but has disappeared. In others there has been no precedent

albuminuria.

Otorrhua is a not uncommon complication of scarlatina. The discharge is often due to an inflammation of the external mestus, and is then, if attended to quickly, of little consequence. In many cases, however, it is a result of extension of the catarrh from the pharynx or masal cavities through the Eustachian tube to the middle ear. It is then a more serious matter, for the tympanum soon becomes distended with its purulent contents. Destruction of the small bones of the tympanum usually follows, and the pus bursting through the tympanic membrane escapes by the external canal. The most serious consequences may arise from this complication, as will be described elsewhere (see Otitis, and its consequences).

Abscesses may occur in the second or third week, or towards the close of the stage of desquamation. These collections of pus often delay convalescence, and if they occur in the neck may be signs of serious import. In the cervical region they are nearly always the result of internal ulceration. In every case, therefore, a careful examination of the throat should be made, and active measures are required to prevent any spreading of the destructive process in the pharynx. A not uncommon seat of abscess at this period is the submucous tissue at the back of the pharynx. This

subject is elsewhere considered (see Retro-pharyngeal Abscess).

Gangrene in various parts may occur. Cancrum one occasionally follows scarlet fever; and gangrene of the vulva, the pharynx, the skin of the abdomen, and that over a suppurating gland may also be met with. Sometimes, as may happen in the case of any fever of a low type which causes rapid reduction of the strength, scarlatina, if severe, is followed by his morrhagic purpura, with bleeding from several nucous surfaces. Even death may ensue as a consequence of the loss of blood. Nervous sequelæ may be also met with. Infantile spinal paralysis has been known to occur; and hemplegia from plugging of the middle cerebral artery is seen in rare instances.

In addition to the above complications, scarlatina is sometimes confused by the presence of other specific fevers. Diphtheria has been already mentioned. Besides this disease, measles and small-pox have been severally known to attack the scarlatinous patient, and run their course at the same time with it. Typhoid fever and scarlatina have been also met with together.

There is a form of scarlatina which has been called latent. In this variety the symptoms are mild and ill-defined, and the rash pale and imperfectly developed, or even quite absent. Indeed, the symptoms generally are so little severe that the existence of the fever is often not suspected

until desquamation begins. It is then remembered that the child had complained of a passing sore throat, and had seemed languid and heavy for a day or two, but nothing more. In these mild cases the after-course of the allness is not always in harmony with its beginning. Indeed, in no case of scarlatina, however slight the early symptoms may appear to be, can we renture positively to predict a favourable course to the illness.

It was long doubted if the form of scarlatina which occurs sometimes after surgical operations was a true scarlatina. The cases are usually of an modfensive type and the general symptoms triting. Still, a more severe form of the disease is occasionally met with. The rash appears a few days (two or three in most cases) after the operation, and may be almost the only examptom. There is often, however, high fever, but the soreness of throat is insignificant. Occasionally desquamation is absent. The healing of the wound is greatly retarded by the complication. That the disease is really scarlatina is shown by the fact that it protects the patient from the

fever poeson in after-life

Dangares. In a typical case scarlet fever is a disease which can scarcely be mistaken. The initial romiting and sore throat, with elevation of temperature and rapid pulse, followed on the second day by a uniform pink rash dotted thickly over with searlet puneta, is sufficiently characteristic. Unfortunately, many cases are not typical. The sore throat may be scarcely perceptible, the rash may be pale, discrete, and partial, and the temperature on the morning of the second day may be little elevated above the norusal level. A child with chronic enlargement of the tonsils, who is subject to stacks of sore throat, is found to be feversh, to have some pain in deglitition, and to present a pale, ill-developed discrete rash limited to the neck, chest, ab tomen, and thighs. In such a case it is allowable to feel some ancertunity as to the nature of the ailment. The appearance of the throat is, however, here of importance. The redness is not limited to the tonsils, but extends over the soft pulate, uvula, arches of the fauces, and often the back of the pharvns. The redness is uniform, but at its margin on the soft palate some punctiform redness may be seen; or the redness may be punctiform in character on the soft palate, and uniform elsewhere. Such a threat, accompanied by vomiting, a hot skin, a quick pulse, and a whitecoated tongue, is very suspicious of scarlet fever. Some forms of erythema antate the rush of scarlating very closely; and if there is a history of a recent unwented indulgence in diet, the illness may be easily attributed to the cause. If such a rash be accompanied by a normal temperature, scarlating may be positively excluded. But it is important to remember that the increase of bodily heat may be very moderate. I have known the morning temperature on the second day to be only 99.5', or one degree above the normal level, although the disease was a true scarlatina, which afterwar is became better developed. A pulse of 110, however mild the other symptoms may be, should make us suspect the existence of the fever very strongly; and in no case where the temperature reaches 100 or over should we venture positively to exclude the disease. An crythematous rash saldon so widely diffused as is the eruption of scarlatina; and in particular is usually absent from the neck and limbs. It also spreads very irregularly. In all cases of doubt we should inquire about pans and stiffness in the articulations, and examine the joints, especially those of the fingers, for aigns of swelling. We should also feel for enlarged glands in the neck. Often these symptoms are present early, when the eruption is very partial and mounpiete.

When the rash is dark colored, discrete, and slightly elevated, it may

be mistaken for measles; but the absence of sneezing and lachrymation, and the presence of bright red injection of the throat, with an unusually

rapid pulse, should furnish a sufficient distinction.

Roseola may be mistaken for scarlatina, but the rose eruption occurs in larger spots, and indeed more resembles measles than the disease we are considering. Moreover, in roseola there is little or no fever; no swelling of the joints; and the rapidity of the pulse is normal or only moderately increased.

Scarlatina may be closely simulated by ague. Dr. Cheadle has described the cases of two children in whom the skin during the hot stage was covered with a bright red rash. This eruption, combined with a quick pulse and a high temperature, was very suggestive of scarlatina, and might easily have been mistaken for it. The distinguishing points are referred to elsewhere (see Ague).

Sometimes in the mild anomalous cases of the disease desquamation may be long delayed, and the absence of peeling may be held to exclude scarlatina. In these cases we are directed by Sir William Jenner to examine the skin about the roots of the finger-nails for signs of scaling, as it may be discovered in this situation as early as a week or ten days from the

cessation of the illness.

Scarlet fover is hardly likely to be confounded with diphtheria, for the invasion and general symptoms of the two diseases are very different. It is important, however, not to overlook the possible intercurrence of diphtheria as a complication of the fever. If this unfortunate accident happen early, during the first week, there is usually an offensive discharge from the nostrils; the voice often becomes hourse; and there are symptoms of great depression. If it occur at a later period, when the patient seems approaching convalescence, the fever returns; the throat becomes again painful; the glands of the neck enlarge and are tender; there is a discharge from the nose; and in most cases the larynx becomes quickly involved. According to Trousseau, scarlatina avoids the larvny, while diphtheria has a well-known tendency to attack the windpipe. The occurrence of hoarseness, or the appearance of an offensive discharge from the nostrils, in any case of scarlating, should cause us at once to make fresh examination of the throat; and probably the appearance in the fauces of the dirty-white tough-looking membrane on the deep red swollen surface will at once prove the accuracy of our anticipations.

Prognosis.—Scarlating is a disease as to the course of which it is unwise to include in confident predictions; for an attack which begins untilly enough may end in a very different manner. Some of the worst cases are those which begin in such a way. Scrofulous children are bad subjects for scarlet fever, and in them an attack of apparently mild type may be followed by a distressing series of complications. Not long ago I attended a young girl who had been subject for years to scrofulous disease of bone in various parts of the body. She was taken with scarlatina. The symptoms were slight at first, and for a fortnight there was no cause for anything but satisfaction at the favourable progress of the illness. In the middle of the third week all this was changed. The patient first began to complain of rheumatic pains. She was then attacked in rapid succession by albuminous pephritis, peri- and endo-carditis, and double pleurisy. Cleerative endocarditis then ensued, which led to cerebral embolism with left hemiplegia, and afterwards to renal embolism, with return of the albuminuria and casts which had previously disappeared. The girl eventually died suddenly on the eighty-ninth day, apparently from clotting in the

pulmonary artery. In cases such as this there may be positively no indication that the hitherto being course of the disease is to change so scriously for the worse. When, however, the fever has assumed a severe form in other children of the same family, we must always be prepared for some such catastrophe; and until the disease is actually at an end we cannot put asole our apprehensions.

Previous ill health from other causes than scrofula does not apparently modely the prognosis; nor does early infancy influence unfavorably the course of the disease. The exact character the fever is to assume appears to depend upon the type of the epidemic and the constitutional peculiar-

thes of the patient.

'Ine malignant forms of scarlet fever are almost invariably fatal, especually those in which the nervous symptoms are violent. A mild nocturned dehrum is not of unfavourable omen; and slight wandering in the daytime, if there be no other symptom of nervous disturbance, need excite no anxiety, but if the delimin is active and persistent, with violent agitation and sleeplessness passing rapidly into stupor and prostration, we can have little hope of a favourable issue. Convulsions occurring after the first day, especially if repeated, are very serious. No indication is to be derived from the colour of the rash, for a dark tint of the eruption is not necessarily an unfavourable sign. There is cause for great anxiety if the temperature recontinuously; if the throat affection be severe; if there be frequent and long-continued vomiting or copious dysenteric diarrhea; if nephritis appear early; or if there be great diminution or suppression of the urmary weretion. Unemic symptoms are not so severe in the child as they are in the adult. At least, according to my experience, it is not common for a child to die of ursemic poisoning, if judiciously treated.

Fromtment.—In cases where any member of a family is taken with a rilet fever, it is of importance to prevent the illness spreading to the others. Prompt isolation of the patient is of course to be insisted on; and it is well, if the step can be conveniently adopted, to send the other

claidren away from the neighbourhood of the sufferer.

Various prophylactic measures have been recommended to arrest the disease in the incubative stage and prevent its further development. Reliationm, which was at one time largely employed with this object, has been now proved to be useless. It seems likely, however, that in arsenic we have an agent of greater value. It has been noticed that a person who is being treated with arsenic cannot be successfully vaccinated; and it is provible that the drug may have a counteracting influence upon other torms of infective matter. Practitioners who have made use of the remedy with this object speak favourably of its prophylactic virtue. Dr. W. G. Walford has given the drug largely to children who had been exposed to the infection of scarlitina, and states that out of nearly a hundred such cases in only two dul the development of the fever follow, and both cases were extremely mil l. He recommends the ordinary liq. arsenicalis (P.B.) in is large a dose as the age of the child will allow, with sulphurous acid (Tv.-xxx.), and a little syrup of poppy. The child should take the dose regularly three times a day at the first; afterwards less frequently.

When the disease actually declares itself, prophylactic measures must of course be laid aside. In a malady such as scarlatina, where the general compteness are often violent, and the complications are various and may be severe, the therapeutic measures at our disposal are necessarily very numerous. Still, we must depend for a successful result more appear eighbut nursing than upon the actual administration of drugs;

although these, especially when complications occur, are often of sensible

However mild the symptoms may be, the child should be kept in bed in a well-ventilated room, from which all curpets, curtains, rugs, cushions, and other woollen articles not required for the comfort of the patient have been previously removed. In order to prevent the spread of the disease, a sheet kept wet with a solution of carbohe acid (one part in forty parts of water) should be fastened so as to hang over the door-way; and care should be taken to disinfect all excreta, soiled linen, etc., before they are removed from the room. The child may be allowed to drink as often as he desires of pure filtered water, but the quantity taken at each time of drinking must be limited. His dict should consist of milk, broth, light puddings, bread and butter, etc. The heat and uritation of the skin is greatly relieved by sponging the surface of the body several times a day with tepid water, and afterwards drying with a soft towel. This is a more pleasant operation than the inunction of fats, which is sometimes recom-

mended, and is quite as serviceable to the patient.

In an ordinary case little medicine is required; but if the throat is painful, a draught of chlorate of potash may be ordered. Should the throat become much inflamed, and the cervical glands of the neck swell and be tender, the child should be made to suck ice, and hot applications (linseed-meal poultices, frequently renewed) should be applied to the neck; or we may use the cold compress, which, becoming heated by contact with the skin, acts in the same way. Cold thus applied internally, while the outside of the throat is kept warm, often produces a myd amelioration in the symptoms. If, however, the throat affection, instead of improving, becomes worse, and ulceration is noticed, it will be necessary to apply some local application to the fauces. In such a case the throat having been carefully cleansed with a brush dipped in warm water, a solution of nitrate of silver (half a drachm to the ounce) should be applied freely to the whole of the ulcerated surface. Moreover, any special ulcer may be touched once with the solid caustic. The weaker application must be repeated every morning for three or four days; and in the interval a solution of common sult in water (half in onnce to the pint) can be injected frequently into the fauces. It is very important in these cases to keep the throat clean inside, in order to remove quickly the poisonous secretions thrown out from the diseased surfaces; and frequent syringing or gargling of the throat with a saline solution such as the above, which dissolves mucus and facilitates the separation of tenscions secretions, will be attended by marked benefit. If required to clean the mucous surfaces, the saline solution may be applied from time to time with a brush. In addition to these measures, disinfecting applications may be made use of; such as a weak solution (two per cent.) of carbolic acid, or a lotion composed of liq. sode chlorinate (II xx. to the ounce of water). In these cases of severe sore throat it is advisable, as much for the sake of others as for the benefit of the patient, to keep the air of the room saturated with a solution of carbolic acid (one part in thirty of water) by Dr. R. J. Lee's steam draught inhaler, or some similar apparatus. The application of sulphurous acid to the throat, as recommended by the late Dr. Dewees, is also useful. This remedy should be used with an atomizer, and the acid, pure or diluted with an equal proportion of water, should be sprayed into the throat for a few minutes every two or three

If there be coryza, the saline solution may be injected into the usual

fosse, or the nose may be syringed once a day with a weak solution of

intrate of alver (gr. v. to the ounce).

Abscesses forming in the neck must be opened directly fluctuation is detected, and be afterwards well poulticed. If hiemorrhage occur, the wound must be stuffed with lint soaked in perchloride of iron. A post-pharyogeal abscess must be also opened early with a large trocar and cannula.

If otorrhoa be noticed, the meatus must be syringed out frequently during the day with warm water. If the tympanic membrane be perfect, the discharge proceeding only from the external canal, a syringeful of some mild astringent lotion should be injected each time after complete cleansing. Glycerine of tannin (one drachm to the ounce of water) or a weak solution of sulphate of zinc (gr. iij. to the ounce) answer well for this

PULTINGE

In the case of any of the above complications quinine in full doses (gr in four times a day for a child five years old) should be given; and a liberal diet should be allowed, due regard being had to the patient's powers of digestion. When the temperature has failed in scarlet fever the child should have meat once a day, an egg or a little bacon for his breakfast, and should take plenty of milk. As long as the water continues clear we may be sure that he is not being overloaded with food; but the appearance of a thick deposit of lithates should at once make us reconsider his dietary, and limit the quantity allowed at his meals.

When the throat affection is severe, iron seems more beneficial than quinine, if administered energetically. For a child of this age fifteen to twenty drops of the pernitrate of iron should be given with glycerine and water every three or four hours. At the same time brandy-and-egg mixture must be supplied in such quantities as seem desirable, according to the degree of prestration of the patient. In such cases children will take with benefit large quantities of the stimulant. Strong beef-tea, meat

extract, etc., can also be given.

If the disease be ushered in with obstinate vomiting, the symptom is best relieved by sucking ice. If diarrhea occur, oxide of zinc (five grains for a child of five years old) or bismath (gr. xv.) and chalk mixture should be reserted to. If at the beginning of the diarrhea the motions are lumpy, a null aperient, such as a dose of castor-oil or a rhuburb and soda powder,

should be administered. In cases of matiguant searlet fever with violent nervous symptoms every kind of treatment will unfortunately be often found to fail. If the temperature be high, it must be reduced by cold bathing. The child may cather be placed in a cool bath (temperature of 70 Fahr.), and kept there until his teeth begin to cluster, or affusions with water of the same temperature may be practised, as recommended by Curric I prefer the former method; and there is no doubt that the immediate effect of the both in lowering the pulse and temperature, dissipating the delirium, and relieving the agitation of the patient is very decided. When the tempersture rises again and dehrium returns the process must be repeated Unfortunately, although there is temporary relief to the symptoms, the patient is sel lom cured by this means, and usually falls after a time into a state of prostration and collapse, in which he dies. A milder way of emplering the same treatment is to wrap the child in a wetted sheet, and by him upon a hard mattress, covering him merely with a thin blanket thrown loos by over him. When he shivers he should be released and returned to his bed. The unkler practice is suitable in the less severe

cases, and has a distinct effect in reducing the temperature. It must be remembered, however, with regard to this question of hyper-pyrexia, that children often bear high temperatures very well; and it is difficult to lay down a broad rule as to the period at which it is necessary to intervene It is better to be guided in this respect by the general symptoms than by the thermometer. If, as often happens, a child seems comfortable and composed, with a temperature of 105° or 106°, there is no occasion for any step more energetic than that of sponging the surface of the body with warm water; but if with a lower temperature (103° or 104') he is dehrious, agitated, and distressed, the cold bath may be used with benefit. Wet packing is often useful in these cases; but when thus enveloped in blankets the child's temperature must be carefully watched. If the skin be induced to act by this means, and the patient sweat profusely, the process is a beneficial one and the temperature will fall. If, on the other hand, the skin do not act, the effect of the packing is to cause a further increase in the pyrexia. Therefore, if the temperature be found to rise instead of falling, the blankets should be at once removed. In all these cases the bath, of whatever kind it be, should be supplemented by energetic stimulation in order to counteract the tendency to sudden collapse.

If the child is from the first in a state of prostration, instead of the cold bath the hot mustard both may be made use of; but such cases are seldem

benefited even temporarily.

If rheumatic pains are complained of and the joints swell, these parts should be wrapped in cutton wool and covered with a firmly applied flannel bandage; and Dover's powder should be given at night if the pains interfere with sleep. Attention must also be paid to the state of the bowels. Inflammation of the serous membranes must be treated upon ordinary

principles.

If albuminous nephritis occur, energetic treatment must be adopted at once. A mere trace of albumen, such as is often met with in cases of scarlatina, is of little consequence, and requires merely tome treatment; but the appearance of copious albumen in a smoky urine shows the presence of acute Bright's disease, and is a very different matter. We should therefore at once proceed to sweat and purge the patient. There is perhaps, no condition in which the beneficial influence of free purgation is more striking than in this complication. A child of five years old should take every night a dose of compound jalap powder (gr. xxx.-xl.) alone, or mixed with five grains of compound scammony powder. Enough should be given to produce two or three watery stools. In the daytime he should be wrapped in a sheet wrung out of tepid water and be then well packed in blankets; taking at the same time a draught containing a solution of acetate of ammonia (5 j.) and antimonial wine (M xx.) to insure the free action of the skin. His diet should be simple. As long as there is any pyrexia no solid food should be allowed; and the patient should have nothing but milk and broth with dry toast. Plenty of fluid is useful. If these measures be adopted, the albumen in the majority of cases will be found to disappear very quickly from the urine. Should it, however, persist, and the renal disorder seem to be passing into a chronic state, iron and ergot are indicated; or three grains of the hydrate of chloral may be given (for a child of five years old) three times a day. In cases of ura mic convulsions purging and sweating carried out briskly are of equal service, and will usually quickly relieve the symptoms, especially if aided by a diuretic. The following is a serviceable form:

B.	Liq. ammoniæ acetatis	TE XXI	ĸ.
	Polassa acetatia	gr. v.	
	Sp. juniperis	TIL V.	
	Sp setheris nitrosi	III xx	
	Glycerini	m xx	
	Aquam ad § 88, M. Ft. haustus.		

To be taken every four hours (for a child of five years old).

A good diuretic for children is digitalis; and the drug is well borne in early life. Five drops of the functure given three times a day with an equal quantity of spirits of juniper may be employed. Jaborandi and its alkaloid palorarpine are useful in these cases; and can be given either by the mouth or by subcutaneous injection. The most convenient way of administration is to make a fresh solution of the nitrate or hydrochlorate of palocarpine in water of the strength of one grain to twenty-four minims. Of this solution three drops one-eighth of a grain) can be injected subcutaneously, and is a suitable dose for a child of five years of age. Children bear this remedy well. If the solution is freshly made, copious sweating follows the injection; there is often profuse salivation; and the secretion of urine is greatly augmented. The child should be between blankets, so as to encourage the action of the skin. The dose may be repeated every lay, if necessary. It often excites nausea and vomiting, but this is imministerial.

During the stage of desquamation measures should be taken to hasten the separation of the epithelium. The child should be oiled all over the body every night with carbolized oil (one part of the acid to twenty parts of obve-oil), and this should be well rubbed into the skin. Afterwards he should be thoroughly washed with soap in a warm bath. If this be carried out in a warm room, there is no fear of a chill.

Even in mild cases the child should keep his bed for three weeks, and his room for a month at least, from the beginning of his illness; and until the peeling has quite ceased the patient is unfit to associate with healthy persons. It must be remembered that desquamation may linger long about the wrists and ankles, the fingers and the toes; and that a considerable time may clapse before the mucous membrane of the throat has completely recovered its normal state. When the child is finally pronounced to be well, it is advisable to send him to the sea-side for change of air before he resumes his ordinary habits and mode of life.

CHAPTER IV.

CRICKEN-POX.

CHICKEN-FOX OF VARICELLA is seldom seen except in young subjects. It is an infectious disorder which occurs generally in epidemics, and attacks by preference children aged from two to six years. At one time it was supposed to be a form of modified small-pox, but few are now of this opinion for the evidence against it is overwhelming. Attempts have been made to

impart the disease by inoculation, but without success.

Symptoms.—After a period of incubation, varying from seven to fourteen days, the child is noticed to be feverish, and within the next four andtwenty hours a number of small rosy-red spots appear on the cliest and over the body generally. These are slightly elevated, and number on the first day fifteen or twenty. In the course of a few hours-in any case by the next morning—the papule has changed into a vesicle or roundish bleb which is filled with clear serum. It has sometimes a very faint punk areola round its circumference. At the same time other papules have appeared, more numerous than on the first day. These in their turn become converted into clear blehs. In this way every morning finds a fresh crop of red spots, and of fresh blebs formed from the red spots of the previous day. The change from red spot to bleb may take place very quickly; in fact, the rash has sometimes been described as vesicular from the first, In any case it is completed within ten or twelve hours of the appearance of the red papule. The spots appear in no regular order, but are scattered about all parts of the body and limbs, and may even be seen beneath the hair on the scalp. They are also occasionally found inside the mouth, on the soft palate, the inner side of the cheeks and lips, and at the sides of the tongue; but when seated on mucous membrane the vesicle changes very rapidly to a small round ulcer. After appearing in successive crops for four or five days, fresh spots cease to be seen. The changes which each individual spot undergoes are as follows:-it increases in size for a day or two, and then its liquid contents, from clear, like pure water, become milky. Some burst and form crusts; others present, after a day or two, a speck of seab on the summit, which to a hasty glance gives a false appearance of umbilication; the vesicle then dries up and leaves a thin crust, which falls off after a few days. No scar is left, as in variola, unless the child have irritated the skin by scratching; in which case a shallow pit may be seen in the situation of the scab. It is difficult to prevent the child from scratching the spots, for the eruption is accompanied by considerable irritation.

The amount of fever varies. At the beginning the temperature may rise as high as 102°, especially if the rush is slow to appear. After the first day or two, however, the pyrexia subsides considerably, and is seldon higher than 99.5° during the remainder of the illness. In some cases a

slight exacerbation occurs with the maturation of the vesicles, but the temperature soon returns to the normal level. In the large majority of cases the constitutional disturbance is of the slightest. After the crusta have fallen the temperature sanks to a lower level than in health.

The duration of the disorder is ten days or a fortnight, counting from the predominary fever to the final fall of the crusts. Afterwards the child may be left in a weakly state for some time; and delicate children may have the outbreak of serious disease determined by this apparently trifting complaint. Thus, I have known scate tuberculosis to succeed after a very

short interval to an attack of chicken-pox.

In exceptional cases the complaint is not over so quickly. Mr. J. Hatchinson was the first to draw attention to the gaugeenous eruptions which sometimes occur in connection with the chicken-pox. This dangerous complication is not confined to weakly, ill-nourished children, although it is most common in them. It is no doubt connected with the currous tendency to spontaneous gangreno sometimes met with in chil-

dren, and described in another chapter.

In gangrenous varicella the vesicles, instead of drying up in the ordinary way, become black and get larger, so that a number of rounded black scales, with a diameter of half an inch to an inch, are scattered over the surface of the body. If a scale be removed it is seen to cover a deep ulcer. Around it the skin is of a dusky red color. All the vesicles do not take on the grangrenous action, so that we find many varicellous scales of ordinary appearance mixed up with the blackened crusts. The gangrenous process often penetrated deeply through the skin to the muscles, but under some of the scales the ulceration is more shallow. These cases are very fatal. If Warrington Haward has reported the case of a weakly baby of twelve months old, who weighed only six pounds and a half. This child was attacked with gangrenous varicella and died in a few days of pyaemia with

secondary abscesses in the lungs.

Introduce. It is often a very difficult matter to distinguish between chicken-pox and modified small-pox. If the cruption follows very rapidly upon the first signs of fever, the disease is probably varicella, for in the case of variobal the rash is usually preceded by two or three days of fever and malaise with vomiting; and the pain in the back may be as intense as to the unmo lifted form of the disease. But there are many exceptions to the rule, for in some cases of varioloid the normal duration of the preemptive period is considerably shortened. Again, the spots in variofold, to in variota, are grouped in threes and fives, while in varicella their distributton is more irregular. Then, the papule in varioloid is always shotty and hard. In varicella it is peculiarly soft, and always disappears on stretching the skin. If there be an elevation left after the fall of the scab, it is conclusive in favour of modified small-pox; while a subnormal tempersture occurring as early as the tenth day would point rather to varicella than to varioloid. A wording to Mr. M seuna, the varicellous vesicle is unilocular, and can be emptied by one touch of a needle. The vesicle in multipox, on the contrary, is always multilocular, and cannot be emptied by a single puncture. In case of doubt this difference will serve as a distinguishing mark.

It is important to be aware that a shallow pit or sear may be left here and there upon the skin after undoubted varicells. Pitting may occur in any case where, from the irritation of continued scratching, or from some constitutional peculiarity of the patient, ulceration of the skin has

been set up in the site of a vesicle.

Gangrenous varicella is distinguished by the history of the case, and the appearance of ordinary varicellous scabs mixed up with the blackened and

gangrenous crusts.

Treatment.—A child attacked by chicken-pox must be removed from other children, and prevented, if possible, from picking or scratching the spots. If there be much fever, he should be confined to bed and his bowels must be attended to. When the disease is at an end, the child will require a tonic, such as quinine or iron. If convenient, he may be taken to the sea-side; and if there be any consumptive tendency in the family change of air during convalescence is not unimportant.

In cases of gangrenous varicella little can be done beyond supporting the strength with good food suitable to the age and degree of feebleness of the patient, and giving the brandy-and-egg mixture as often as is required. If the gangrenous crusts are few in number, the scabs may be removed and the underlying ulcer filled with iodoform powder, as recommended by

Parrot for gangrene of the vulva.

CHAPTER V.

COW-POX .- VACCINATION.

The cow-pax, or vaccinia, is a disease with is natural to the milch cow, but never occurs in the human subject except as the result of direct vaccination. In the cow it appears on the tests and udder as isolated spots, which at first are papular, but afterwards pass through the vesicular and pustular stages, as in true small-pox. They scale on the thirteenth or four-teenth day, and full off in the following week, leaving pits on the skin. This disease is now satisfactorily proved to be the real small-pox, altered in character and modified by its passage through the animal, but still capable, when conveyed to the human subject, of imparting as much protection as

would be derived from a direct attack of the original disease.

It is now a familiar story how E-lward Jenner, then hving as apprentice to a surgeon in Gloucestershire, determined to investigate the truth of a belief, current in the neighbourhood, that milkers who had become inoculated with cow-pox in the pursuit of their calling, were no longer susceptible to the contagion of small-pox; and how, by careful observation and experiment, he succeeded in establishing the important conclusions that cow-pox communicated by inoculation to the human subject did actually confer immunity from small-pox; also that the disease, so engrafted, might be transmitted indefinitely from person to person without any abstement of its protective power. Since Jenner's time the practice of vaccination has become universal, and to this great discovery we owe it that small-pox, as it used to be, with all its dreadful consequences, is almost unknown in the

present day. Specificans and Course. - After the introduction of the lymph under the skin of a child previously unvaccinated the following is the course of the is ineed disorder. For two days no change takes place, but at the end of the second day, or beginning of the third, a small elevated papule is seen at the site of the puncture. This enlarges, and by the fifth or sixth day has become a circular raised pearly-gray vesicle, with a depression in the centre. The vesicle grows, and by the eighth day is fully developed. It is then seen as a flattened, round, gray-colored vesicle, still depressed in the centre and filed with a colorless lymph. It does not remain stationary, but begins at once to lose its transparency; a red arcola forms round its bee and quickly spreads so that by the tenth day the vesicle is found and on a hardened red base, with the red areola extending for one or are menes over the skin around. The vesicle has now become a pustule with purulent contents, and around it the subcutaneous tissue is hard and After the tenth day the areola gradually faces, the fluid contents of the pustule undergo absorption; and by the fourtcenth or fifteenth day a sent less formed, which gradually loosens and becomes detached. The crust usually falls in about three weeks from the time of puncture, and in its place is seen a round sunken sear pitted with little depressions.

The disease is at first purely local, but afterwards becomes general According to Dr. Squire a continuous rise of temperature begins on the fourth or fifth day. This suddenly increases on the eighth day, and as suddenly falls a day or two afterwards, when the arcola has ceased to extend itself. The maturation of the vesicle is also accompanied by other signs, showing that the disease has begun to affect the system. The chid is restless and uneasy; there is some digestive disturbance; and the lymphatic glands in the armpit become tender. Sometimes a rescolous red rish makes its appearance on the affected limb, and may extend to the other extremities. This rash may become papular or even vesicular.

The above is the course of the disease when the morulating lymph is taken from another child. Some practitioners prefer to use lymph obtained directly from the cow. But with "primary" lymph there is more difficulty in operating successfully; and when the vaccination takes effect, the constitutional symptoms are more severe. There is also another difference. With such lymph the whole process is retarded. The papile does not appear until a week or even a longer time has elapsed, and the arcola does not become complete until the eleventh or even the fourteenth day. The swelling and hardness around the pustule are greater, and the secondary rashes are more frequently seen. The scabbing stage is also prolonged, and the crust may not fall for a mouth or six weeks from the

day of operation.

Even when humanized lymph is made use of, the process is occasionally retarded. This may be the case when dried lymph is employed, and is invariably seen if the patient happen to be incubating measles or scarlatina. Sometimes, too, it appears to be owing to a constitutional peculiarity. Mere retardation does not, however, affect the value of the result if the development of the induced disease be normal. Instead of being retarded, the process may be accelerated; but this, again, is immaterial, provided the course of the pock be regular. If, however, for whatever reason, the course of the disease be not regular, and the pock be in any way incomplete, the result must be looked upon as unsatisfactory, and the protection so afforded cannot be relied upon. Vaccination is apt to be rendered irregular by the presence of acute febrile disease, of discribea; or of certain skin diseases, especially herpes, eczema, intertrigo, lichen, and strophulus. In all such cases, directly the child's health is restored, the operation should be repeated. Unfortunately it will then often fail; for after a spurious vaccination the child may be left - temporarily, at least—insusceptible to the action of the lymph.

In cases of revaccination the result is often irregular. The whole process is then hurried. The papule appears early; the vesicle is fully developed by the fifth or sixth day; and then at once declines. On the eighth day a scab forms, and becomes detached a day or two later; so that in less than a fortnight the disease has run through all its stages. With this, the constitutional symptoms are more severe, and the itelang and local discomfort greater, than in cases where the inoculation is prac-

tis d for the first time.

Protective Value of Vaccination.—Effectually performed, vaccination is, in the majority of cases, a permanent protection against small-pox; that is to say, the protection afforded by it is as great as that furnished by an actual attack of variola. Jenner himself never claimed that it would do more than this. As a rule, an individual who has been successfully and sufficiently vaccinated is either insusceptible to the contagion of small-pox, or is capable of taking the disease only in a mild and modified form.

It is, then, very important to ascertain what constitutes an efficient vaccan tion. This question has been answered by Dr. Marson, who found, as a result of thirty years' observation of small-pox cases in the London Fever H equial, that while in unvaccinated persons the mortality was as high as 37 per cent., the percentage gradually dimmashed in exact proportion to the number and completeness of the vaccination creatrices; so that in persons who could show four or more well-marked scars the mortality was only .55 per cent. It should therefore be the aim of every vaccinator to produce four or five genuine well-developed vesicles upon the arm of the patient. With less than this number the vaccination, although it may be successful, cannot be considered to be sufficient, nor the protection as complete as it can be made. As a further precaution it is usual to revaccinate the individual after he has attained the age of puberty. Should this be imsuccessful, it is advocable to repeat the operation if at any time the person become liable to be exposed to the contagion of small pox; especially if upon examination of the arms he is seen to bear only imperfeet evidence of a former vaccination. The protective power of vaccinafriend Dr Twiting. The cases were under the care of Dr. Gayton, of the Homerton Small pox Hospital, Between 1871 and 1878, 1,574 children came under observation, suffering from small-pox. Of these, 211 had been efficiently vaccinated, and one of them died: 396 had been imperfectly vaccinated, and of these 39 died: 179 were said to have been vaccinated, but bore no marks, of these 46 died: 785 were known never to have been vacamated, and of these 385 died. Taking the last two groups togother, the mortality in unvaccinated children was 41 per cent, under ten tears of age.

Meth of Varinating. The lymph used should be taken from the arm of a bealthy child at some time between the sixth and eighth day of vesication, while the vesicle still retains its purity and transparency. After the with day it should not be used. The child, the subject of the operation, should be in good health. If he be poorly, especially if he be feverish, or by suffering from some skin eruption, the operation should be postponed. It was Jenner's own direction to sweep away all eruptions before macring the lymph. This rule is a very important one, for although the vaccination may possibly take effect, it is more likely that it will fail, and a spurious the in then may render the child's system insusceptible to the vaccine by ph without affording the desired protection against small-pox. Many to the is of inserting the lymph are now in use. The simplest, and perhaps the issat is to make three separate punctures on each arm, inserting the print of a perfectly clean kneet, moistened with fresh lymph, sufficiently deeply to draw a little blood. In making the punctures the skin is stretched between the finger and thumb, and the point of the bincet is inclined downwards, so as to enter the skin obliquely. If fresh lymph cannot be obtained from the arm of another child, lymph stored in capillary tubes, or dro don points, may be used. The dry points must be first well moistened with water, and then inserted into the punctures made by the lancet. As can should be used as there are punctures made; and the points should to proved down into the little wounds and allowed to remain for a minute. On being withdrawn, they should be pressed against the sides of the punc-

ture, so as to insure the lymph being left in the skin.

(Assessed Sequelar of Vaccination, -Sometimes erysipelas has been set up by vaccination, and even pyremin has been known to follow, and cause the death of the child. These unfortunate consequences are not to be

attributed necessarily to any carclessness or awkwardness on the part of the operator, nor to any impurity in the lymph employed. They are due to the constitutional state of the child at the time of the operation -a state in which the puncture of the lancet is followed by these untoward accretents just as any other trifling operation might be followed by them. A re-colour and papular rash has been already referred to as sometimes following the maturation of the pustule; but other rashes, such as eczema and the various skin eruptions to which children are liable, may be seen after vaccination. These rashes are always attributed by parents to the insertion of the vaccine lymph. In some cases vaccination may have been indirectly a cause of the skin affection by lowering the child's general health a result which in childhood is apt to follow any feverish attack; but often the occurrence of the eruption at a short interval after the vaccination is a mere coincidence, and is owing to an entirely different cause. In outpatients' rooms of hospitals it is not uncommon to find even scables attrib-

uted to a recent vaccination.

Syphihs and scrofula are said to have been conveyed from child to chill by the vaccine lymph. With regard to the first of these diseases, it was long demed that such transmission was possible. Experiments were made, and in France children were deliberately vaccinated with lymph taken from other children suffering from inherited syphilis; but in no case was syphilis found to be communicated by the operation. Many cases, however, have been since published which leave no doubt that communication of the syphilitic virus may take place by this means. The old notion that the fact of a vaccine vesicle undergoing its normal development and presenting its normal appearance is distinct proof that the lymph within it is uncontaminated by foreign views, appears to be a correct one. In syphilitic children vesicles may assume this appearance, and are then incapable of transmitting any disease other than the cow-pox. If, however, in taking bruph from these vesicles, the puncture be made carclessly, and, with the lymph, some of the blood be taken up by the point of the lancet and inoculated into a healthy child, syphilis may follow. No doubt many of the cases in which a syphilitic rash has followed vaccination have occurred in children the subjects of inherited syphilis, in whom the febrile movement induced by the process of vaccination has determined the outbreak of an already existing disorder. So also in scrofulous children, a little derangement of the health will often rouse up the latent cachexia, which but for this might have remained dormant a little longer.

CHAPTER VI.

SMALL-POX.

Owns to the beneficent discovery of Edward Jenner the full terrors of small-pox as it used to prevail can now hardly be realized. In unwaccinated persons, and those upon whom the operation has been performed imperfectly, the discusse may still rage with all its natural violence, but in ordinary cases the form of the discusse met with is the milder variety which is called variound. It is the same discuss as various, although modified more or less by occurring in a subject partially protected by vaccination.

Small pox is one of the most infectious of the acute specific fevers, and in this respect the modified form is as dangerous as true variola. The patient seems to be capable of communicating the disease even before the emption appears, probably, therefore, from the very beginning of the early fever. He also continues to be a source of danger to others as long as any particle of scale or scab remains attached to his body after the subsidence of the disease. One attack usually protects against a second, but it is far from uncommon for a person to take the fever two or even three times.

Martial Anatomy, -As in most of the infectious fevers, the blood in (stal cases is dark and coagulates unperfectly; fibrinous clots are often found in the right ventricle of the heart; and in very severe cases hemorruscie extravasitions are scattered about in the loose tissue beneath the rous and mucous membranes. Internal organs, such as the heart, liver, and sples n, are either pale, flabby, and soft, or deeply congested. The museus no inbranes, especially of the air-passages, are intensely hyperacinic, at 1 are thickened, softened, and sometimes ulcerated. Their conthelium is partially separated, and their surface is covered with a brown tenacious mucus. The same condition may be found in the mucous membrane of the moved fosse, the mouth, fauces, and gullet. In all of these parts small excornations may be noticed. They are small round spots on the mucous surface, either covered by a whitish false membrane or presenting a round point of superficial ulceration. These are probably due to an eruption on the mucous membrane of a like nature to that which takes place upon the kin. No such appearances are seen upon the gastro-intestinal mucous a carbrane, but the intestinal follicles and the glands of Peyer's patches are lurge and projecting. The lungs are often intensely congested, and are - a-times the scat of pneumonia. Moreover, the pleura of one side may be filed with scro-purulent fluid.

In the skin the morbid changes are as follows. A punctiform hyperamia takes place at various spots which extends through the cutis to the rete innecession. The cells of this part swell and proinferate, so that a solid harply defined nodule is formed at the inflamed spot. Next, the epiderams is reason up by fluid exudation into a vesicle. If this be formed round a frur-folliele or sweat-gland, it is umbilicated in consequence of the summit being held down by the duct. The reside is multilocular, for its in-

terior is divided into several chambers by delicate partitions. These are not fibrinous, as used to be thought, but are formed by compression of the altered cells by the effused fluid. They disappear, as well as the umbilication, when the process of maturation is complete. The vesicular fluid contains many leucocytes and some red blood corpuscles. As the profiferation of the cells of the rete mucosum continues, the fluid becomes purulent and the vesicle is changed into a pustule. The true skin is sometimes destroyed by this suppurative process to some depth, and there is a

depressed permanent scar then left after the fall of the scab.

Symptoms - The period of incubation of small-pox when contracted by infection is, according to Mr Marson, thirteen times twenty-four hours, i.e., twelve whole days and parts of two others. If the disease is produced by moculation, the period is shortened to seven or eight days. During this stage there are no symptoms in ordinary cases, although a certain amount of urritability and peevishness is sometimes noticed, not usual with the child and indicative of unessiness; but no definite symptoms can be observed. On the fourteenth day the first decided indication of the illness appears and the stage of invasion begins. Chilliness with a rise of temperature, sickness often distressing, and severe pains in the back and long, sometimes in the limbs as well, are the characteristic features of this period. The pain in the back may be associated with temporary paraplegia, and is often combined in children with incontinence of urme and ficces. Other symptoms are: thirst, loss of appetite, a coated tongue, grinding of teeth, frontal headache, and constipation or diarrhea. A severe amount of nervous disturbance is often seen, and the child may be thrown into violent and repeated convulsions with intermediate delimin and stupor. The violence and frequency of these attacks are not to be relied upon as an index of the severity of the illness which is to follow, as they are probably dependent less upon the intensity of the variolous poison than upon the natural nervous sensibility of the child. A little gark aged mx years, began to have fits on November 27th; they continued until the 29th. Between the convulsive seizures the child was drowsy and stupid, and often vomited. On the 29th the cruption appeared. The nervous symptoms then ceased, and the disease ran a particularly favourable course.

The period of invasion lasts for forty-eight hours. During all this time the initial symptoms persist and the temperature continues to rise The pyrexia is not always great at this stage. A boy, aged eleven years, a patient in the East London Childrens' Hospital, suffering from heart disease and pleurisy, who had not been previously feverish, was found one morning to have a temperature of 101 6. The next morning it was 99, and in the evening 102°. On the following morning (the third day) the thermometer marked 102 2°, and the eruption appeared. In many cases, however, the pyrexia is greater, and the temperature may reach 165 or higher. In the case of the little girl before referred to it was 103.6 on the morning of the second day. Occasionally during this stage a roseolous eruption, very like the rash of scarlatina, appears upon the skin. This is most common in cases of modified small-pox. It is right to say that the symptoms of the pre-cruptive stage are not always seen in this marked form. Dr. Twining of the Homerton Fever Hospital informs me that of the children who are admitted into that institution suffering from variola, many have complained merely of malaise, headache, or sickness; and in not a few cases the first symptom noticed was the rash of the

ente,

The emptive stage begins on the third day. In exceptional cases—

usually those of a malignant character—the rash may appear on the second day. Occasionally it does not show itself until the fourth. These excep-tions are found in all the eruptive fevers. The special small-pox eruption be ans as small red papules scattered more or less thickly over the surface. They are first noticed on the chin, nose, or forehead, and then quickly spread to the whole face. They are next seen on the wrists, and in the course of the following twenty-four or forty-eight hours spread gradually to the chest, the arms, the trunk, and the lower hunbs. The spots are not sprinkled irregularly over the surface, but may be noticed to group themselves in threes and fives, often arranged in a senucircle when two of these crescents come together, they may by their junction complete the circle. The spots are set more thickly on the face than on the boly, and as they appear earliest in this situation, they run through all their stages, and seab earlier here than on the trunk and limbs. The papule is hard, and gives to the finger the sensation of a small shot embe ided in the skin. All are not, however, of equal firmness. Some have much more of a shorty character than others. Between the papules the skin is of normal colour and appearance; but if the spots are set very closely together, there may be a general redness and granular look of the face without any intervening normal tint of the skin being visible.

At the same time that the papules appear on the skin, spots may be also seen, if looked for, on the inside of the cheeks and lips, on the inside of the mose, and sometimes even on the conjunctive. At first, as they cause little discomfort, these are scarcely complained of; but after a day or two they produce salivation, and pain in swallowing, and, if the airpassages are similarly affected, hourseness and cough. There is also some smulling, and the eyes are red and watery. Later, when the rash is appearing on the lower limbs, the mucous membrane of the vagina, or

urethra and prepure, also become the seat of eruption.

The changes which occur in the rash are as follows: The papule enlarges, becoming a flat-topped nodule, and in the course of the second or third day (tifth or sixth of the disease) changes into a vesicle. change takes place, as has been said, earlier on the face than on the body or limbs; and, indeed, while the papules are coming out on the lower extremities, those on the face are already changing into vesicles. vesicle is browl flat-topped, and umbilicated. Its contents are opaque, an last first whitish in colour; but by the sixth day (eighth of the discuse) have become distinctly purulent, a deep red areola has formed round the pock, and the subjecent skin is swollen by inflammatory effusion. The and is now a pustule seated on a thickened base. From the eighth to the eleventh day the pock enlarges; and the union of neighbouring arcola and the thickened bases of the pustules produces a general redness and swelling which completely obliterates all distinctive character in the features of the patient, and causes a distressing tension and smarting irritahon of the skin which is greatly complained of. There may be also extreme ten lerness, so that the slightest touch is painful. The eyes are often closed by the swelling, and the lids are glued together by the vitiated secretions from the Meibomian glands; the nose is stopped up; the secretion of saliva is profuse, and swallowing is very difficult and painful. The voice, wo, is hourse and the cough distressing. Often the eyes are inflamed, painful, and very sensitive to light. The process of maturing of the pustules (stage of maturation) lasts from the sixth to the ninth day (eighth to the eleventh of the disease) on the face; on the lower limbs it begins and ends a day or two later. Consequently, the vaginal and urethral

rashes and the distress they produce are at their height when the faucal and laryngeal mucous membranes have begun to improve. On these and the other mucous surfaces the eruption does not pass beyond the vesicular stage, but is accompanied by considerable reduces and swelling of the membrane. While the pustules are maturing on the skin, the supparating spots give out a peculiar and unpleasant olor, which is, however, characteristic of the disease.

The eruptive stage lasts about eight days - from the third to the eleventh of the illness. The appearance of the rash is usually the signal for a remission in the fever, and in the symptoms of general constitutional disturbance; but there is soldon a notable fall in the temperature until the eruption is fully out. If the pyrexia remain high after the papular stage is completed, the disease is severe and unmodified, or some complication is present. In confluent small-pox the remission is very imperfect and transient, the reduction of temperature is inconsiderable, and whereas in a mild discrete case the patient feels almost well at this time, in the severer form of the discuse the alleviation to the distress is much less complete, and even at this early stage of the illness photophobia, salivation, pain in deglutition, and hourse cough may be the source of great discomfort. In an ordinary case of discrete small-pox when the eruption is fully out, the temperature, although still above the normal level, is comparatively little raised; nervous symptoms are no longer noticed; and except for the local inconvenience of the state of the skin, the condition of the patient is greatly improved.

When the pustular stage is reached and the process of maturation begins (about the sixth day of the rash, eighth or ninth of the disease), the temperature rises again, and what is called "the secondary fever" begins. The intensity of this later pyrevia varies according to the severity of the attack. In mild cases it may be slight or even absent; but in severe cases, especially in the confluent form of the fever, the temperature rises to a higher level, perhaps, than in the earlier stage; the child is stupid or debitious, and often wakeful at night; his tongue is furred and often dry; his pulse gets quick and feeble; his weakness is great; and tremors, subsultus tendinum, with other symptoms of prostration, may be noticed. In not a few cases the disease has ended in death before the period of secondary fever is reached. In the severe cases, if the patient do not die at this time from the violence of the disease, he is very apt to succumb to an in-

flammatory complication.

The secondary fever lasts until the maturation of the pustules is completed on the eleventh or twelfth day of the illness. The disease then enters into its latest period, that of desiccation and decline. In the course of two or three days the pustules discharge their contents; the redness and swelling of the skin subside; the odor from the child's body becomes extremely offensive; and yellowish-brown, thick scabs form from eaking of the purulent secretion. Nearly at the same time—unless some febrile complication arise—the pyrexia begins to subside and the tongue to clean; the painful symptoms connected with the mucous membranes disappear in the order in which they occurred; the pulse slackens and the appetite improves. The falling of the crusts is accompanied by some itching of the skin. It takes place earlier in some parts than in others, and is delayed in proportion to the amount of ulceration which is present in the cutis. If this be great, the scabs become very thick and horny, and remain attached for a long time. Sometimes successive crops of scab are thrown off before the underlying surface has become healthy. The size of the fallen crusts

is also subject to variety. If the pustules have been thickly set, the edges of the neighbouring scabs may unite, so that large pieces of dark brown, horny crust become detached at the same time. The separation of the scates is often very slow on the scalp in children; and often new crusts continue to form after old ones have been removed with wearisome persistence. When the crusts have all fallen, the surface is left mottled with slightly elevated red spots, which eventually either disappear leaving no trace, or, if there has been ulceration, change into depressed white deep scars with inverted edges and an irregular floor.

Complications—In severe cases, even if the child survive until the period of the secondary fever, he is very apt at that time to be carried off by some one of the many complications which are liable to come on in the third or fourth week of the illness. The severe forms of small-pox, especially the confluent variety, are most commonly attended by these acci-

dents; but they may also follow the milder forms of the disease.

Buls are very frequently seen; and the intense inflammation of the conis which occurs in the severer attacks may pass into partial mortification of the tissues. Spots of gangrene are thus formed in the skin, and the same thing may be observed in the genitals. If a scrofulous child who suffers from vaginitis be attacked by small-pox, there is great danger lest gangrene of the vulva supervene. Such cases, it need not be said, are very dangerous.

.therears and acute cellulitis may occur. Deep-scated collections of matter often form and may reach a considerable size. They are slow to

heal Sometimes the joints are the seat of suppuration,

Ecosopeles and pretent are common in small-pox hospitals—less common in private houses, although they may be met with anywhere when the disease is conduct or very severe. The latter of the two sometimes succeeds to the former and is very fatal.

Outs with supportation in the middle ear is a not uncommon complication. The results which may follow from this distressing affliction are

described elsewhere,

In all bad cases of small-pox there is conjunctivitis, which may come on as early as the fifth or sixth day of the cruption. If swelling prevents the fids from being opened, conjunctivitis may be suspected if the child complain of pain in the eyeball, increased by movement of the eye, and of a feeling of dirt beneath the lid. In very rare instances we meet with a development of small pustules on the nucous membrane of the eye, but slight ophthalma of this kind as a rule is easily overcome. The severe influentation which leads to ulceration of the cornea and destruction of the eyeball sets in about the beginning of the third week (on the fourteenth day, according to Mr Marson). An ulcer appears on the margin of the cornea, sometimes on both sides of the cornea at the same time. The various layers are quickly penetrated; the aqueous humour escapes; and often the lens and vitreous humour are discharged. The process is generally very rapid, and may be accompanied by no pain to the child. Sometimes instead of ulceration, general sloughing of the eyeball may occur.

To some form of chest affection many deaths in small-pox are owing. Incursy is common and very fatal. Pneumonia may begin insidiously, and is also a very serious complication. Bronchitis is sometimes a cause of death; and according to Billiet and Barthez, pulmonary addema is occasionally met with. Besides these, peri- and endo-carditis may supervene, and it is stated on the authority of Desnos and Huchard that acute fatty degeneration of the walls of the heart may be a cause of sudden death.

The laryngeal symptoms during the period of secon lary fever may be complicated by addena of the larynx. This, however, is soldom seen except in cases of confluent small-pox. In other instances a severe laryngitis may be set up, leading to ulceration of mucous membrane, perichendratis, and necrosis of cartilage with consequent chronic aphonia. Laryngitis may be one of the earliest complications, and is sometimes seen on the tenth or eleventh day.

In the case of any of these complications the fever is high and the child, who is burely entering upon convalescence after an exhausting disease, is in a state of great weakness, which is instantly aggravated by the presence of the intercurrent lesion. So that, if the patient do not succumb to this new danger, his illness is seriously protracted and convalescence propor-

tionately delayed.

rapidly fatal.

Varieties.—Many varieties of small-pox have been described; but for practical purposes it will be sufficient to remember the special forms of Discrete, Confluent, and Mahamant small-pox, and the modified form found

in efficiently vaccinated persons which is called varioloid.

In the discrete variety the spots are separated from one another by healthy skin of normal tint. The general symptoms are usually milder, and the fever less high, especially the secondary pyrexia, which is much less severe. Still, even in this form serious complications may arise, and when death occurs, it is usually owing unless the patient be a young m-

fant-to one of these secondary lesions.

The confluent form is attended by a very high mortality. From the records of the London Fever Hospital it appears that of those attacked by this variety lifty per cent. die. In children probably the proportion of deaths would be much greater. The danger consists not only in the severity of the eruption, but also in the intensity of the general symptoms. The initial fever is very violent, and is often accompanied by high delirium; there is little remission in the pyrexia when the development of the rash is completed; tremors and signs of profound nervous depression come on early, the swelling and inflammation of the mucous membranes produce great distress; and the secondary fever is very violent. If the child survive to the third week, which rarely happens, a serious complication usually occurs, and this in his exhausted state proves

These cases, on account of their severity and fatality in young subjects, might be justly described as malignant. The term is, however, usually confined to cases in which the pervous symptoms are overwhelming, and the child dies rapidly from blood-poisoning in a state of profound depression and come; or to cases where the disease assumes a hamorrhage character. In this hamorrhagic form bleeding occurs from all the mucous membranes - the nose, the mouth, the air-passages, and the bowels. The urine is smoky or red with blood; the eruption is dark, and mixed up with petechia or larger subcutaneous extravasations; and the fluid in the vesicles is tinged with blood. The general symptoms are severe, the prostration great, and death takes place after a few days. My friend, Dr. Twining, has described to me a variety of the malignant form of small pox which has often come under his notice at the Homerton Fever Hospital. In this the child appears overwhelmed by the violence of the disease. He lies in a state of stupor, and has no true variolous rash nor any of the ordinary symptoms of the illness. On inspection of the skin a number of deep purple, almost black, spots are seen. These are well defined, and are more or less circular in shape. They vary in size from a rape to a millet seed,

and are twenty or thirty in number. Mixed up with them are larger patches of subcutaneous extravasation, like bruises. These patients have a very offensive smell, as if putrefaction had begun before death, and survive but a few hours.

Firedeat, the modified form of the disease, is usually a mild complaint. The early symptoms are the same as in true small-pox, and may even be of some severity. A child may have high fever, much pain in the back, repeated vomiting, and be convulsed, but the after-course of the disease is usually beingn, and in particular the secondary fever is slight or commistely absent. Often, the rash is preceded by a rescolous eruption. The proper rash of varioloid, which comes out at the usual time, is in most cases comparatively thinly scattered over the surface, and the spots are very mirely set sufficiently closely to be confluent, even on the face. As in various, the mucous membranes are affected; and salivation, difficult deglutition, snuttling, hoarseness, and cough are common symptoms. The spots run through their stages more quickly than in the unmodified form, and the stage of desicertion usually begins on the fifth or sixth day of the eruption. The stage of maturation is also less severe; there is less swelling and redness of the skin; and pyrevia is slight or absent. Generally the pustales, instead of rupturing and discharging their contents, dry up, so that the pock gradually changes into a thin brown scab, which falls off in a few days. There is besides little or no ulceration of the skin, and consequently no pitting is left after the subsidence of the disease, except here and there where the inflammation had proceeded farther than usual. Lastly, in varied a l complications are rare, and the disease is usually at an end in a fortanglit.

Dispuss. Before the eruption appears the diagnosis of small-pox is difficult in children, for fever and vomiting usher in many of their acute dispuss, and pain in the back is not always complained of. In young children the existence of the spinal pain can seldom be ascertained; but if a child, in addition to vomiting and fever, loses control over his sphineters, we may suspect small pox, for such incontinence is not a common symptom, and points to some special condition not present at the onset of an ordinary acute illness. In small-pox it may be the consequence of the spinal arrivation.

When the cruption first appears on the face it is often mistaken for moreles. The colour is very similar; and the early papiles may be easily confounded with that form of measles rash in which the spots are more than usually elevated above the surface. On closer inspection, however, differences will be noticed. The measles spot is much less raised than the mistless papile, and is not hard and resisting to the finger. Moreover, in measles the cough, coryza, and lachrymation are significant symptoms, and are quite absent in the early period of variols. The temperature, too, is less elevated in measles during the stage of invasion than in small-pox. In measles it is usually between 102.5° and 104°, while in variols it is often between 105° and 106°. After a day or two the change of the papule into a vesicle removes any doubts that may have been entertained as to the nature of the illness.

The respolous rush which sometimes precedes the papular eruption may be mistaken for scarlatina. It is distinguished from it by noting its less complete diffusion over the surface, its brighter tint, and more mottled character. Moreover, according to M. See, in cases of small pox, when the respolous eruption is present, the variolous papule has already begun to appear, and may be discovered by careful examination.

The remission of the fever, which often takes place when the papular eruption is completed, cannot be relied upon for diagnosis, as it is very uncertain. In the boy whose case was referred to at the beginning of this chapter there was no remission of the fever at the early period of the cruptive stage. On the contrary, the temperature rose still higher, and when the patient was sent away to the small-pox hospital on the third day of the rash, the spots being then vesicular, his temperature (at 8 a.m.) was 103.4

Varicella may be readily mistaken for modified small-pox. The differ-

ences between the two diseases are described elsewhere.

Prognosis—The mortality from small-pox in childhood is very high up to the age of ten years. Infants usually succumb to the disease even in the discrete form. The previous health of the child is an important item in estimating his chances of recovery, for weakly children have small propert of passing safely through so formidable a trial. Lattle information can be gained from the severity of the initial stage, for violent convulsions may usher in a benign form of the disease. Remission of the fever and constitutional symptoms at the beginning of the cruptive stage, scantiness of the rush, normal development of the spots, and absence of subcutancess been orrhages, are favourable symptoms; but even in these cases a scrious complication may arise during the third stage and carry off the patient.

Of special symptoms, profusiness of sulvation is not an unfavourable sign, although it occasions much discomfort. Mr. Marson even regards it as of auspicious omen, especially if combined with much swelling of the face and marked tenderness of the skin. Bleeding from a nucous surface, if limited to one tract of that membrane, is not, according to Dr. Collie, to be viewed with apprehension; but if more than one tract is a source of harmorrhage, the prognosis is very unfavourable. Harmaturia is not necessarily dangerous; but harmorrhage into the skin, if anything more than a

few scattered petechize can be seen, is of very serious unport.

Destructive alcoration of the eyes may be expected in cases of the confluent form of the disease when the secondary fever is high and the skin is very hot and dry. If, in such a case, the eyes do not suffer, some otier serious complication is certain to occur, according to Mr. Marson. The same authority asserts that if an ulcer be found at the same time on each

side of the cornea, that eye will be entirely destroyed.

Treatment.—In varioloid and the inilder cases of discrete small-pox the child merely requires to be kept in bed in a large well-ventilated room, and to be fed with such articles of diet as are suitable to his age and degree of pyrexia. While the fever is high, he should take nothing but naik and broth; but when the pyrexia subsides, he may take to once cooked meat, light puddings, etc. His whole body should be sponged daily with tepr I water, and if there is much heat of skin, this process may be repeated several times in the twenty-four hours. He may be allowed to drink freely of pure cold water, and his bed and bo by linen should be changed every day. No medicine will be required unless constipation be present, when a moderate dose of castor-oil is indicated. As in scarlation, the room should be cleared of all carpets, rugs, curtains, and other woollen fabries not absolutely indispensable. Open windows, whatever be the season of the year, are maisted on by Dr. Collie.

The severer forms of the disease, and especially the confluent variety, require very careful treatment. The diet should be liberal, given in such form as the child can digest, and in quantity suitable to his power of assumation. Milk, strong beef-tea, essence of meat, yolks of eggs, light

puddings, and jelly can be given frequently and in small quantities at a time. Stimulants, such as brandy and the brandy-and-egg mixture, will also be needed whenever signs of failure of strength are observed. It is best, however, to withhold stimulants during the earlier period of the illness, unless they are imperatively required, for they will certainly be wanted at the end of the second or beginning of the third week, when complications generally appear.

If the patient be restless at night and wakeful, a little chlorodine may be given cautiously, but we must be careful in giving narcotics, partly on account of the casely depressed condition of the patient, partly because the air-passages become readily choked by the abundant nucous and sali-

vary secretion.

The treatment of the skin cruption is an important matter; for in small-pox, unlike the other cruptive fevers, the dermatitis which accompanies the maturation of the pustules may produce severe local injury as well as marked constitutional disturbance. Very many different methods have been recommended and adopted for checking the ulcerative process and preventing pitting of the skin; but none of these can be said to be successful. The application of salves of various kinds appear to be useful, but eather through the oil or fut they contain than through the chemical ingredient which was supposed to give their their value. Dr. Colhe pronounces against distressing the patient by efforts in this direction, which are certain to prove in effectual, and merely recommends the use of olive-oil the skin. A thirtieth part of carbolic acid increases the value of this application. German writers speak highly of cold compresses to the face and hads, and to any other part where the cruption is copious. They state that the application diminishes pain, heat, and redness, and contributes greatly to the comfort of the patient.

The sore throat is best treated by barley-water and other mucilaginous drinks. A draught containing perchloride of iron and glycerine, taken

three times a day, is often of service.

At the end of the swood week we must be on the watch for complications. Laryngitis is often the first to appear, and indeed this intercurrent desorder may begin as early as the tenth day. When this complication occurs, the room must be kept warm (a temperature of 70° is sutherent); the cot must be surrounded with an atmosphere of steam from some one of the many apparatus constructed for this purpose; and the throat should be enveloped in hot lineed-meal poultices. Stimulants must be given as wm desirable. If signs of suffication are noticed, trucheotomy should be performed at once. In cases of cedema of the glottis, where life is in the greatest langer, and immediate measures have to be taken to avert a fatal issue, much benefit may be derived from rapid vesicution. This is best done by means of boiling water. Dr. Owen Rees directs that the corner of a towel should be soaked in water as this boils on the fire, so as to acquire the full temperature, and that it should be then applied rapidly to the region of the throat Before doing so, the surrounding parts which it a not wished to blister must be covered with thick cloths.

Distribute, if it be troublesome, must be treated with a small dose of easier-oil followed up, if necessary, by a draught containing dilute suplaries seed and a drop or two of tineture of opinin. An enema of starch with five or ten drops of laudanum is also useful. If the diarrhosa resist this treatment and become exhausting, intrate of silver or gallic acid and

opials must be resorted to,

The various forms of chest affection must be treated upon general prin-

ciples. They are excessively dangerous. As the patient is usually by this time in a state of great exhaustion, stimulants must be given liberally, and strong beef-essence and other forms of food containing much nourishment in small bulk must be administered in small quantities at a time.

If an ulcer appear upon the cornea, it should be touched with a solution of nitrate of silver (gr. xx. to the ounce), and afterwards some obve-oil should be dropped into the eye. A blister to the temple is also of service. The conjunctivitis may be treated in mild cases by a solution of sulphate of zinc (gr. nj. to the ounce), dropped into the eye three or four times a day; or a solution of the nitrate of silver (gr. j. to the ounce) may be used. If the case is severe, with much muco-puralent discharge, Mr. Makuna recommends the stronger solution of the nitrate to be dropped into the eye once a day. The lids may be prevented from adhering by bathing frequently with warm water, and then placing a drop of castor-oil between them.

Abscesses must be opened early. Any sign of suppuration is a signal

for stimulants, and for quinine with or without perchloride of iron.

If hamorrhage occur, the patient must be kept perfectly quiet, and stim-

ulants must be given as required.

In all cases where the skin eruption is profuse, cleanliness is of the utmost importance. Dr. Collie especially directs the removal of all crusts about the nostrals and lips as they form, for they poison the air as it enters the body of the patient. He also insists upon the early removal of all scabs under which pus is forming, and recommends that the patient be bathed daily in a bath medicated with carbolic acid. He also points out the necessity of frequent changing of the body linen. If, as often happens, the child's head is slow in recovering, the scabs must be removed by poulticing, and zinc ointment must be applied, or the following:

B.	Liq. plumbi subacetatis	3 j	
	Ziuci oxydi	3 j	-
3.0	Vaseline	3 1	j,

Cod-liver oil and iron are also indicated.

In the malignant form of the disease no treatment is successful, and the patient invariably dies.

CHAPTER VIL

MUMPS.

Munus, or Parotiditis, is one of the milder infectious disorders of childhood. It is rare in infancy, and cannot be said to be common before the fourth or fifth year. Again, after puberty the liability to the disease dimunshes. It seldom occurs a second time in the same subject. Mumps is usually epidemic, and is especially common in the spring of the year. Its infectiousness is extreme, so that if the complaint break out in a school, or other institution where young people are congregated together, few are likely to escape. The virus is supposed to be conveyed in the breath. The duration of the illness is from a week to ten, twelve, or fourteen days. There is, besides, a period of incubation which has been variously estimated at from one to three weeks.

Method Anatomy — The disorder consists in an inflammation of the ducts of the parotal and other salivary glands, with infiltration of the cellular tissue of the glands. Exudation also invades the subcutaneous tissue for some distance around, so that very widespread swelling may be the consequence. The diseased action does not go on to suppuration, but ter-

inmates in resolution in the course of a few days.

Symptoms. After a period of incubation which, according to Dr. Dukes, varies from sixteen to twenty-five days, the earliest signs of the disorder are noticed. The first symptom is fever, which usually precedes by some hours any sign of local discomfort. The temperature is generally ligh, rang sometimes to 103', and, as is often the case with children, the pyrexia is apt to be accompanied by headache and vomiting. Swelling of the parotid gland may occur at the same time as the fever, or may even precedent. In any case attention is soon attracted to the face. Aching and tenderness are complained of, situated immediately below the ear, and behind the ascending ramus of the jawbone; and on inspection the normal depression between the face and the neck is found to have disappeared. The swelling strikes forward into the face, and backward and downward into the neck, so that when fully developed it covers the whole of the parotid region. If, as often happens, the inflammation extends to the submaxilary glands, and attacks both sides, the familiar face is curiously distigured, and is scarcely recognizable by the friends. It is enormously walened at the level of the nose and lip, and the chin may almost disappear in the swelling of the neck. The swelling is very tense and elastic, and is extremely sensitive to pressure. The skin over it is either pale or is suffused with a rosy-red blush. The full development of the swelling occupies from three to six days; then, after remaining unaltered for one or two days longer, it begins to subside, and by the tenth or twelfth day from the beginning of the disorder all fulness has disappeared. During the whole of this time the aching continues, and is greatly intensified by movement of the jaw; so that mastication becomes impossible, speech is

hampered, and even swallowing is difficult and painful. One consequence of this is that saliva tends to accumulate in the mouth, and is a cause of much discomfort. Fortunately, however, its secretion is seldom greater than natural.

While the disease is in progress the fever remains high. When the swelling has reached its full development, the temperature falls, suddenly or gradually, and during the process of resolution the heat of the body is natural. The disease seldom attacks the two sides of the face quite simultaneously. One side generally precedes the other by some hours or days. In rare cases the inflammation remains limited to the gland first attacks d

Although the parotid glands are primarily and principally affected in the large majority of cases, this is not the invariable rule. Sometimes the inflammation is localized in the submaxillary glands, and the parotids suffer little if at all. Dr. Penzoldt, of Erlangen, in an epidemic of undoubted mumps occurring in that town, noted some cases in which the swelling of the parotids was so slight as to be scarcely observable, while the submaxillary glands were considerably enlarged and very painful. In one

case there was in addition swelling and redness of the tomals.

One of the most curious features of this disorder consist in the metastases which occasionally occur. As the inflammation subsides, or even a day or two after the swelling has disappeared, a similar condition develops itself in a distant part—the testicle, in the case of a boy; the breast, if the patient be a girl. These complications are accompanied by fever and general poorliness, but subside in the course of a few days. In rure cases orchitis has been known to precede the affection of the parotid glund Thus, a young gentleman described to me how he had had an attack of orelatis, accompanied by severe pain but a normal temperature. At this time there was absolutely no symptom connected with the face. Sixteen hours afterwards, however, slight swelling and tenderness of the parotial gland began to be noticed, and the temperature was found to be 100.6° As the mumps subsided, the second testicle became inflamed. In this attack the temperature rose to 105°, and for some days was as high as 104°, with delirium and distressing vomiting. Sometimes the appearance of swelling in the organ secondarily attacked is preceded by severe constitutional symptoms. There may be high fever and delirium, or great prostration with coldness of the extremities; or violent vointing and purgang. In any case, great alarm is excited by the condition of the sufferer; but all apprehensions are removed by the appearance of the local lesion. These complications are less common in chaldren than in adults who suffer from mumps, but it is well to remember that it is possible they may occur.

There is another and occasional after-consequence of mumps which it is important to be acquainted with. This is deafness, coming on some time after the parotiditis has subsided. The hearing may be affected in one of two ways. An extension of the inflammation may take place to the Eustachian tube and middle ear. These cases are very amenable to treatment and usually recover. There is, however, another class of cases of a much more serious character, to which attention has been directed by Mr Dulby. In these the deafness comes on quite suddenly. The child goes to bed with his hearing perfect; in the morning he is found to be deaf. Little can be done for this form of deafness. It is probably dependent upon some altered condition of the auditory nerve, for no appreciable lesion can be detected in the auditory apparatus. Whether the loss of hearing

be complete or merely partial, little hope of material improvement can be entertained.

In some rare cases an attack of munips has been known to be accompanied by facial paralysis from extension of the inflammation to the Portio Dura.

Primares. Mumps can only be confounded with inflammation of the partial gland of a non-specific character, such as may occur in the course of some fevers. Symptomatic parotiditis, as it has been called, or parotid bubb. In this case both sides of the face may be attacked, but the fact of the lesion being a secondary, and not a primary disease, and of the rapid supparation which takes place when the inflammation is symptomatic, should clear up any uncertainty which might be felt as to the nature of the case.

Mumps is probably infectious from the very beginning of the disorder, and remains so for some time after the swelling has subsided. Dr. Squire is of opinion that for at least two weeks after the disease has cleared away, the child should not be allowed to return to his healthy companions.

Trentment.—As the disease cannot be arrested, but must run its course, little active treatment is required. It is best to put the child to bed, and to keep him there as long as the temperature is elevated. Hot poultices should be applied to the parotid region and be frequently changed. If the pain be not relieved by this means, an ointment composed of equal parts of extract of belladonna and giveerine may be smeared gently upon the . skin over the inflamed glands, and the poultice be applied as before. The jaws must be kept at rest, and no solid food can be allowed. Instead, the child should have strong beef-ten or gravy soup, ment jelly, milk, volks of eges, etc.; but if there be high fever, with foul tongue and derangement of the digestive organs, as is most usually the case, the stomach must not be overloaded even with liquid food, and care should be taken to supply pourishment in small quantities at a time. If the fever be high and cause restlessness, the surface of the body can be sponged with tepid water. The lowels must be attended to and constipation relieved by some gentle aperient, such as compound liquorice powder or the liquid extract of rhamnus frangula.

In cases of metastasis to the mamma or testicle, perfect rest must be enforced; and the local treatment recommended for the face should be had recourse to. The alarming symptoms which sometimes precede the appearance of the secondary lesion usually pass away in the course of a few hours. If there be great prostration, stimulants must be given, and

warmth be applied to the extremities.

CHAPTER VIII.

CEREBRO-SPINAL FEVER.

(Epidemio cerebro-spinal meningitis.)

CEREMO-SPINAL fever is a specific inflammation of the membranes covering the brain and cord. The malady is no mere local disorder, but a blood disease, of which the inflammatory affection of the meninges is the anatomical expression. It usually prevails in epidemica, and outbreaks of the disease have been noted in various countries widely differing in

climatic and other conditions.

Causation. The epidemics of cerebro-spinal fever generally occur during the winter months; but isolated cases are often noticed for some time before the disease becomes more generally diffused. Thus, before the opdemic which prevailed in Ireland in 1867, sporadic cases had been observed in the country for some years. The disease appears to be mildly infectious It fastens upon old and young, rich and poor, but males appear to be more liable to suffer from it than females. In 1846 some cases occurred in the Dublin and Bray Workhouses, and shortly afterwards in the Belfast Workhouse. In these cases the sole victims were boys under the age of twelve The girls and adults escaped. In all epidemics children are largely affected for unlike typhus, of which cerebro-spinal fever was at one time supposed to be merely a variety, the disease readily attacks young subjects, and is most fatal in early life. Although not generated, like typhus, by insuntary conditions, the onset of the fever seems to be favoured by them; and foul air, had food (especially ergotized grain, according to Dr. Richardson). exposure to cold and damp, and physical fatigue, no doubt tend to encourage the spread of this fatal malady.

Morbid Anatomy.—The vessels of the pia mater, both of the brain and cord, are congested, and lymph is exuded into the subarachnoid tissue. Sometimes it is also seen in the ventricles. It usually consists of opaque purulent matter of a greenish-vellow color. The amount varies. It may occur only in patches, or may be more general. The lymph is especially abundant at, or is confined to, the base of the brain—usually the posterior portion, the surface of the medulla oblongata, and the upper part of the spinal cord. There is often congestion of the substance of the brain, and there may be serous effusion or actual extravasation of blood. The choroid plexus is much congested, and the cervical part of the cord may be covered with a thick layer of bright-red vessels. In the worst cases of the

disease the blood is very dark in colour and unusually liquid.

The exudation appears to be thrown out with great rapidity, for it may be found in cases where death occurred within a few hours of the child being attacked. Ebert and others have found micrococci in the purulent effusion of the meninges, and according to some observers the disease is essentially due to micro-organisms.

Of the other organs: the spleen is generally unaltered, although cometimes it, as well as the other viscera, may be congested. There may be sains of pleurisy, and scattered patches of hepatization may be seen in the longs. It is each that the aguinated and solitary glands of the intestine have been found in some cases to be swollen.

Symptoms. The disease generally begins suddenly during sleep, having been preceded by few or no premonitory symptoms. In certain cases—usually the milder ones—the could may complain, if old enough to do so, of wandering pains, and may seem poorly for a day or two before the outbreak; but there is seldom anything to fix the attention before the first violent symptoms of the disease make their appearance. In rare cases there may be headache, vomiting, and general tenderness for some days

previous to the actual beginning of the illness.

As a rule, the first noticeable feature is a rigour or a fit of convulsions; and the younger the child, the more likely is the attack to begin with a convulsive seizure. Sometimes severe headache and vomiting may usher in the disease. If the patient, as is often the case, seems heavy and stuped after the fit, he still shows by his restlessness, his moans and cries, and by frequently carrying the hand to the head, that he is suffering severe pain. The pupils are contracted; the pulse is quick, seldom lowered in frequency; the temperature (which should always be taken in the recturn is 101 2; and the breathing is hurried. An early symptom is retraction of the head upon the shoulders. It has been suggested that this position is at first partly voluntary, to relieve the pain (which we know, from the case of the winit, to be of a very severe character) shooting down the back, but it soon becomes involuntary from spasmodic contraction of the muscles of the nucha. It may occur within a few hours of the onset of the illness, and is rarely delayed beyond twenty-four hours. The tetanic spessor of the numeles of the neck may extend to the whole back, the jaws, or even the limbs, and may be varied by clonic convulsive movements. In a short time the cries and manifestations of pain cease as the senses become duller and the stupor increases. If consciousness is lost early and

does not return, the symptom is a very grave one.

About the second or beginning of the third day a herpetic eruption appears upon the face, and purpuric spots may come out upon the body and limba. This eruption, which is not invariably present, has given to

the disease one of its names-"spotted fever.

When the disease is at its height, the child lies on his side in the cot with his head retracted, his limbs flexed, and his spino often rigidly curved. He is completely unconscious, but still remains uneasy and restless, often moving one or both lower limbs monotonously. The pupils are now generally dilated, usually sluggish, and perhaps unequal. The belly is flattened; the bowels are constipated; the pulse and respirations are quickened. At intervals spasins are noticed; the head is drawn more lackward, and the curve of the spine is increased. When the stuper is complete the bladder is evacuated involuntarily, or there is retention of arme.

In fatal cases the come continues, the breathing is accompanied by ratting within the chest, and the child sinks and dies. If the case is to the favourably, the stupor grows less profound and the restlessness diminishes. The rigidity is late in relaxing, and usually the mind becomes clear while the head is still retracted upon the shoulders.

The special symptoms above referred to vary considerably in severity

in particular cases :-

The fever is very variable and has no regular course. The internal heat, as tested by a thermometer introduced into the rectum, is generally higher than the surface of the body; but even in the rectum the mercury may only mark a degree over the normal temperature. At other times it rises to 104° or 105°. If early collapse come on, the temperature may sink to below the normal level.

The skin eruption is a valuable sign. In some epidemics it is a rare symptom; in others almost all the cases exhibit a number of purpure spots. In every recorded serious outbreak both the unculated and the non-maculated forms of the disease have been observed, although one may have been more common than the other. The rash consists of dark purple spots or blotches due to effusion of dissolved hamatin into the true skin and areola tissue beneath it. They generally occupy the legs, han ls, face, back, and neck. They are sometimes slightly elevated, and vary in size from a pin's head to a walnut. According to Dr. J. A. Marston's observations in the epidemic which occurred in Ireland in the year 1867, there is no necessary relation between the occurrence, the number, and the extent of the spots upon the skin and the amount of the intra-cranial and intra-spinal mischief. Dr. Mapother, referring to the same epidemic, states that the spots cannot be produced artificially by pressure on the skin as in true purpura. Besides the petechie, there may be herpes, urticaria, and patches of crythema or roscola. The skin may have a dusky tint and is often moist. Cerebral flush is not a marked symptom

The mental condition also varies in different cases. When the disease is violent and death occurs early, the child may be unconscious from the first. In other cases stupor comes on by the second or third day. In the mil-lest cases the mind may be little affected, or there may be shight delirum with curious hallucinations. Thus, Dr. Lewis Smith refers to a case in which the child answered questions with perfect clearness, but constantly mistook his mother for another person. Usually, in all cases before death the coma is profound.

The pains referred to the head and spine are always a distressing and prominent symptom. They are often so severe that the child, until he becomes commtose, is constantly morning and screaming. The pain is increased by movements of the back, and especially by attempts to press the head forward. The general tenderness of the skin adds greatly to the child's discomfort; and sometimes a touch on the body, as in moving him to alter his position, causes the greatest distress.

In some cases paralysis is noticed. It is, however, a comparatively rare symptom, and is usually partial, being limited to one or more limbs. It may affect the cerebral nerves, especially the third, the sixth, and the facial. The lesion of the nerve-trunks is due to purulent infiltration of the neurilemma, or to contraction of the hyperplastic connective tissue of the nerve-sheath. In cases of recovery the paralysis may last through life, but sometimes it passes off as the patient improves.

Convulsions, general or partial, are comparatively common in the case of children, certainly much more common in them than in the adult. They are especially frequent in the more severe forms of the disease. The clonic spasms sometimes alternate with tonic contractions; and may be general or limited to one-half of the body. Nystagmus may be noticed.

Vomiting is soldom absent at the beginning of an attack. It is often severe, and like all forms of nervous vomiting is independent of taking food. The thirst is great. Constipution is the rule; although in some opidemics the disease has been noticed to be ushered in by purging as well as

remuting. The tengue may be clean or furred; towards the end of the library it becomes dry. Abdominal pain, if present, is like the hyperestical of nervous origin. The belly is seldom retracted, and never to the largest of served in cases of tubercular moningitis. Occasionally it is full

or even typipanitic. The spleen is sometimes enlarged.

The pupils are at first contracted, but dilate as the stupor deepens. They are often sluggish, and may be unequal in size. A squint is sometimes noticed. Bilindness may occur from kerntitis owing to imperfect closure of the cyclods, or from neuro-retinitis due to the spread of the paralent influencation along the optic nerve; and in some rare cases the cyclod has been known to be completely destroyed by suppuration. The hearing may be also affected. A temporary deafness with noises in the heat may occur during the first days of the disease and be afterwards recovered from. If it occur later, it is probably due in most cases to purulent influencation within the labyrinth. This form of deafness is usually bilateral, complete, and permanent; and if the patient be a young child, may lead to deaf-mutests.

The pulse is soldom otherwise than quickened; but it rarely attains at first a high degree of frequency, and is subject to rapid alternations. It is not often intermittent, but is usually very feeble. The breathing is also quickened, and is often irregular and interrupted with sighs. The normal relation between the pulse and the respiration is preserved.

The urine is often natural in quantity, color, and reaction. It has been

known to contain albumen and even blood.

There are many differences in the various cases of cerebro-spinal fever met with in the course of the same epidemic. In some the symptoms from the first are in-heative of profound blood-poisoning. Consciousness is affected from the beginning; there is extreme prostration, a feeble fluttering pulse, and labored breathing. Then spots appear early and are extensively distributed. The stupor deepens into coma, and death takes place with startling rapidity. In these cases the more special symptoms arising from the local inflammation are overshadowed by those dependent upon, the general condition, and the patient dies from blood-poisoning. In atother class of cases the symptoms of cerebro-spinal inflammation predominate, and the more marked phenomena are the convulsions, the drawmy backward of the head, the hyperosthesia, and the tetanic contraction of manly in this form if the disease and unfavourably, death is owing mainly to the local lesion. As a rule, the affection is most severe when the epidemic is still young. As the cases get more numerous they become milder; and at the end of the epidemic it is common for recoveries to take place.

In some instances curious intermissions occur in the disease. These may be found quite at the onset, evident premonitory symptoms appearing, passing off, and returning, perhaps several times, before the actual outbreak occurs. In other cases during the course of the disease more or less complete remassion of the symptoms lasting for several hours or a day may take place. According to Dr. Frey, this is very common at the end of the second or third day. Again, during convalescence the same variations may be seen, the bendache and retraction of head being at times distress-

ing, at other times scarcely noticeable.

According to Dr. Oscar Medin, of Stockholm, infants under twelve menths old are especially liable to the disease. At this early age the illness generally ends fatally; but sometimes mild cases are observed lasting from a last to a week. This physician, who at the Orphan Asylum of Stockholm had many opportunities of observing the malady, states that the

mild cases began with fever, somnolence, and twitchings during sleep. In most instances there were other symptoms, especially during sleep, such as restlessness, great heat of head, changes in the colour of the face and in the sensibility of the body. In a few of the milder cases slight convulsive spasms were noticed, with rigidity of the limbs and neck, strabismus, and dilatation of the pupils; but in such cases these symptoms soon disappeared. In all the epidemics which came under Dr. Medin's observation such mild cases were the exception, and a large proportion of the infants died. In the severer forms the symptoms did not differ from those observed in older children.

Dr. Mcdin, like other observers who have had opportunities of studying this form of illness, speaks of a pneumonia of a low type, occurring without nervous symptoms, as being frequently present in epidemics of cerebro-spinal fever; and holds with them that in such cases, the infective material attacks the lungs in place of the cerebral membranes. Still, meningitis may be present in such cases, although it gives ruse to no symptoms; for in some instances where during life the symptoms were exclusively pulmonary, inflammation of the cerebral and spinal meninges was discovered on post-mortem examination of the body. Besides pneumona, peri- and endo-carditis, pleurisy, parotitis, and purulent effusion into the joints may be complications of the disease.

The duration of the attacks is very variable. Death may take place in five or six hours in the most malignant forms of the distemper. In other cases the illness may be prolonged for one, two, three, or four weeks, or even longer. Convalence its always slow, and is often intermittent. A profound debility, lasting for a long time after the fever is at an end, is one

of the characteristics of the malady.

Diagnosis.—Every case of rigid retraction of the head in a child is not one of cerebro-spinal fever. The symptom is the consequence of a basic meningitis spreading to the cervical portion of the spinal cord; and it may therefore be present in any case where the membranes of the brain are the seat of inflammation. It is not uncommon in the course of a tubercular

meningitis.

Cerebro-spinal fever not only gives rise to severe local symptoms, but is also accompanied by more general phenomena indicating a profound constitutional affection. Its epidemic form, its violent and abrupt onset, the extreme debility which is invariably present, and the petechal rash, remove the disease from the list of purely local disorders, and amply justify its being ranked amongst the specific fevers. The disease was at one time held to be merely a form of typhus fever complicated with meningitis; but the difference between the two diseases are neither insignificant nor few. Cerebro-spinal fever prevails equally amongst the rich and the poor; it particularly affects children, and is very fatal to them; it runs a rapid course, often causing death in a few hours; its temperature as a rule is little elevated; the rapidity of the pulse is moderate, and when the fever is high, is not increased in proportion to the degree of pyrexia (indeed, according to some observers, it does not become rapid until the temperature falls); lastly, retraction of the head is one of the most common symptoms.

Typhus loves "fever haunts," and seldom attacks the well-to-do; it rarely affects children, and if it do, runs in them as a rule an especially favourable course; its duration is longer, and even in the adult it rarely appears in the overwhelming and malignant form so often seen in cases of cerebro-spinal fever; lastly, meningitis with retraction of the head is a rare

complication.

The diagnosis of cerebro-spinal fever is much easier in the midst of an epidemic of the disease. The abrupt and violent onset, the severe pain in the head and spine, the vomiting, the retraction of the head, the general stupor and the peterhal and other eruptions—this combination of profound constitutional symptoms with nervous excitement followed by depression, is sufficiently characteristic, especially if at the same time, as often happens, the temperature is only moderately raised and varies irregularly. In cases of sample cerebro-spinal meningitis the retraction of the head is not so extreme, and the stiffness and pain in the spino, the hyperesthesia, and the pains in the joints are seldom present. As a rule, too, the non-specific disease is preceded by prodromata and runs a less rapid course Still, this is not always the case, for in exceptional instances simple meningitis may prove fatal to a young child in the course of twenty-four hours. The fever in the latter is, however, always high, and the convulsions are in most cases repeated and general.

It would be difficult to confound tubercular moningitis accompanied by retraction of the head with cerebro-spinal fever. The hereditary tubercular tendency, the long prodromal period, the gradual onset of the illness, the more protracted and characteristic course, and the slow intermittent

pulse, would serve to distinguish the tubercular disease.

In infants under twelve months old the disease is very difficult to detect. It may, however, be distinguished by close attention to the course and symptoms of the illness; especially if the case occur in the midst of an outbreak of the malady.

Progress —In all cases of cerebro-spinal fever the prognosis is very serious. The disease is especially fatal to children, and the younger the patient the less hope can we entertain of a favourable termination to his

Liness

In babies an arched and tense fontanelle, which shows the presence of profuse exudation and adema, is a very grave symptom. In all cases repeated convulsions and signs of severe nervous excitation, such as violent and messant vomiting, intense cephabilgia and pain in the back, strong tetrnic spasms; also early appearance of depression, continuous coma or return of the stupor after a period of apparent improvement, and irregular breathing, are all signs calculated to excite the gravest apprehensions.

Treatment.—The disease unfortunately is little amenable to treatment, in all cases ice-bags should be applied to the head and spine as long as the period of excitement continues. When symptoms of depression are noticed, the ice should be removed, or supplemented by the application of hot bottles to the feet, and the administration of stimulants by the mouth. Sometimes hot applications relieve the severe headache better than cold. The ether spray has been used to the occiput and back of the neck, and is said to be of service. Large doses of chloral sufficient to produce signs of parcotism have been recommended. All writers, however, speak highly of the subcutaneous injection of morphia. For a child of three years of age one-twentieth of a grain may be used, and repeated every one or two hours until some sensible effect is produced; or four or five grains of chloral may be given by the mouth.

During protracted convalescence the iodide of potassium must be given to further absorption of the exudations; and iron and tonics, with removal

to a dry bracing air, are of value to hasten the child's recovery.

CHAPTER IX.

ENTERIC FEVER.

Extense or typhoid fever is common in children. A large proportion of the cases formerly described as "Infantile Remittent Fever" were no doubt cases of this disease. Fortunately in young subjects typhoid fever usually runs a mild course. It would be, no doubt, too much to say that properly freated and nursed, no child should die of typhoid; but certainly when placed from the beginning under favourable conditions for recovery.

death in the child from such a cause is very rare.

Infants and children during the first four or five years of life seem less susceptible to the typhoid poison than at a later age. Perhaps, however, it is difficult to recognize the disease in such young subjects; and it is not impossible that many cases of febrile diarrhou in the young child may be cases of typhoid fever which have escaped recognition. Boys are more commonly affected than girls; and the fever seems to attack by preference previously healthy children. At any rate the patients who are brought suffering from the disease to the Children's Hospitals are generally well-nourished, strong-looking little persons, with exceptionally good instories.

Causation.—It is now well known that enteric fever arises as the consequence of absorption into the system of a specific poison which is generated by the decomposing discharges of typhoid patients. It is therefore largely distributed by the emunations from cesspools and faulty drains. Warm weather, which encourages putrefaction, increases the prevalence of the fever. Dr. Murchison has shown, from the records of the London Fever Hospital, that cases of enteric fever become more numerous after the warmth of summer, and dimmish in number after the cold of the winter months. Thus, in August, September, October, and November, the fever prevails largely; while in February, March, April, and May, it is much less frequently seen. Whether the poison can be generated de novo is a question which has been often debated and on which opposite opinions are held. It seems certain that the decomposition of ordinary feeal matter under ordinary conditions of atmosphere cannot produce it; but it is probable that the specific poison may be generated from non-specific ordere under extraordinary conditions. At least, it is difficult under any other hypothesis to explain outbreaks of the fever in country villages where the strictest search fails to discover any means by which the discover can have been imported from without, and in which the same insanitary state has existed unchanged for years. There is no doubt that the discharges from the patient are highly contagious. The disease cannot, however, be communicated by the breath or by emanations from the skin. It is held by some that the discharges themselves are at first comparatively innocuous, and only become hurtful after putrefaction has begun.

The poison enters the system by the mucous membrane of the lungs or of the alimentary canal. In most cases, no doubt, contaminated water is the means by which it is conveyed. Several epidemics of typhoid fever in London, of late years, have been traced to milk to which water containing typhoid matter had been added. It is also probable that untrapped or faulty drains, allowing the effluvia of cesspools charged with the specific poison to penetrate into a house, may be another means of imparting the disease.

One attack of typhoid fever does not necessarily protect against anoth-

er; and relapses are very common.

Marbad Austony, -The characteristic lesion in typhoid fever consists in a swelling of the solitary glands of the small intestine, of the againsted glands constituting Pever's patches, and of the mesenteric glands in connection with them. The swelling is a pure proliferation of the cellular clements, which are seen by the microscope to be much increased in minber. Some corpuscies become enlarged and develop smaller cells within their walls. The hypertrophic change in the glands begins early, probably at the beginning of the disease, and proceeds rapidly. It involves a certain number of Peyer's patches. These are fully developed by the ainth or tenth day, and form thick oval plates with abrupt edges and an uneven, manufacted surface. Their consistence is softer than natural, and more friable. The solitary glands may be unaffected; but they also often swell and form small projections from the surface of the mucous membrane. After reaching their full size the glands, in mild cases, begin slowly to shrink. The newly proliferated cells undergo a fatty degeneration and are absorbed. The mesenteric glands also diminish in size by the same process of fatty degeneration, and gradually resume their former dimensions.

In more severe cases the diseased glands, instead of undergoing healthy resolution, take on a further morbid action. Small points of ulceration appear on the surface of the patch. These enlarge and unite so as to form an ulcer which may cover the whole of the diseased surface. Sometimes, instead of ulcerating at separate points, the nucous membrane covering the affected patch sloughs over a larger or smaller area and separates from the tissue beneath. If the whole of the patch have been thus uncovered, the resulting ulcer is oval, and has its longer axis in the direction of the canal. Smaller ulcers may be circular or samous. The solitary glands may also go through the same process, and leave small, round ulcers scattered over the surface of the nucous membrane. The edges of the ulcers are thick and sharply cut, or even undermined; and the floor is formed by the submucous tasue, the nuscular coat, or, in bad cases, merely by the peritoneal covering of the bowel.

After a time, a process of repair is set up and the ulcors begin to heal.

This favourable change seldom occurs before the end of the third week, and
the process of ccatrization occupies a variable time. Under favourable conditions it may be completed in two or three weeks, but it is often spread
over a longer period. The healing of the ulcor is not followed by any con-

traction of the bowel.

The morbid process above described attacks especially the glands in the neighbourhood of the dec-cacal valve, and extends upwards for a variable distance. In some cases the solitary glands in the cacum and part of the ascending colon may be also affected. The deeper ulcers are usually in the lower part of the ilium near the valve; and when perforation occurs, it is by rupture of one of these, whose floor is formed only by the peritonnal cost of the intestine. That this accident does not occur oftener is due to a local peritonitis having been set up, gluing the affected part of the bowel to a neighbouring organ. Children who die from this disease die almost invariably from perforation of the bowel; but an unfavorable ending to enteric fever is comparatively a rare accident in young subjects, in whom the unhealthy action in the glands often stops short of ulceration.

Besides the special changes in the glands, the whole mucous membrane of the bowel is swellen and relaxed. The enlarged mesenteric glands seldom suppurate in the child. They usually rapidly undergo resolution as soon as the process of repair has begun in the intestine. The spleen is enlarged and congested. It is dark red in color and is softer than natural. The kidneys are sometimes congested. In all cases of typhoid fever the laugs are the seat of catarrh, so that the mucous membrane of the air-tubes is red and congested, and the bronchial glands are

enlarged and vascular.

Symptoms. After exposure to the contagious poison there is a period of incubation varying from ten days to a fortnight, at the end of which the symptoms of the fever begin to manifest themselves. These are at first very slightly marked; so much so, that it is sometimes difficult to fix the exact time at which the illness began. In most cases, however, careful questioning of the parents will enable us to determine the first day of the disease. One of the earliest symptoms is frontal headache. It is common to be told that a child returned from school saying he had a headache, that he looked pale, was languid and could cat no dinner. There is fever at this time, but the child, not being supposed to be really ill, is not treated as an invalid. In other cases headache is not complained of at first. The child is merely pale and listless, with some fever, and cannot be persuaded to eat. For the first few days little else can be discovered. The tongue is coated with a thin, white fur, through which red papille project. There is often slight redness of the throat. The bowels are either confined, or one or two loose, rather offensive, stools are passed in the twenty-four hours. The child is drowsy, but sleeps restlessly, although without debrium. He generally complains of his head, and often of achieg pairs about the body and limbs. Sometimes there is vomiting after food, and there may be trifling epistaxis. Cough is a more or less constant symptom, but varies greatly in amount. Usually it is insignificant at the first. During this time, unless medical assistance be summoned, the patient is seklom confined to his bed, but is dressed in the morning as usual. Indeed, in mild cases, children will often walk considerable distances to the out-patients' room of a hospital, for the muscular weakness is much less marked than night be anticipated.

So far, then, the symptoms are vague; and if it were not for the decided character of the pyrexia, there would be nothing to help us to come to any conclusion as to the nature of the illness. It is only at the end of the first week that more characteristic symptoms are observed. About the sixth or seventh day the spleen begins to enlarge. The organ can be felt to project inward towards the middle line from under the cover of the ribs. Its texture is soft, so soft, indeed, in many cases, that the enlargement can be only detected by a practised finger; and it appears to be tender, for pressure over its substance usually produces some manifestation of discomfort. Tenderness can generally be noticed at this time over the whole belly, and is not confined to the region of the spleen. The belly is now a little swellen; borhorygun are frequent; and gurgling may be often felt on pressure in the right iliac fossa. This, however, is a symptom as often absent as present. The bowels are relaxed in the ma-

prity of cases, although, as a rule, only moderately so, and the stools exhibit the vellow other "pea-soup" appearance which has been so often remarked upon. Still, constipation is a more common phenomenon in the child than it is in the adult, occurring in at least one-third of the

The hendache now usually subsides, and the patient begins to have shrift delirum at night. He asks constantly for drink, but seldom shows any disposition to take food. His expression at this time is dull and heavy, and he hes quietly on his back, often with a dull flush on his cheeks, taking little notice of what passes around him. By the end of the arst week the fever has reached its maximum. The skin, however, although generally dry is not always so, and there is occasionally a ten-The breatling is quickened, and the frequency dency to perspiration. of the pulse is increased. There is no constant relation between the pulse and the heat of the body. The pulse may be only moderately quick with a high temperature, and its rapidity undergoes frequent variations. (Thus, Edith H-, aged thirteen, on the eighth day at 9 P.M.: pulse, 86; respiration, 36; temperature, 103.6. At 9 a.m. on the following morning: pulse, 100; respiration, 36; temperature, 100.8".) By the end of the first week the cough becomes more troublesome, and may assume such prommence that a lung affection is suspected; but only dry rhonchus, with perhaps an occasional coarse bubble, is heard about the chest.

After the eighth day the typhoid cruption should appear. In children this symptom is sometimes absent; but careful inspection of the chest, abdomen, and back will generally discover a few—it may be only one or two of the characteristic spots. Sometimes they can be detected upon the limbs. The rash appears in the form of small, slightly elevated, lenticular spots of a deheate rose tint, varying in size from half a line to a line and a half, and disappearing completely under pressure of the finger. Their number vames, but they may be very numerous. These spots come out in successive crops, each one lasting two or three days. If scanty, they have to be searched for with great care, especially when the back is examined, for here, on account of the general congestion of the surface, they may not

be readily seen.

In this the second week of the illness as each day passes the child seems to become duller and more indifferent. He is drowsy and sleeps much during the day, but at high may be more restless, and sometimes he tries to leave his bed. His weakness has now become more marked. The pulse is quick and feeble, and towards the end of the week muscular tremors and twitchings may be noticed. The belly is much swellen and assumes the characteristic barrel shape. The looseness of the bowel continues, or is replaced by constipation, and sometimes—although this is rare in the child—the motions contain blood. At this time the heart-sounds become his ble and soft to the ear, and there is often a prolongation of the first sound at the apex, or even a soft systolic murmur. On the other hand, in odd standing cases of cardine disease a murmur previously heard may be list as the heart's action becomes enfeebled, only to reappear when the attempth is restored.

In the third week of the illness the fever usually begins to diminish. In the mild cases the temperature becomes natural as early as the fourteenth day. If it persist, its mean is lower than before, and the morning temperature may be almost normal. The feebleness of the patient is now submently pronounced, but as the days pass by his symptoms become more favourable. He grows less heavy and lethargic; the swelling of his

belly diminishes; the spleen retires under the ribs; diarrhoes, if it had previously existed, ceases, and the motions become more natural; and as the tongue cleans, the child begans to show some disastisfaction at being still restricted to liquid food. As the fever subsides, the pulse often becomes intermittent, and is very soft and compressible. When the fever is at an end the child is left very weak in the mildest cases, and he only slowly regains his strength. In bad cases the prostration is very great, and the child has to be nursed through a protracted period of convalescence. Sometimes ardema, more or less general, is seen as a consequence of the impoverished state of the blood.

The above is a sketch of the ordinary course of enteric fever in the child. There are, however, many variations in the symptoms, and it is desirable therefore to refer again to some of the principal phenomena.

The Ingestere Organs.—The tongue in mild cases remains moist throughout the whole course of the illness. It has a delicate coating of grayish fur, through which the papillie are seen to project. The tip and edges are only moderately red. Thirst is often a marked symptom, and liquid food is taken readily to satisfy this craving for fluid. Appetite is generally lost, but not in every case. A little boy in the East London Children's Hospital complained to me on the sixth day of the disease that he was hungry, although his temperature was then 105°, and his tongue was thickly furred, with sordes on the lips. His mind was quite clear. If the symptoms are severe the tongue generally becomes dry in the course of the second week. It may be fissured across the dorsum, and the lips may be cracked and blackened. Sore throat is a very common symptom during the first few days, and there is some little redness of the fauces. Vomiting is frequent at the beginning; occasionally it recurs later and may then give trouble.

The swelling of the abdomen is due to accumulation of flatus through decomposition of food and inability of the bowels to expel their gaseous contents. This loss of contractility is the consequence of lack of nervepower or of local injury from ulceration. Consequently, if in the third week of illness there is deep ulceration of the intestine and great bodily prostration, the distention of the belly may be extreme. The amount of abdominal tenderness varies. In the mildest cases it may be absent. When present it may be local, hmited to the splenic region and the right iliac fossa, or may be general over the abdomen. It is sometimes a well-marked symptom, the slightest touch being productive of great pain, and this in cases where there is no reason to suspect the presence of peritonitis. The bowels may be confined throughout, or loose throughout, or constipation may alternate with a mild diarrhum. It must be remembered that looseness of the bowels is due not to the ulceration but to coexisting catarrh. If catarrh be insignificant or absent, the bowels are not relaxed. As a rule, in children the looseness is not extreme and is easily controlled. The relaxed motious always assume at one time or another the "pea-soup" character; they have an alkaline reaction and a faint offensive smell. Hemorrhage from the bowels to any amount is rare, but small black clots of blood may be sometimes found in the grumous matter at the bottom of the stools,

The arms is at first scanty, with a high density. It contains an excess of area and arise acid, but is poor in chlorides. Later it becomes more copious, the specific gravity falls, and it may contain a trace of albumen. During the height of the fever there may be retention of urine, with distention of the bladder and tenderness over the pubes. Sometimes the catheter has to be employed. There is no gravity about this symptom, and it need cause no anxiety if care be taken to empty the bladder by

degrees. The distention is due to loss of contractile power of the muscular cost. If, then, a greatly distended bladder be suddenly and completely emptied of its contents, the organ contracts imperfectly, and a certain amount of air enters and causes great irritation. An obstinate cystins may be produced in this way.

The pulse is quick as a rule, but sometimes for a time sinks in rapidity although the fever continues high. The frequency of the pulse is not, as less already been stated, any trustworthy guide to the degree of fever; nor, as taken at a single examination, is it necessarily any test of the severity

of the illness.

The respirations are hurried, and there may be slight disturbance of the normal pulse-respiration ratio without any pulmonary complication being present. (Thus John H—, aged four years, sixth day, 4 E.N.; temperature, 103; pulse, 120; respiration, 46). If a pulmonary complication actually arise, the breathing increases in rapidity and there is lividity of the face.

The stre may be moist at times during the course of the disease, and towards the end of the third week, especially if the fever has subsided, there may be copious sweating. Sudamina then appear on the chest. The abundance of the rash varies greatly in different cases. It may be served to rempetely absent; but these extremes bear no relation to severity or indicess of attack. It is well to be aware that fresh crops of toxe-spots may continue to appear for a week after the temperature has fallen to the normal level. I have noticed this on several occasions. The faces is important. The child seldom looks very ill in the early stage; and even later, unless the abelianial mischief be severe, it is exceptional for his face to wear the anxious haggard look which is so common in many ther stroug discusses, and forms such a striking feature in acute tuberculars. In ordinary cases the expression is more stupid and listless than anxious.

The special scases may be affected. Deafness is common. Epistaxia is a frequent symptom, and may be repeated again and again. The conputative look red, and the pupils are large. The headache in children is ablum very severe. It ceases about the end of the first week, when the debrum begins. Semetimes corvical neuralgia is noticed after the second seek, and every movement of the neck may be accompanied by pain. Debrum is the rule, beginning towards the end of the first week. Sometimes from this cause older children try to get out of bed and are noisy. Convilsions may precede death in fatal cases; but typhoid fever, unlike many other febrile complaints in childhood, is very rarely ushered in by a convilsive attack. Still, a form of disease is usually described in which the early symptoms are those of high nervous excitement. The child is convilsed and has marked delirium. I have never met with a case of this form of typhoid fever in a young subject.

The pare co, like most forms of febrile movement in the child, is remittent, but the degree of remission varies at different periods of the disease. In the second week there is, as a rule, less variance between the maximum and minimum temperatures than at an earlier or a later stage of the compliant. To test the boddly heat with any exactness, the temperature should be taken every three or four hours, both day and night. Very take conclusions may be drawn from a merely diurnal use of the thermometer, for the mercury is not necessarily at its lowest point at 8 or 9 a. a. nor at its highest at 6 or 7 o'clock in the evening. Again the minimum temperature may be non-febrile, or even subnormal. (Thus, in the

ease of Lilly F-, aged eleven years, a patient in the East London Children's Hospital, the temperature during the morning hours from b o'clock to noon was subnormal after the ninth day. It was often as low as 97°, and yet this was an undoubted case of typhoid fever. In the evening the heat was 102° or 103°.) It is difficult to lay down a rule in a matter which is subject to such endless variety; but perhaps the minimum temperature is reached more often between the hours of 10 a.m. and noon than at any other time, and the maximum shortly before midnight or a the early morning hours. In the third week of the disease the remission generally become very marked, and the minimum registered is often little higher than a normal temperature. This is especially noticeable towards

the end of the week.

During the first few days of the fever it is rare for the child to be under skilled observation, and a record of the temperature at this time is not easy to obtain. Occasionally, however, a hospital patient, admitted for some chronic complaint, sickens of the disease. Such a case occurred lately in a little girl, aged nine years, who was being treated for hip point disease in the East London Children's Hospital by my colleague Mr. Parker, and was transferred to my care on the outbreak of the fever. The child, whose temperature had been normal, complained of headache at 2 km. Her temperature was then found to be 102.6°. At 10 km, it had fallen to 100°. On the second day, at 6 km, it was 90°; but rose gradually, bong taken every four hours, till 6 P.M. when the thermometer nurked 1032. It then fell suddenly to 99 at 10 P.M. On the third day at 10 A.M. it was 1024'; at 2 r.m., 1024°; at 6 r.m., 101.8'; at 10 r.m., 102.6. After this it varied between 101° and 103.8° in the twenty-four hours, until the middle of the third week when it rose rather higher.

In a case kindly communicated to me by my friend Dr. Gee, the tenperature in a little girl under his care was 103° on the first day at 2 p.m.

and at 10.30 P.M. it was 103.6.

In a case published by Dr. Ashby, of Manchester-a little garl of nice years—the temperature was 100 on the first evening. On the second day: morning, 99.4°; evening, 101.8°. On the third day: morning. 100.4°; evening, 100.4°. Fourth day: morning, 101; evening, 103.4°.

From these three cases it appears that there may be great variations in the degree of pyrexia at the beginning of the disease. In my own case the temperature reached its height on the second day at 6 P.M.; but dur-

ing the first two days the variations were very great.

The duration of typhoid fever is from fourteen to twenty-six days as a rule. The temperature often falls in young subjects at the end of a fortnight; and sometimes, although very rarely, may become normal at a still earlier date. The possibility of so short a duration for the fever has been

doubted, but that it may occur is proved by the following case.

A little girl, aged nine years, was perfectly well on September 14th On the following day, the 15th, she complained of chilliness and frontal headache. That night the skin was noticed to be hot, and for the next week the child was apathetic, languid, and feverish, compluming of healache and abdominal pain. She did not vomit, and there was no bleeding from the nose. The child was seen on the 22d. Her temperature was then 102°, and a ross-spot was noticed on the abdomen by the house surgeon. On the 23d (ninth day) she was admitted into the hospital The abdomen was then moderately distended; the spleen could be felt two fingers'-breadth below the ribs; no spots were to be seen; the temperature in the evening was 102.6".

After this date the temperature was never higher than 99° and a fraction; the child looked and expressed herself as well; the spleen quickly retired node; the ribs, the appetite was good, and the patient complained much at being restricted to liquid food. On October 5th, the temperature having been normal for twelve days (with the exception that on one occasion, in the course of September 27th, it rose to 100.3°), and subnormal for six, the child was put on ordinary diet. Two days afterwards the temperature nose to 102, the spleen began to enlarge; rose spots appeared on the ablemen; and the patient passed through a well-marked relapse of typhoid fever which lasted the usual nine days.

In this case the early cosmition of the pyrexia seemed to exclude typhoid fever, and as the temperature continued low, a meat diet was allowed under the idea that our first impression of the illness had been a mistaken one. The prompt occurrence of a typical relapse, however, at once re-

mored our doubts as to the nature of the primary attack.

In some cases the temperature remains high after the usual time of falling at the end of the third week. In many cases this is due to progressive ulcerative enteritis. Indeed, Dr. thee lays it down as a rule that when pyream and enteric symptoms last longer than twenty-six days this is the cause of the prolongation of the disease. He also suggests that "subintrant relapse" may be an occasional agent in producing the same result.

Death from the intensity of the general disease, so common in the abult is very rare in early life. In very exceptional cases, however, the durrhors may be excessive; the temperature may rise to a high level; the pulse may be frequent, feeble and dicrotous; the abdomen may be swollen and tympanitie; the child is dehrious, then comatose, and dies with a temperature of 108° or 109°. Still, although this type of the disease is occasionally met with in the child, it must happen to few practationers to meet with such cases. When children die from typhoid fever, they die almost invariably from perforation of the bowel and general peritentis. The rupture occurs in the floor of a deep ulcer and takes place quite suddenly. It is followed by an escape of gas and of the fluid contents of the intestine into the peritoneal cavity. Immediately, the abdomen becomes distended, and there is intense pain and tenderness. Sometrues there is counting, but the patient in any case sinks into a state of o llapse with dusty haggard face, cool purple extremities, and small rapid pulse. Although the surface of the body feels cool, the internal heat rematna high (103-104). The respiration is thoracic. According to Niemeyer, suction desappearance of the liver dulness, on account of that or can being separated by the tympanitis from the abdominal wall, is one of the most certain signs of peritonitis from perforation of the bowel. This accident does not often happen before the end of the third week. When the perstantis is general, it is almost invariably fatal, and death is sometimes preceded by an attack of convulsions. If the intestine have been previously matted by local inflammation, rupture of the floor of the alter may not lead to such serious consequences. In such a case when perforation occurs, the extravasated contents of the bowel remain encysted, as i the resulting peritonitis is limited to the neighbourhood of the lesion. In the end the absecss thus formed generally makes its way to the surface and discharges its contents at some point of the abdominal wall.

Other complications which give rise to discomfort or danger are:—undumnation of the parotid gland, or of the middle car, brouchtts, pleurisy, preumonia, and catarrhal preumonia. In one case—a lay aged thirteen, under my care in the East London Children's Hospital—an extensive

plastic pericarditis arose during the third week of illness. Bedsores rurely occur unless the child is greatly reduced by protracted illness; but boils and abscesses are not uncommon. Ulceration of the larynx has been described, but must be very rare. Another rare complication is thrombosis of the veins of the lower extremities.

After the fever has subsided, the temperature usually remains subnormal for some time. Not unfrequently, however, after the lapse of a few days, the child is noticed to be feveral again. These secondary pyremas are very common. They may be due to a real relapse; to the presence of some irritant in the bowel, such as hardened fecal matter or undigested food; or to some febrilo complication which may be called accidental, as an abscess.

Real relapses are far from uncommon. They begin after a variable interval—four or five days, or longer—and seem in many cases to be determined by injudicious feeding in the stage of early convalescence. The temperature rises; the spleen again enlarges; fresh spots appear; and the bowels may be again relaxed. Usually the symptoms are nulder than in the primary attack and last a shorter time. The average duration of a relapse is nine days.

Constipation and the irritation of the bowel by hard fecal masses is a common cause of secondary pyrexia. The temperature usually rises to 102 or 103, but may be higher. When the irritant has been removed by a copious injection, the pyrexia at once disappears. These attacks of temporary elevation of temperature may recur again and again in the course

of convalescence, but need occasion no anxiety.

Convalescence from typhoid fever is often tedious. The child is left weak and low, and nutrition may not at once be re-established. It is a remarkable fact—to which attention has been drawn by Dr. West—that the patient is enfeebled intellectually as well as physically by his illness. For some weeks after the fever is over he may remain dull and indeferent, taking little interest in pursuits and amusements which formerly delighted him. A child of three or four years of age may seem to have forgatten how to talk; and the persistence of this mental weakness for some time after the strength has been restored is often a cause of great anxiety to the patient's friends. Such anxiety is, however, groundless, for the return of

mental tone at no long interval may be confidently predicted.

These cases appear to be due sometimes to defective action of the kidnevs. In one case which came under my notice the child (a boy of seven) was left after typhoid fever in an apathetic, stupid condition, taking no notice of anything, and never speaking even to make known his natural wants. He appeared to be in a state of great weakness, and had occase pally nervous seizures in which he became quite stiff, and seemed to be un-His skin was dry and excessively inelastic; there was no discoverable disease of any of his organs; his temperature was subnormal. At first he had a slight trace of a dema of the legs, but this quickly passed off. His urine never contained albumen, but its quantity was small. For a long time the boy passed no more than ten or twelve ounces in the twenty-four hours, with a specific gravity of I 015. The excretion of solid matter by the kidneys was so evidently deficient that dioretics were ordered, and the boy was forced to take a larger quantity of fluid. Under this treatment he soon began to mend; his urme became more copious with a higher density; the elasticity of his skin returned, his nervous seizures ceased; and his strength, mental and bodily, rapidly improved.

A child with any diathetic taut may have his predisposition strength-

ened by his illness. Tuberculosis sometimes occurs; and scrofulous ten-

It ignores On account of the negative character of the symptoms at the beginning of the illness, enteric fever is often difficult to recognize in the early stage; and even at a later period the nature of the complaint must be sometimes a matter of doubt. Still, the disease is one of such trequent occurrence that we should always remember the possibility of its being present, and should never omit in a doubtful case to make inquiry as to the existence of the disease in the neighbourhood. The beginning of measles, scurlating, and variola is sufficiently distinctive to prevent their ing confounded with this disorder, and moreover, the absence of the citie eruptions of these complaints will serve for their exclusion. A is the temperature on the second day in a child who suffers from nothing but an ill-lefined malaise is enough to give grounds for suspicion. If, as the days pass, no other symptom develops itself, our suspicions are materially strengthened; and when at the end of the week, enlargement of the splien with swelling and tenderness of the belly can be detected, especially if there is also looseness of the bowels, there is hardly room for further besitation.

Acute tuberculosis may present a very close resemblance to enteric fever in the child, especially as we sometimes see a rose spot here and there on the bodies of tubercular children which, except for being rather larger than the typhoid spot, and perhaps a little less delicate in colour, may be, and indeed has been, mistaken for it. In both tuberculosis and enteric fever diarrhea may be a prominent feature; in both there is fever; and in both the general symptoms may be very indefinite. Often, in these cases we cannot decide, but must writ for time to relieve our uncertainty. But in many cases we may venture upon an opinion, for in tuberculosis the absence of any definite time of beginning; the less clovated temperature, the bodily heat being rarely higher than 101' in the evening; the instrumental size of the spleen are all points in which that form of linear and the natural size of the spleen are all points in which that form of linear from typhoid fever, and may serve to help us to a conclusion.

Sometimes enteric fever may be mustaken for tubercular meningitis. The illness may begin with drowsiness and sickness; the healuche may be stere and provoke cries from the child such as are common in the intrarantal inflammation; the vomiting may persist, and the bowels may be obstant by continued. Still, the belty is distended, and has not the dought, for a learning of the paracters so peculiar to tubercular meningitis; the pulse, until convalescence begins, is not slow and intermittent; the respiration is not sighing; the pupils do not become unequal, and there is no square. The temperature, too, is much higher in the case of typhoid fever, for an the earlier stages of tubercular meningitis the bodily heat is seldotagreater than 101. Later, none of the symptoms of the third stage of tubercular meningities can be discovered.

Leute gastric catarrh, accompanied as it is in scrofulous children with pyrexis, may cause some embarrassment, but here the temperature is less aid than in enteric fever, and does not undergo the same alternations; there is no distention of the abdomen, and no enlargement of the spleen. Still, in many cases, before the fever subsides on the ninth or tenth day, we cannot say positively that we have not to do with the more serious disease.

When the purging is severe the case may be confounded with one of adammatory distributes, and it is possible that in young children under

three or four years of age the mistake is often made. I think, however, that the shorter course of a non-specific muco-enteritis, the severity of the purging from the first, the haggard aspect of the patient, and, if the disease last long enough, the absence of splenic enlargement, of the rosy rash and of the signs of pulmonary catarrh, should be sufficient to furnish a distinction.

Simple or tubercular ulceration of the bowels with enlargement of the mesenteric glands may be also mustaken for enteric fever. But in these disorders the temperature is less elevated than in typhoid fever, and the lustory of the illness is very different. Their course, also, is very much longer. There is, besides, absence of the rash, of the splenic enlargement (unless, as may happen, there is tubercular disease of the spleen) and of the signs of pulmonary catarrh. Further, in tubercular ulceration the lungs are generally the seat of consolidation and the emaciation is extreme.

Chronic tubercular peritonitis, with its rough harsh skin, its pseudo-fluctuation, and the caseous masses to be felt on palpation of the abdomen,

can scarcely be confounded with enteric fever.

Lastly, the distinction between typhoid and typhus fevers is now sufficiently established. In the latter disease the onset is always abrupt, the rash, abundant and quite different in its appearance from the rosy typhoid spots, appears on the fifth day; the face is dusky; drowsiness and super are early symptoms; and the end—whether favourable or the reverse—comes in a sudden crisis.

Prognosis.—It has been already said that comparatively few children die from this disease; but small as is the percentage of mortality, it is greater than it need be. This is partly due to the way in which the disease begins, and the mildness of its early symptoms making diagnosis doubtful. It is also owing in part to the character of the early symptoms and the abuse of domestic remedies. A child is found to be poorly; he vemits and complains of headache. Immediately he is treated to a dose of castor-oil or other aperion; and as the symptoms are not found to be relieved by this measure, the dose is repeated, perhaps several times. There is no doubt that such treatment is excessively injurious; and in hospital practice the cases which terminate fatally generally have a history of active purgation having been adopted before admission.

However severe the symptoms may be, we may look forward hopefully to the issue provided perforation has not occurred. Children respond well to stimulants in typhoid fever; and a patient who is seen stupid and drowsy and profoundly depressed on one visit, may present a very different appearance on the next under the free use of brandy. I think even muscular tremors have not the same unfavourable meaning in the child that they have in the adult. Still, if the tongue quivers when protruded, the lower jaw trembles when the mouth is open, and general tremulousness of movement is pronounced, we have reason to fear the presence of a deep ulcerative lesion in the intestine. Our apprehensions are strengthened if at the same time the belly is much distended, and the temperature remains persistently elevated after the end of the third week. In such a case the danger of perforation is imminent.

If perforation take place, the prognosis is most grave; but even in this strait death is not absolutely certain. If the collapse which follows the extravasation be quickly recovered from, even although considerable tympanitis, pain, and tenderness remain, we may hope that the peritonitis has been localised by intestinal adhesions, and that further improvement

may take place.

Treatment.—In every case of typhoid fever, if there is any reason to suppose that the disease has been contracted in the house, the drains should be thoroughly examined at the earliest opportunity, and every care must be taken to prevent the entrance of sewer-gas into the passages. All scal-papes should be ventilated: waste-pipes should be cut off from direct communication with the sewers; cisterns supplying water for druking and cooking should be entirely separated from those whose purpose is merely summary; and the water itself—unless its purity be above suspicion—should not be drunk without having previously been boiled and nitered.

The treatment of typhoid fever consists mainly in careful and judicious aurang. Sir William Jenner has insisted strongly upon the absolute to bed at once, and if the attack has occurred at a distance from his home, 11 16 better that he should remain where he is, than run the risk of increasing the severity of his illness by the fatigues of a removal. Fatigue not only exhausts nerve-power, which is already reduced by the fever, but if also increases destruction of tissue at the same time that it checks chinination by the excretory organs. The bedroom should be a large one, and the air must be kept as pure as possible by judicious ventilation. Its temperature should not be allowed to rise above 65. The patient should be lightly covered and not overloaded with bedclothes. There is, however, one precaution which it is expedient to take. As in all cases where the mucous membrane of the bowels is the seat of catarrh, flaunel in the shape of a dannel bandage should be applied round the belly so as to aroud the risk of chill. All discharges from the body must be at once disinfected before being removed from the room, and linen, etc., soiled by such discharges must be subjected to the same disinfecting process before being washed. If there he reason to suspect the purity of the water-supply, none should be used for drinking purposes without previous boiling and altering. This, however, the child may be allowed to drink without stint, provided too large a quantity be not taken at once. A free supply of water assists the depurating action of the skin, kidneys, and lungs; but distention of the stomach by too much fluid is provocative of nausea and dataleuce For this reason effervescing drinks are to be avoided; they are and to distend the stomach and cause uneasiness.

The question of diet is a very important one. The old plan of "starving the fever 'and reducing the patient has been fortunately abandoned, but we must not fly to the opposite extreme and overload the stomach with food in the hope of supporting the strength, however digestible and well selected the food may be. Farinaceous matters, on account of their tendency to ferment and form acid, are better avoided. Fruit for the same remain is out of the question. It is better to restrict the diet to meat broths made fresh in the house, and to milk. The broths may be flavoured with vegetables, but must be carefully strained. The milk should be dilated with an equal quantity of barley-water, so as to split up the curd and prevent its coagulating in the stomach in large lumps. Masses of hard cupi are a frequent source of irritation, and may excite restlessness and abdominal pains. They may also, perhaps, increase the diarrheea. The quantity of food to be given at one time should never be left to the discretion of the attendants. Nourishment should be administered in prescribed doses at regular intervals - the quantity and the length of the interrals to be decided by the age of the patient and the facility with which the meal can be digested. Nausca, restlessness, excitement of pulse, increase of fever, and flushing of face, are signs that the digestive organs are

being taxed beyond their powers.

The question of stimulation is closely allied to that of food. Stimulants must not be given too early. They are useful to strengthen the action of the heart and increase nerve-energy, but are seldom required before the end of the second or beginning of the third week of the disease. Exer then, they should be only given in severe cases where the heart's action gives signs of failing, and there is marked delirium or great muscular prostration with tremor. Tremor, "out of all proportion to other signs of nervous prostration," is, in the opinion of Sir William Jenuer, evidence of deep destruction of the howel. In these cases alcohol is of the utmost value The signs connected with the heart which may be taken to indicate the necessity for stimulation are diminution or suppression of the impulse with feebleness of the first sound. The effect of stimulation should be carefully watched. If the fever diminish, the tongue and skin get or remain most, the pulse and respiration become slower and fuller, and the mind clearer, we may know that we have benefited our patient. If, on the contrary, the temperature rise, the heart's action become feebler and more frequent, the debrium increase, and the child get restless with malahity to sleep; or if he become duller and seem sinking into a comatose state, we may conclude that alcohol is acting injuriously, and that it must be discontinued or given in smaller quantities,

In typhoid fever, as in all other febrile diseases, it is important to watch the temperature and regulate it. If, for instance, with a temperature of 105°, we find restlessness and excitement with wakefulness, the child should be sponged over the whole body with tepid or cold water. This lessens fever, calms irritability, and induces sleep. More than tepid or cold sponging is seldom necessary. If, however, the temperature be not appreciably lowered by the sponging or rise again immediately, the child may be placed gently in a bath containing water at 70°, and be kept immersed for ten, fifteen, or twenty minutes. It is well to continue the bath until distinct shivering has been produced. The child must be then removed, wiped dry, and returned to his bed. A stimulant may be given at this time if thought desirable. The cool bath should not be used unless there is a real necessity for it. Children can bear a continued high temperature better than older persons; and if there is a daily remission, as

occurs in most cases, mere sponging will do all that is required.

Delirum is scarcely sufficiently violent in children to require treatment—at any rate in ordinary cases, and headache is seldom a trouble-some symptom. If it should be so, it is usually relieved by cold applications. Sleeplessness may be generally relieved by the tepid spenging above referred to. If necessary, a draught containing bromide of potas-

aium in combination with chloral may be given.

Diarrhes may sometimes require remedies. In every case where the stools are too frequent and watery we should examine them for curd of milk. If this be present, the amount of milk taken at one time must be reduced. We should also take care that the child does not drink duid in excess, and if necessary his drink must be given to him in smaller quantities. When drugs are required to arrest the purging, chalk and catechar should be given if the motions are frothy. If they are strongly alkaline, dilute sulphuric acid is most useful. In the later period, when there is indecration of the bowel, bismuth in large doses is indicated. Hamorrhage from the bowels is a comparatively rare symptom in the child and seldem requires treatment by drugs. If necessary, however, gallic acid and dilute

sulphuric and may be administered with small doses of opium. In such a case the child should on no account be allowed to raise himself from the recumbent posture even to relieve the bladder or the bowels. It is well also to give him his food in small quantities and in a concentrated form. Strong beef-essence, well iced, and good meat jelly should be empoyed; and but little milk should be allowed, for fear of irritating the

intestane with lumps of curd.

If perforation and peritonitis occur, opium should be given in small does, but frequently, so as to produce some of the early physiological effects of the drug, such as drowsiness and tendency to contraction of pupils. In my experience opium is in such cases of small value unless posted to this extent. The belly should be also smeared with an ointment composed of equal parts of extract of belladonna and glycerine, and be kept covered with hot tinseed meal poultices frequently renewed. The food in these cases also must be concentrated and given frequently in small quantities. Brandy and egg will be required to sustain the strength.

During the period of convalescence careful feeding is still necessary, for errors in diet at this time are a frequent cause of relapse in the fever. I have always made it a rule to allow no solid food until ten days have passed after the final fall of temperature. But even then the usual diet

of health should be only slowly returned to.

In order to prevent relapses Immerman recommends, in addition to the utmost vigilance with regard to diet, the daily administration of saliculate of sods in full doses; beginning directly the fever subsides, and continuing the use of the drug for ten or twelve days. The after anemia and weakness must be combated by iron and good food. Change of air to a dry bracing place or to the seaside is very useful.

CHAPTER X.

DIPHTHERIA.

DIFFERENT is an acute contagious disease which, on account of its prevalence, its gravity, its consequences, and the frequency with which it is met with in the child, takes a prominent place amongst the disorders of early life. The disease induces great aniemia and prostration, and is characterized anatomically by inflammation of various mucous surfaces and the formation on them of a more or less tough and leathery false membrane. The inflammation often spreads to some distance from its point of origin, but at first is usually confined to a comparatively limited area. The seat varies in different cases; and the symptoms are therefore subject to great variety according to the part in which the chief local expression of the disease occurs.

When the inflammatory process attacks the larynx the malady is called membranous croup, and this was long held to be a distinct affection. Whether all cases of membranous croup are diphtheratic in their nature -whether a false membrang can be developed in the air passages apart from the diphtheritic poison—is a question upon which pathologists in this country are still divided. That membranous croup arises in many cases from this cause is undeniable. Instances have been met with in which diphtheria has attacked the pharyux in some members of a family and the larynx in others. Thus, Dr. Woodman found membranous laryngitis in two infants, aged respectively eighteen months and two months, while others of the family suffered from false membrane in the month and pharynx. Dr. Wilks has seen in different inmates of the same house the disease remain confined to the throat, or spread thence to the larynx, or begin in the larynx; and Trousseau refers to a case reported by Dr. A. Guerard in which a little girl died of laryngeal croup, and other members of the family suffered immediately afterwards from pseudo-membranous pharyngitis. Moreover, it is admitted by the best authorities that the laryngeal false membrane has exactly the same anatomical characters. whether it be due to the spread of a pharyngeal diphtheria or arise primarily as a case of membranous croup.

Advocates of the essential difference between the two forms of illness maintain that the character of the two diseases is not the same. Croup, they say, is a sthenic disease, while diphtheria is asthenic. But some cases of croup are accompanied by severe constitutional depression and all the signs of profound general disease; while diphtheria is not invariably accompanied by symptoms of prostration. Indeed, one of the pscularities of this affection is the occurrence sometimes of marked paralysis after

an attack of sore throat so mild as to be almost overlooked.

Secondly, it is pointed out that in diphtheria the glands at the angles of the jaw are invariably enlarged, while in membranous croup they are little if at all offected. But the larynx has little connection with the su-

perficial cervical glanda. As Dr. Morell Mackenzie has pointed out, in cancer of the larynx the cervical glands are not enlarged, while if the malignant disease affect the pharynx these glands are always involved.

Thardly, the contagiousness of diphtheria is insisted upon, while membranous croup is said not to be communicable by one child to another. But the risk of infection is in direct proportion to the amount of exudation, and the readiness with which the membrane can be detached and dispersed. In the glottis the membrano is very firmly adherent; in the pharynx its connections are much looser, and it is much more easily separable from the mucous surfaces. Moreover, as Sir William Jenner has observed, the conditions in which the patient is placed vary greatly in the two cases. A child with diphtheria in its early stage is up and about, kisses his brothers and sisters, and has every opportunity of conveying the discase to them. A patient with membranous croup is kept in bed apart from the other children and carefully tended. Still, there is strong evidence that, in spite of these hindrances to its ready communication, membranous croup may be conveyed from one child to another. Dr. Trend states that he has seen the larengeal disease in more than one child of a family at the same time. Dr. Wilks believes that he has seen diphtheria begin in the house as a case of supposed membranous croup, and afterwards attack others of the inmates in the form of diphtheritic pharyngitis. Dr. A. Guerard's case, already referred to, is another instance of the contagiousbees and interchangeability of the two varieties.

Fourthly, albuminuria, which is common in diphtheria, is said to be care in membranous croup. But this is not altogether the fact. Moreover, albumen does not always appear in the urine at the beginning of an attick of diphtheria, but may be delayed for several days. Now the duration of fatal cases of croup is often terribly short; so that the patient may

die before the albuminuria has had time to occur,

Lastly, paralysis is a not uncommon sequel of diphtheria, while in membranous croup it is very rare. But it must be remembered that true membranous croup is an excessively fatal disease and comparatively few cases recover. Even as a consequence of diphtheria the occurrence of paralysis is variable in different epidemics; and taking the milder cases with the severer, the proportion has been estimated by Dr Greenfield at no more than one in twelve. In convalescents from membranous croup the proportion who are likely to suffer from paralysis would, therefore, under any circumstances be very small.

From consideration of the above facts and arguments the only conclusion to be drawn is that a large proportion of cases of membranous croup are cases of laryngeal diphtheria. It does not, however, follow that membranous laryngetts is never due to any other cause than the diphtheritic poison. The child's larynx is especially prone to membranous inflammation; and if, as has been positively stated, a true false membrano may be set up by burns, scalds, and other irritants to the air passages, it is possible that the disease may occasionally occur independently of the diphtheritic

STEEL

Diphtheria is met with both as an epidemic and as an endemic disease, and varies much in character and severity at different times and in different localities. It may attack children who are apparently in robust health, may arise in cachestic subjects, or appear as a sequel of severe general disease. Lake typhoid fever the disorder is apt to occur more than once in the same individual, for the protection it affords against a recurrence is no means complete. Sometimes the second illness may be more severe

than the first, for a child who has passed safely through one attack may succumb to a second.

Causation. - On account of the susceptibility to diphtheria in early like childhood may be considered to be one of the predisposing causes of the malady. Infants under twelve months of age are not often attacked; but after that age and up to the fifth or sixth year the disease is frequently met with. After the sixth year it again becomes less common, and is comparatively rare in the adult. Besides this natural susceptibility, there is probably in many cases a special susceptibility inherent in the constitution of the patient. Sometimes whole families are cut off during an epidemic of the distemper. Sometimes successive children of the same parents fall victims to the disease at various times and in different places; and in many cases this unfortunate predisposition appears to be a hereditary defect. Besides these general causes, special delicacy of the throat may render the child more sensitive to the diphtheritic poison, inchning him to take the disease where a stronger subject would escape altogether. Also the presence of a catarrhal condition of the fauces at the time of exposure to the unhealthy influence increases the likelihood of infection. The scrofulous constitution has been said to induce a susceptibility to the diphthentic virus; and there is no doubt that the subjects of this diathesis are, as a rule, keenly sensitive to all forms of zymotic poison.

Cold and moisture appear to have some influence in quickening the activity of the contagious principle, for the disease is common in country districts, especially in damp places, and is more prevalent during the winter

months than at any other period of the year.

With regard to the exciting causes: There can be no question as to the highly poisonous nature of the exudation from the affected surfaces, for the discharges have often communicated the disease by coming into contact with a healthy nuccous membrane. The virus may, however, be also conveyed by more subtle emanations from the affected person; and it is believed that the contagious principle may be carried to a distance in the clothes of the patient himself after convalescence, or in the dress of a nurse who has not herself suffered from the disorder. Indeed, all the surroundings of the patient appear for some time to be capable of communicating the disease. It is even stated that in certain cases a convalescent may be still the channel through which the diphthernic virus is conveyed to exceptionally susceptible subjects, although a period of months has chapsed since recovery from the disorder; but in such a case it would be difficult to exclude other and more recent sources of infection.

The poison may be drawn into the lungs with the air or swallowed in contaminated water; but much uncertainty exists with regard to the laws which govern the transmission of the infective matter. Old cesspools and drains appear to preserve the contagium for a long time in a state of active virulence, but there is no proof that the poison can be generated spontaneously from ordinary fifth. The distemper may originate in a district under one set of conditions and be distributed under other and different conditions. There is no doubt that insanitary surroundings tend to favour the spread of the disease; still it is probable that other influences also regulate the diffusion of the infection; for when an outbreak occurs in any district, it is not always in the poorest and least cleanly localities—in paris, that is, where the disease would be expected to be most active—that the largest number of cases occurs.

In many outbreaks certain faulty conditions, such as polluted watersupply, long standing accumulation of excrementitious matters, and imperlect sewerage and drainage generally, are found to be common to all the dwellings in which the disease appears. These sanitary deficiencies are then held to furnish an explanation of the source of the infection. In other cases no such common conditions can be discovered, and the origin of the outbreak is less easy to account for. This was the case in an epidemic of dipatherra which occurred at King's Lynn, and was reported on by Dr. Airy. Here personal conveyance of the disease was positively excluded in the majority of cases. The nulk was not at fault. The water-supply, the system of drainage, and the method of disposal of the excrement were insufficient, either singly or together, to explain the distribution of the infection. It was however, noticed that excavations had been in progress in the mind of the ancient river-bed and of a creek which had once been a sewer in connection with the town. Dr. Airy suggests that by this means "long-burned germs of some indigenous diphtherm, causing microzymes." may have been disengaged; and that these carried amongst the inhabitants, and saided by season and atmosphere, may have given rise to the outbreak

Diphtheria is no doubt the consequence of a specific poison, however this may originate. The essence of the disease has been attributed to apherical bacteria (microco xi), which have been discovered swarming in the faise membranes and exudations from the inflamed mucous surfaces; but as similar bacteria have been found in the secretions thrown out by ordinary non-specific stomatitis, too much importance must not be attributed to the presence of these organisms. The real nature of the virus has yet to be discovered. The disease with which diphtheria has the closest affinity appears to be scarlatina. Epidemics of the two disorders are frequently cen to prevail in the same neighbourhood at the same time, and it was once supposed that the exciting causes of the two diseases were the same. It is now, however, acknowledged that they have no mutually protective power; and there is no evidence that the contagion of diphtheria has ever given use to scarlatina.

Morbel Anatomy.—When the pharynx is examined the changes found on the inflamed inucous membrane are as follows: the surface becomes hypercenic and swollen, and after a few hours is covered with a whitish or redlowish layer which adheres closely to the mucous membrane beneath it, litting accurately into every depression of the surface. The layer when first formed cannot be removed; but as it increases in extent and thickness, it gradually becomes tougher, and can then be peeled off the surface to which it adheres. Later, it begins to loosen and may separate spontaneously. When uncovered the mucous membrane may be found to be reddened and thickened, and if the inflammation has been severe, raw-look-

ing or even ulcerated.

On examination of the false membrane, it is found to present to the make i eye the appearance of coagulated fibrine; but under the microscope seen to consist of proliferated epithelial cells which are fused together into a network. These cells are cloudy from a peculiar degeneration of their protoplesm. A vertical section of the layer shows the undermost cells to be much smaller than those at the surface, and in a far less advanced stage of degeneration. Minute extravasations of blood are also scattered through the substance of the layer. If the vertical section be made in sata and be carried down through the mucous membrane, it will be seen that the exacted layer is scatted directly upon the basement membrane, taking the place of the ordinary epithelial conting. When the morbid process comes to an end, degeneration ceases; a little purulent matter, formed by

unaltered new cells mixed with serum, appears between the mucous surface and the false membrane covering it, and the latter is detached.

In the largest the mucous membrane is inflamed and swollen, and a fibrinous exudation is thrown out between the basement membrane and the epithelial covering. This on examination can be separated into layers can entitle (leucocytes) and of fibrine. The superficial epithelial layer very quickly disappears. The micrococci, which are found in immense numbers in the false membrane, have been already referred to. According to Senata, these organisms are common to all forms of stomatitis, and are probably

identical with the spores of the leptothrix buccalia.

The consistence of the false membrane varies in different cases. It is often tough and tenacious, especially in the air-passages; but sometimes is very soft and pultaceous. The latter condition is common when the false membrane occupies the pharynx in cases accompanied by severe constitutional symptoms and great bodily prostration. The more usual seats of the false membrane are the tousils, uvula, soft palate and back of the pharynx; the nasal passages; the larvnx and trachea. Less commonly it is found on the conjunctiva; at the borders of the anus, and in girls of the vagina. Sometimes it appears on wounds of the skin. The mucous membrane is usually, as has been said, congested and swollen. It is very pritable and bleeds easily. Sometimes there is superficial ulceration, and in rare cases the ulceration extends deeply, and sloughing of the tissues may occur. Small ulcerations about the edges of the glottis are especially common in cases where the inflammation occupies the larvax. The cervical glands are swellen from rapid preliferation of small round cells, and the surrounding tissues are infiltrated with serum containing scattered pus-cells.

Besides these local pathological changes, other organs of the body are

often affected. Thus :-

The lungs may be the seat of lobular pneumonia or collapse; and the air-passages are sometimes lined with false membrane as far as their smaller branches.

The heart, although itself showing no signs of disease, may have its right ventricle filled with a colourless ante-mortem clot which extends into the ventricle. It is sometimes stated that the lining membrane may be the seat of endocarditis; but Parrot asserts that he has never met with endocarditis in a case of fatal diphtheria. He believes that the beading elsewhere described, which is almost a natural condition in many young infants, has been mistaken for the result of inflammation. Pericarditis, however, is occasionally present; and in a few instances a granular degeneration of the heart-walls has been observed. This degeneration is considered by Leyden, of Berlin, to be of an inflammatory character. It consists in a multiplication of the intermuscular nuclei which atrophy and form spots of degeneration. At the same time the muscular fibres undergo fatty degeneration. As a consequence of these changes the heart-walls become softer in consistence; extravasations of blood take place into them; and their cavities are dilated.

The kidneys may be enlarged and pale, with more or less granular deposit in the renal cells. The cells themselves are often detached so as

to block up the tubes. They are mixed with hyaline casts.

Besides the above changes, there may be extravasation of blood into the various organs and beneath the mucous and serous surfaces. This occurs in the malignant form of other varieties of acute specific disease. On account of the frequent occurrence of paralysis during convalescence from diphtheria, the nervous system has been carefully examined for signs of degeneration. Charcot and Vulpian were the first to discover indications of pathological change. In the year 1862 these observers detected granular de retration of nerves and muscles of the soft pulite. In the motor nerves of this part the tubules were emptied of their medullary substance, and their neuralemma contained many granular cells. Oertel, in 1871, found meny extravesations in the substance of the brain, spinal cord, and spinal nerves in a case where death had occurred from diphtheritic paralysis with general atrophy of muscle. Similar extravasations have been found by Buil In addition, this observer noticed the nerves to be thickened at their roots, and their sheaths to be filled with hypertrophied lymphold and nuclei. Dejective, in five cases of death in children from diphtheretic paralesis, found in each instance changes strictly limited to the nerves supplying the puralysed parts. These changes consisted in a degeneration of the autorior roots similar to that which takes place in the distal end of a nerve after section. He attributes the degeneration to changes in the gray matter of the anterior cornua.

There is no doubt that diphtheris is a specific contagious disease, and that it is, at least finally, a constitutional one; but opinions differ as to whether the induly is constitutional from the first. The more commonly received opinion is, perhaps, that the affection is always a constitutional one, and that the throat lesion is its chief local expression, analogous to the rash of specific fevers. Some pathologists are, however, inclined to believe that the lesion of the mucous membrane is at first a purely local adment resulting directly from contact with the poison, just as the pustule of small-pox may be excited locally by the process of morulation. According to this view the constitutional suffering would be of the nature of septimental, the blood being directly contaminated by absorption of a specific arms from the diseased spot. The well-known influence of a catarrhal state of the fauces in increasing the susceptibility of the individual to the

lighteritic contagion seems to lend support to this theory.

Symptoms —As in all forms of zymotic disease, the onset of the illness is preceded by a period of incubation. This period may occupy only a few hours or may last for a week or eight days before the symptoms of insecon are noticed.

Coss of diphtheria may be divided, according to the gravity of the

symptoms, into the mild, the severe, and the malignant forms.

In the mild form of the disease the child is a little feverish, often compliants of headache, and is unwilling to swallow solid food. The fever is light, the temperature often rising to between 101 and 102°, seldom argher. (Thus, in the case of a little girl, aged two years and ten months, temperature: second day, morning, 99.4; evening, 101.6°. Third day, morning, 99.4; evening, 101°. After this date the temperature was normal both in right, and evening.) In all cases there is some languor and loss of spirits with a certain expression of distress in the face. Even in slight the same is noticed in the quality of the voice, which becomes assal or throats. Vomiting is not common in the mild form, although in the severer cases it may be a frequent and distressing symptom. Sometimes the symptoms are even less marked. The child may take his food to usual without any complaint, and only show his indisposition by a certain pullor of face and want of sprightliness in his look.

When the threat is examined, the fauces are found to be red and swellen but more on one side than on the other; the usula is distinctly becaused in size; and on one or both tonsils a gray or fawn-colored,

tough-looking opaque patch will be seen, usually occupying the anterer face. The patch may be a continuous layer of some consistence, or may be composed of spots of false membrane scattered over the surface. They however, soon units so as to form a more coherent coating. In all cases the glands at the angles of the jaw are tender and enlarged; but the symptom is often not marked until the end of the second or the beginning

of the third day.

In the mild form the temperature often falls after three or four day. The general symptoms continue trifling; the child takes food with appetite; and unless he attempt to swallow solid food, deglutition is accompanied by little distress. The false membrane may spread a little along the soft palate, but usually remains limited in extent. Very quickly it begus to separate at the edges and then becomes detached. In rare cases after spontaneous separation of the first patch of membrane a second appears upon the mucous surface. I have known this to happen in one usatance. The sore throat may be accompanied by some discharge from the nose. Usually, at the end of a week or ten days the child is convalescent from the throat affection; but it still remains to be seen whether he will escape after ill-consequences.

In the serve form the disease may be severe from its intensity or dangerous from its sent. Thus, it may spread widely over the pharynx and be accompanied by signs of serious constitutional suffering; or may attack the larynx and, although limited in extent, produce the gravest consequences from interference with the respiratory process (membranous

ezoun).

Secret pharyageal diphtheria may begin with the mild general symptoms which are common in the slighter form which has been described; or may be accompanied by much more serious phenomena. Thus the child complains of difficulty of swallowing and of racking headache; his face is pale and distressed; fever is high; vomiting may occur on any attempt to take food; and the patient may even be convulsed. The false membrane in the throat is thick and generally coherent. It spreads rapidly over the tonsils, the soft palate, and the back of the pharyax; often penetrates into the misal fossic, or forms patches on the checks, the gums, and the lips. The odor of the breath is soon noticed to be fetid or even gangrenous; and a thin offensive discharge escapes from the nostrils and forms crusts at the openings of the nares.

The submaxillary glands are enlarged and tender; and there is much swelling of the neck. Sometimes bemorrhages occur from the nose, throat, and gums. The face is pale with a tendency to lividity; the pulse is rapid and feeble; appetite is completely lost; the bowels are generally relaxed with thin offensive stools; and there is great prostration. Sometimes in these cases the false membrane is loose in consistence and may even be pultaceous. It may assume a dirty gray or brownish hue, and is

nometimes almost black from admixture with blood.

When the end is favourable this form lasts for ten days or a fortnight. After a time, if no serious complication occurs, the false membrane separates and is not renewed; the swelling subsides; the pulse becomes stronger; the appetite begins to return; and the child enters into convalescence, although for some time he remains amenic and feeble. Often, however, the patient dies at the end of the week either from exhaustion, from extension of the unfamination to the larynx, or from one of the complications to be afterwards described. The mind is usually clear throughout, although in the worst cases—those in which the disease approaches

most nearly to the malignant type—death may be preceded by delirious manderings or stuper. In such cases a real septicemia may occur, the blood being poisoned by the absorption of foul putrescent matters in content with the tissues of the pharynx. The child often shivers and his temperature rises to 103 or 104, often sinking again in rapid daily variations. The pulse is small and feeble; the eyes sunken and dull-looking; the complexion of a dirty yellow tint. There is often epistaxis; the certical giants swell to a large size; and the loose arcolar tissue of the neck is mattrated with serum. The prostration is extreme; apathy is complete; delirium comes on; and the child quickly dies.

In severe diphtheria the amount of fever varies. Even in very bad the set need not be high. Sometimes the temperature is 103° or 104° at the beginning of the illness, and sinks to the normal level or even below to when the more serious symptoms declare themselves. Sometimes after falling it may again become elevated and reach 106° or higher before thath. Some inflammatory complication is then probably present.

Albumnum is a frequent symptom. It occurs in about two-thirds of the cases, but does not necessarily imply gravity in the prognosis. Its amount is usually in proportion to the extent of surface involved. The Minimum appears to be the consequence of a rapid chimination through the kidneys of poison absorbed from the affected nucous membrane. In some cases it may be found as early as twenty-hours from the beginning of the illness. This is, however, exceptional. Usually it appears on the third or fourth day, but it may be sometimes delayed as late as the ninth or tenth. Sometimes the urine is smoky. It contains an excess of area, and hyaline and granular casts may be detected in the deposit. The kidneys are in a state of mild parenchymatous nephritis, but this passes off as anywhescence becomes established, and rarely leaves ill consequences behind. It is very rare for unionic symptoms or dropsy to occur.

When the disease attacks the larynx (laryngeal diphtheria; membranous arough the child is at once in serious danger. In the impority of cases the laryngeal disease is due to extension of inflammation from the fances. It is commonly the inflammation begins in the tracker and spreads thence in wards and downwards. Cases where the disease develops originally in the 2dottes, the 50-called true membranous croup) are very rare. Still larger are the cases where the false membrane remains lamited to the glottis. In my own experience I cannot call to mind a single case of membranous largingitis in which some evidence of false membrane in other larges was not to be obtained. In most cases there was also exudation in the fauces. In a few the membrane had spread down the tracker and the fauces were free, but even in these cases patches of exudation were usually found on examination after death at the back of the narcs.

The extension to the air-passages often takes place quite suddenly and mexpectedly. The preceding symptoms had been slight, attracting little stention, when suddenly the breathing is noticed to be stribulous. The symptoms of membranous croup then develope themselves with startling applity. Usually the sore throat and signs of catarrh continue for several days before any more aluming symptoms are observed. The child is not thought to be ill. He seldom refuses his food; and although a little languard and unusually anxious for drink, does not appear to be dis-

When the laryngeal disease begins the breath-sounds lose their ordinary ractor and become larsh and strilulous. At the same time the cough is and and harsh and the voice and cry are hourse. The change in the char-

acter of the breathing may be the earliest of the new symptoms, or may

be preceded by the change in the voice and cough.

This stage of the disease may continue for several days; but often after a few hours the breathing becomes greatly oppressed, and attacks of violent dyspuces throw the patient into the greatest distress. In these attacks however violent they may be, there is no orthopnea, for the breatling is not more oppressed when the head is low. As a rule, the child has back in his cot or in his mother's arms. His face is livid; his mouth is open; his eyes stare wildly, and he looks dreadfully anxious and frightened. The dyspness affects both respiratory movements. Each inspiration is prolonged, high-pitched, and metallic; the expirations shorter and barsh; the cough hoarse and whispering. If the chest is uncovered at this time it will be noticed that at each inspiration the lower half of the breast-hone bends inwards so as to leave a deep pit in the epigastrium. At the same time the intercostal spaces deepen and the supra-sternal notch is depressed. The attack of dyspacea lasts from a few minutes to a quarter of an hour or longer. When it subsides the child's terror disappears; his breathing becomes less noisy and stridulous; his respiratory movements less laborious, and he passes into a state of comparative ease. Still, the breathing is rapid and audible; the nares work violently; some lividity remains in the face, and there is considerable recession of the soft parts of the cliest in inspiration. On examination of the chest, the breath-sounds are accompanied by a stridor conducted from the larynx, and this may completely conceal all natural vesicular murmur.

The attacks of dyspness return at short intervals, and are easily excited by movement or by anything which irritates or agitates the patient. The cough occurs frequently and is house and whispering. Sometimes the patient expectorates patches or shreds of false membrane; but unless the trachea be opened the child rarely expels enough of the obstructing substance to produce appreciable relief to his symptoms. At each recurrence of the dysputes the attack is more severe than before, so that gradually the child passes into a semi-asphyxiated state. Ho lies back with purple lips and livid face; his pulse is feeble, frequent, and very irregular; his breathing rapid and shallow, although his nares still work; his forchead clammy, and his extremities cold. He often moves his arms restlessly, and has heart's action may become very intermittent, a curious pause taking place between every two or three pulsations. On examination of the chest there is usually good resonance, except perhaps at the extreme base. The breathsounds are obscured by conducted stridor and may be accompanied by div rhonelius. If no operative procedure be attempted the drowsin as deepers into stupor, and the child sinks quietly or dies in a last struggle for

breath.

If at this stage the trachea be opened, the immediate effect of the operation is most striking. In a favourable case, where the trachea below the opening is not obstructed, the child is at once relieved from almost all his distress. Air again penetrates deeply into the lungs; the lividity disappears; the restlessness subsides; the breathing becomes natural; the nares cease to act, and the look of terror and suffering passes off and may even be succeeded by a smile.

When the disease thus attacks the larynx the duration is usually very short. From the time when the first signs of stridulous breathing are noticed to the end only a few hours may clapse. In other case, the child may live two or three days; but this longer duration is due to slower progress in the earlier part of the illness. When serious dyspnæs super-

weres the child, if not relieved by operation, seldom survives the next twenty four hours. Sometimes, however, if the false membrane is very hunted in extent, recovery may take place. In these cases the symptoms are seldom very severe, and in particular the attacks of dysphoea, if present at all, are mild and infrequent. The favourable change is marked by a less laboured character of breathing, a brighter look in the face, increased looseness and more natural quality of the cough, and a return of tranquility to the manner. Still, there is little doubt that many cases of supposed recovery from membranous croup are really cases of stridulous lary agits, which is a much milder complaint and rarely ends fatally.

In the malignant form of the disease the constitutional symptoms are very severe, and may be quite out of proportion to the amount of local lesion. Vomiting is usually frequent. There is often diarrhoea. The child is pale and haggard-Rocking, and seems stupid and drowsy. His skin is spotted with petechice. His pulse is rapid, small, and feeble. His feet and hands are cool and clammy, and even the internal temperature of the body schlom reaches a high elevation. Sometimes, indeed, it is normal or even subnormal. Thus a hitle boy, aged two years and a half, was admitted into the East London Children's Hospital with wash-leather-like explation on the fauces, great swelling of the cervical glands, and marked postration. In this boy the temperature never rose above 98.2, and a few hours before death was only 97° in the rectum. The child died two days after admission in a convulsive fit.

The false membrane is generally of a dirty-brown colour. Extension of the inflammation takes place rapidly into the nose; epistaxis often occurs, or there is a flow of thin blood-stained fluid from the nostrils. Sometimes the lachrymal duets become obstructed; the eyes then look watery, and false membrane may even appear on the conjunctive. The mucous membrane of the fawers may become ulcented or gaugerenous, and the smell from the mouth is very offensive. Harmourlages may occur from the gams and threat. The urine is often smoky and almost always albuminous. Delirium comes on followed by stupor, and the child dies exhausted.

Secretary Department.—Sometimes diphtheria occurs secondarily to some mente disease. Thus it may arise as a complication of typhoid fever, py emia, erysipelis, mensles, scarlatina, whooping-cough, or other form of acute illness. In these cases the amount of false membrane is usually limited in extent, but the inflammatory process is apt to run on into ulceration or even gangrene. The ulcera are rounded or simious, and may penetrate deeply into the tissues. Gangrene is not common. It usually occurs in the tonsils and pillars of the fauces. These parts become gray and exhale a most offensive odour. The sloughs separate after a time and leave grayish, unhealthy-looking pits which in favourable cases may heal, with considerable contraction of tissue in the affected parts.

Completions.—The ordinary course of diphtheria may be interfered with by various complications which delay recovery or unfavourably influence the issue of the illness. The occurrence of albuminuria cannot be looked upon as a completation. This symptom is found in mild as well as in severe cases, and is far more often present than absent. It appears to be the consequence of elimination of the poison by the kidneys, and has probably little influence on the prognosis. The complications which will be considered consist of the formation of false membrane in unusual situations; the occurrence of inflummation of special organs, such as the lungs, the heart, and the pericardium; the formation of a thrombus in the heart or large vessels; and the appearance of paralysis.

ĩ

Nasal diphtheria has been already referred to as constituting a symptom of the malignant type of the disease. A diphtheritic coryza is, however, sometimes seen as a complication of milder attacks. In these cases a thin discharge flows from the nostril, usually at first on one side only. It produces some excertation of the margin of the masal opening as well as of the upper hip, for these parts are often red and raw-looking. No doubt the presence of false membrane in the nasal passages is a sign of the utmost gravity; but I have known coryza with excertation of the nostril to occur in cases of a comparatively mild nature without producing an unfa-

yourable influence upon the course of the illness.

Sometimes in epidemics of diphtheria more unusual manifestations of the disease are met with. The false membrane may form upon the cotjunctive, the external auditory meatus, the outlets of the vagina and retum, upon the glans penis, and upon any wounds or abunded surfaces present on the skin. Often after tracheotomy the edges of the wound quickly become covered by the diphtheritic exudation. These executional seats of the false membrane may be the only local signs of the disease to be discovered, or may be accompanied by the usual affection of the thront. When a wound or abraided surface becomes attacked by the diphtheritic process, its borders become purple red and swollen, and the surface pours out a profuse, watery, fetid discharge. Soon a pellele forms on the sore, and from this point the disease may spread over the skin. Thus the discharge irritates the neighbouring cutan our surface; little vesicles form, break, and become themselves converted into diplithe ritic sores covered by the characteristic false membrane. In this way, according to Trousseau, the diphtheritic process may spread over a large extent of surface; and the layers of membrane, constantly moistened by the discharge, undergo rapid decomposition, and give out a most offensive gaugrenous steach. The general symptoms in such cases are very severe, and the patient usually sinks rapidly from exhaustion.

Inflammatory complications sometimes arise in the course of diphtheria. After the operation of tracheotomy for membranous croup, it is unfortunately far from uncommon to find the temperature rise to 102° or 103°, and to discover, on examination of the chest, all the signs of acute consolidation of the lung. Sometimes, however, the pulmonary lesion is an early complication. In any case it greatly lessons the child's chances

of recovery.

Inflammation of the pericardium and endocardium are occasional complications of the illness. Pericardius occurring alone will probably be overlooked without a careful examination of the precordal region. Endocarditis also may give rise to but few symptoms, and is often only discovered on examination of the body after death. We must however, be on our guard, and avoid attributing to endocarditis the lineartomatous beading of the intral valve described by Parrot. (See page 546.)

When a thrombus forms in the heart, death may occur cather suddenly at the moment of formation of the coagulum, or gradually after an interval of much anxiety and suffering. Usually the symptoms appear quite suddenly, and at a time when the child seems to be going on favourably to convalescence, or even after recovery is far advanced. If the formation of the clot does not bring the case to a sudden termination, marked dyspiners is

one of the earliest signs of the accident.

Dyspiners arising from want of blood in the pulmonary circulation is shown, as Dr. Richardson has pointed out, by symptoms very different in character from those due to an obstructed larynx. In the first case, al-

though the breathing is laboured, the lungs are full of air and may even be distended with it sufficiently to produce in the younger subjects a peculiar prominence in the anterior part of the chest. There are no signs of imperfect aeration of blood, but all the symptoms indicate obstruction to the circulatory current. Thus the lips and checks are blue; the jugular veins distended; the heart-impulse quick, feeble, and irregular. The body is cold and pale; it may be marbled, especially at the extremities; and there is intense anxiety and constant movement. When death occurs, the heart crases to act before the respiratory movements have come to an end.

On the other hand, when apnoa occurs from laryngeal obstruction the symptoms all point to imperfect acration of blood. The surface of the body is diskly instead of pule; the heart-sounds are clear; the cardiac impulse is feeble but rarely tumultuous; the lungs are congested but not emphysematous; there is great recession of the epigastrium and soft parts of the chest at each inspiration; the muscles are convulsed; and the breathing

stops before the movements of the heart cease.

Sud ien death is due in most cases, probably, to the rapid formation of a clot in the right side of the heart. It may be also the consequence of paralysis of the cardiae branches of the par vagum; but in cases where the su blen and has been attributed to this cause, a granular degeneration of the cardiac muscular fibres with softening of the walls and dulatation of the cardiac muscular fibres with softening of the walls and dulatation of the cardiac failure is the result of these changes. According to this observer, dangerous weakness of the heart from this cause is indicated by gallop-rhythm of the heart-sounds with weakness of the impulse and irregular traindous contractions. Vomiting, due to a reflection of the disturbance to other parts of the pneumogastric nerve, indicates that the danger is pressing. Other observers have noted precorded distress, extreme dyspans. Am illness and irregularity of the pulse, and attacks of palpitation alternating with slowness of the pulsations. H. Weber has found the pulse fail to twenty-right or even sixteen beats in the minute.

In a certain proportion of cases of diphtheria convalescence is interrupted by the appearance of paralytic lesions. The frequency with which this complication is found to occur has been variously estimated. Probably it depends in some measure upon the character of the epidemic. The degree, too, to which the nervous system is affected is subject to great variety. In some cases the lesion is so trilling as scarcely to attract attention. In others it amounts to well-defined and general loss of power. Taking mild and severe forms together, the proportion of patients who suffer from the complication is probably one in every ten or twelve cases.

D.phtheritic puralysis is not limited to cases in which the throat affection has been severe. The slighter forms of the distemper are as hable as the more serious forms to be followed by the nerve-lesion. Nor is its occurrence determined by the seat of the diphtheritic manifestation or the presence or absence of albuminuria. It may follow in cases where the false membrane has been limited to the skin, and in cases where albuminuria has not been observed. The period at which the paralysis appears is also subject to variety. From an analysis of sixteen cases Dr. Abercrombic found that the piralytic complication might appear from two to five weeks from the beginning of the illness. Some has noticed it as early as the second or that day of the disease, but states that it generally comes on from one to two weeks after the disappearance of the false membrane. According to this observer, when the paralytic symptoms appear early they usually develop gradually and spread slowly from one part to another.

When the onset is retarded, the development of the paralytic phenomena

is much more rapid and regular.

The motor lesson may be preceded by increase of languor and irritability of temper. Dr. Hermann Weber has noticed in many cases a marked diminution in the rapidity of the pulse. The paralysis is symmetrical as a rule. Usually it begins either by loss of power in the soft palate and plarying or, by what is equally common, paralysis of accommodation of the eye. It is noticed that when the child attempts to swallow he coughs volently and fluids return through the nose. His voice has a masal quality and he shores in his sleep. If the patient is old enough we can ascertan by inspection that he has no power of elevating the uvula, and parliags also, that there is more or less anosthesia of the fauces. If the ocular muscles are affected the child complains that he sees double. Reading is difficult or impossible, and sometimes there is an evident squint. In rare

cases there is temporary blindness.

When the pharynx is first affected the paralysis may remain limited to this part. If it be complete, the power of swallowing is lost and food car. no longer be propelled down the gullet. The food taken is found to colleet in a pouch formed by yielding of the walls of the osophagus. In such cases nourishment has to be conveyed to the stomach by mechanical means The use of the stomach-tube is of the greatest service in these cases, both as a method of maintaining nutrition and also as a means of preventing the entrance of food into the glottia. From the pharynx the paralysis may spread to other parts. The tongue and hps may become affected so that the child dribbles and speech is greatly interfered with. Loss of power may also be noticed in the limbs, the neck, and the back. Of the limbs, the legs are affected more commonly than the arms. The paralysis almost invariably takes the form of paraplegia, for even if the weakness is more marked on one side, it will be usually found on examination that the side which appears to be sound has not entirely escaped. The motor paralysis may be accompanied by some disturbance of sensation. In rare cases control over the sphineters is lost. Paralysis of the respiratory muscles sometimes occurs. There is then dyspnea: mucus collects in the lungs, for there is no power to cough it up; and the child usually dies suffocated If the diaphragm is paralysed the child has attacks of dyspnon, coming on at the slightest excitement or when an attempt is made to cough. Death may ensue in such an attack. The most moderate catarrh in such a condition adds an additional element of danger to the case.

Besides these forms of motor lesion, sudden death, attributed to paraly-

sis of the heart, has been already referred to (see page 99).

Diphtheritic paralysis is fatal only in exceptional cases. When death occurs, it is usually the consequence of cardiac thrombosis or syncope, less commonly it is due to impaired nutrition through difficulty of swallowing, or to nervous exhaustion. Recovery is the rule, and the rapidity with which this takes place is very variable. The course is much shorter in cases where the paralysis is limited to the palate. This usually passes off in a fortinght or three weeks. When the loss of power becomes general, a cure is effected with much greater difficulty; but even in those cases it seldem lasts longer than three, or at the most four months. Sometimes the limbs recover their power very rapidly while the plantynx remains obstinately paralyzed for a considerable longer period.

Diagnosis.—When diphtheria gives rise to well-marked symptoms, its detection is easy. The tough-looking gray or fawn-coloured membrane in the throat, the redness and swelling of the fauces, and the enlarged cer-

vical glands are sufficiently characteristic. In tonsillitis the uvula is not swollen, and the whitish exudation occupying the mouths of the crypts, and sometimes spotting the surface of the tonsils, is very different in appearance from the consistent false membrane of diphtheria. It never forms a coherent layer, and never invades the nares or the larynx. Moreover, in quinsy, although the swollen tonsils can be felt externally, the cervical glands are seldom appreciably enlarged. If, in diphtheria, the exudation is soft and pultaceous, instead of being coherent and tough, there is still enlargement of the superficial cervical glands, and the general symptoms indicate profound depression. Any huskmess or weakness of the voice implies extension of the inflammation to the larynx, and points unmistakably to diphtheria. The difficult cases to detect are those in which the throat affection is imperfectly developed, or is slow to appear. At first, a thing may be noticed but redness and swelling of the fauces, with some discomfort in swallowing. In such cases until the false membrane appears, we cannot say that we have not to deal with an ordinary inflammators were throat; for although the weakness and pallor of the patient are usually out of proportion to the apparent mildness of the local affection, no positive inference can be drawn from this discrepancy, as some chiliren are more depressed than others by a trifling ailment. If such a conlation be met with at a time when diphtheria is known to be prevalent, we should regard the symptoms with much apprehension. Indeed, in any case of sore throat, if enlargement of the glands of the neck can be discovered, we should withhold a positive assurance that the complaint is one of little consequence. Sometimes the appearance of albumen in the urine comes opportunely to clear up a doubtful case. Sometimes after the terministion of an ill-defined angina, the occurrence of paralysis throws a new hgist upon the past indisposition.

Laryngeal diphtheria, or membranous croup, may be confounded with stradulous laryngates, with abscess of or about the larynx, or with retropharyngeal suppuration. The distinctive points between these diseases will be referred to in the chapters treating of these affections. It is possible that a foreign body in the air-pussages may be mistaken for croup; but the attack of dyspinea produced by this means comes on quite suddenly and follows at once upon an attempt to swallow. There is spassible cough but no hourseness; and the first paroxysm of suffocation and cough is usually succeeded by a period of quiet in which, for the time, the

breathing is fairly easy and the child seems to be well.

It is very important to be able to discriminate between cases in which tracheotomy may be expected to succeed and those in which no permanent good can be anticipated from the operation. Dr. George Buchanan, of Glasgow, has pointed out that in cases where the air-passages below the point of obstruction are free, and the lungs are in a normal condition, there is great recession of all the soft parts of the chest. At each inspiration the intercestal spaces fall deeply in, and the epigastrium forms a deep bollow. If, on the contrary, the smaller bronchial tubes are full of mucus or diphtheritic exudation, the movements of the chest-wall are impeded, and the chest is puffed out so as to resemble the distended thorax of chronic emphysems.

If the patient be seen for the first time when the paralytic symptoms have declared themselves, the history of the attack will declare the nature of the disease. Even if, as sometimes happens, the throat affection has been too slight to constitute a regular illness, we shall find, probably, that other members of the bousehold have suffered from diphtheria, and that,

in the child himself, any signs of general nerve-lesion have been preceded by a nasal tone of voice, some trouble in swallowing, and the occasional

return of fluids through the nose,

According to M. Landrouzy, if a child who is convalescent from dipterer begins to suffer from attacks of dyspanea excited by an attempt to cough, or by any small vexation, we should suspect paralysis of the displacement in the absence of any more evident explanation of the distressing

phenomenon.

Prognosts—Even in the mildest attack of diphtheria we must be guarded in the expression of our opinion as to the probable assue of the illness. Indeed, it is wiser to express no opinion upon the matter, but to confine ourselves to reporting the daily progress of the case, and speaking cheerfully so long as no symptoms arise indicative of danger. We can never feel certain that the inflammation may not spread to the larynx, or that other ill consequences may not ensue, however favourably the disease may appear to be going on. Caution in prognosis is especially necessary if the epidemic is a severe one, for outbreaks of the distemper vary greatly in the severity of type of the illness, and in some the mortality is much greater than it is in others. The age of the patient is also an important item to take into consideration, for a young child has fewer clances of recovery than an older one.

Different dangers are to be apprehended at different periods of the disease. During the first week we dread lest the inflammation should spread to the larynx, or lest the child should die from septicemia. We therefore notice carefully the character of the breathing and the quality of the voice. If the breathing become shrill and the movements laboured or the voice get weak or husky, we can have no doubt that the larynx is becoming involved. So, also, in cases where the false membrane is thick, pulpy, and putrescent the occurrence of shivering or a sudden rise in the temperature, with a dull yellow that of the face and a rapid feeble pulse, makes us fear that the blood is becoming possoned by absorption from the affected mucous membrane. Dr. Jacoby has pointed out that in hasal diphtheria septicamia is especially liable to occur. In this form of the disease, therefore, the regular use of disinfecting injections is imperatively

called for.

After the first six or seven days the child is in danger of death from syncope, from electing of blood in the heart, and from inflammatory complications. At this time we carefully watch the pulse. If this fall notably in frequency and strength, especially if at the same time comining occur and be often repeated, the danger is imminent. At this period of the discuss harmorrhages sometimes come on as a result of profound blood contamination and are very exhausting. Other signs of bad augury are a very feeble frequent pulse, cardiac dysphora (see page 98), general swelling of the neck, great prostration, and delirious wanderings. Albuminutia, unless excessive, is not necessarily a grave symptom.

When the diphtheritic exudation invades the trachea the danger is very serious; but if the operation of tracheotomy be performed in time, and a marked retraction of the chest-wall indicates that the smaller tubes are free below the point of obstruction, and that air, if admitted, will be able to penetrate to the alveoli, recovery is far from impossible. After the operation, success depends chiefly upon the child's capability of taking and digesting his food, and upon the lungs remaining free from pneumonia. If there is difficulty in administering nourishment, the child can be still fed through the stomach-tube; but loss of appetite usually implies feeble di-

gestive power, and the prospect is not favourable. If pneumonia occur, the

prognosis is gloomy.

After the end of the second or third week nervous symptoms may be expected. In these the prognosis is favourable. It only becomes serious when the lesion is widely diffused, when all the muscles of deglutition are affected so that swallowing becomes impossible, or when the diaphragm and respiratory muscles are attacked. No child, however, should be altowed to due of starvation, for nourishment can always be administered at regular intervals through the stomach-tube passed through the nose.

Treatment.—Diphtheria is an infectious disease, and the ordinary precautions must therefore be taken against its spread. The sick room should be divested of carpets, rugs, curtains, and superfluous furniture; and proper measures should be taken to disinfect all discharges from the patient

before removal.

The child must be kept quiet in bed. It is well to place him in a tent bedstead and to envelop him in an atmosphere of steam impregnated with thyin dicreasote, or other disinfectant. This may be most conveniently done by the use of the "croup kettle" designed by Mr. R. W. Parker, on the principle of Dr. Lee's "steam draught inhaler." Creasote or carbolic acid may be added to the water in the kettle in the proportion of twenty drops to the part, or a saturated solution of thymol can be made use of. So many technical matters have to be attended to in the treatment of these cases that whatever be the age of the child the assistance of a skilled nurse is indepensable. Amateur nursing, seldom if ever satisfactory, is here a serious disadvantage to the patient, and introduces into the case an additional element of danger.

The treatment of the disease comprises general and local measures, and

these are of about equal importance.

The general treatment consists in employing every means to support the strength of the child, so as to enable him to struggle successfully against the exhausting influence of the disorder. The patient should be supplied with food of a nourishing and digestible kind. Strong beef essence, yolk of egg, milk thickened with Chapman's entire wheat flour baked in an oven, pounded underdone meat made fluid with strong meat juice or meat essence, all these are very useful. Alcohol must not be forgotten, and will often have to be given in full doses. Old brandy or whiskey, with or without yolk of egg, should be given at the first sign of feebleness of the pulse. A child five years of age will take with benefit thirty drops of good brandy every two hours. In infants white wine whey given freely is very useful. In giving stimulants we must be guided by the state of the pulse, or in infants by the condition of the fontanelle. As long as the pulse is firm or the fontanelle little depressed, alcohol is not required, when the pulse gets soft and compressible, or the fontanelle sinks, stimulants must be given without delay. It some cases they will be required from the first.

In the selection of medicines preference should be given to such as do not cause depression. In diphtheria there is a tendency to failure of the heart's action; and this tendency is likely to be favoured by the use of depressing remedies, such as the solicylate of soda, which has been sometimes recommended. A simple febrifuge may be given while the temperature is high and the skin dry; but directly the strength shows signs of failing, iron and quinine should be resorted to. The perchloride is perhaps as good a preparation as any other. Ten or tifteen drops of the tincture may be given with one grain of quinine every three hours to a child five years of

age. Much larger doses of the drug are often recommended; but young children vary greatly in their capacity for benefiting by chalybeate remedies, and in weakly subjects the stomuch may be reachly deranged by an excess of the medicine. Now it is of the first importance to maintain the digestive power, as incomparably the best tonic for a child is nourishing food.

Instead of quinine, chlorate of potash is often conjoined with the iren: but this remedy should be given with caution as it has a depressing elect on some children. It is well to begin the treatment with a mercural purge, such as gray powder with jalapine, but the aperient need not be

afterwards repeated.

In the use of local remedies we have to fulfil three indications—to arrest the spread of the false membrane; to promote its removal, and to present septicemia from absorption of putrescent matters in contact with the tissues.

Many measures have been employed to prevent the extension of the local lesion in the throat. At one time strong cauterising agents were resorted to to effect this purpose, such as the solid nitrate of silver, equal parts of strong hydrochloric acid and honey, and the strong solution of perchloride of iron. The repeated use of these agents is now almost universally condemned, but one thorough swabbing of the throat is stall advocated by some writers. I have occasionally employed equal parts of strong perchloride of iron solution and glycerine, and have thought that used efficiently, once for all, the application has been followed by benefit Many writers, however, deprecate the use of these powerful agents; and certainly, since I have abandoned their employment, I have not found the

disease less tractable or more dangerous to life.

To promote the liquefaction or removal of the false membrane many agents are employed. Rough tearing away of the diphtheritic exadation is injurious as well as useless; but gentle measures to further its destruc-tion are decidedly beneficial. To be of service, however, the application must be used repeatedly, and can be applied with perfect efficiency in the form of a spray from one of Siegel's spray producers. Lame-water, alone or with carbolic acid (twenty drops to the ounce of hine-water), liq. potassa-(twenty drops to the ounce of water), boracic acid (a scruple to the ounce), lactic acid (twenty-six grains to the ounce), benzoate of soda (one scruple to one drachm to the ounce), all these are of service, and the addition of glycerine (half a drachm to the ounce) increases the officacy of the solutions. Lotions of chlorate of potash (ten grains to the ounce) and of salicylic acid (three or four grains to the ounce) are praised by some, as well as dry maniflations of flour of sulphur, of alum, and of tanian. These latter have, however, the disadvantage that they cannot be employed without distressing the patient. If thought more desirable, any of the above liquid preparations may be used with a brush, but this method of employment is distressing, and except perhaps in the case of infants, presents no special advantage.

The third indication, viz., to destroy the poisonous products of putrefaction so as to prevent absorption and blood contamination, is partly affected by the use of many of the preceding agents. But besides these, special disinfectants may be sprayed into the throat, such as the solution of chlorinated soda or lime diluted with water (half a drachm to the ounce), permanganate of potash (five grains to the ounce), sulphurous and, pure or diluted with an equal quantity of water, etc. The comfort of the patient is also promoted by the use of the steam kettle, as already recommended, and by warm applications externally to the throat. If the child be old

enough, he may be allowed to suck lumps of ice.

In most diphtheria, where septicemia is especially to be dreaded, the thorough cleaning of the nasal passages with a mild disinfecting solution should never be omitted. The importance of this measure is insisted upon by Dr. Jacobi, who recommends that the process should be carried out by the fountain syringe wherever practicable. Failing that, an ordinary ear syringe can be made use of. He directs that the injection should be repeated as often as every hour, and that if the obstructed nostrils resist the passage of fluid, the coarser matters must be removed by a probe or forceps. Dr. Jacobi states that these injections, efficiently employed, give great relief to the patient and rapidly reduce the size of the swellen glands. He advises a warm solution of carbolic acid (two to four grains to the

ounce, or, if there is no fector, of lime-water.

When the discuse invades the larvex the danger is at once imminent, and the question of operative interference has to be considered. In cases of larvageal diphtheria true membranous croup), tracheotomy is the only hope left to ne-the child's last chance for his life. Directly, therefore, we feel sure that the buyny is involved, the operation should be undertaken without unnecessary delay. It must be remembered, however, that dyspacea alone is not always a sufficient indication for this step. As has been before explained (see p. 99), lividity and laboured breathing are sometimes due to an impediment to the circulation of blood through the lungs. In such a case there is no want of air, and opening the laryax will bring no relief to the child's distress. The signs by which these two very different conditions are indicated have been already enumerated. When, therefore, we notice that the respiratory movements have become laboured, with great recession of the epigastrium and the soft parts of the chest in inspiration; that the breathing is hissing and stridulous, the voice whispering, and the cough husky and stiffed, the operation should be no longer postpined. We have nothing to hope for in delay; on the contrary, the earlier the tube is introduced into the traches, the sooner will the child's suffering be relieved and the better be his prospect of a cure. The success which often attends the operation of tracheotomy in membranous croup is very encouraging, and even in the case of an infant we should not hesitate to have recourse to it. Even at a later stage, when the child seems to be at the last gasp, the operation should still be undertaken, for nothing short of actual death can render it hopeless.

In performing the operation, if the asphyxia is far advanced ancesthetics will be unnecessary. If the lividity is not marked, chloroform should be administered, and if the child be made to inhale it gradually so that he does not breathe in too large a volume at first, the ansesthetic may be given without fear. The details of the operation, as they come under the department of the surgeon, need not be here referred to; more especially as they will be found recorded at length in all works on practical surgery. It may be only remarked that the size of the tube to be employed should be the treest which can be introduced without violence; that it should be as short as is consistent with safety; and that before its introduction the tracked in a warm solution of carbonate of soda through the opening. The importance of this pressution has been strongly insisted upon by my col-

league Mr. Parker in his well-known treatise.

The relief afforded by the operation is usually complete. If the difficulty of breathing still continues, it is a sign that the traches is obstructed below the opening, and that there is probably extension of the false membrane far down the ramifications of the bronchi. The after-conduct of these cases is of the utmost importance, as success depends upon judicious nursing and scrupulous attention to small points of treatment. Our object is to furnish a constant supply of properly prepared air to the lungs. The utmost care has therefore to be taken to maintain the inspired air at a suitable temperature and degree of moisture, and to see that the tube is kept in place. Moreover, the strength of the child has to be supported, and the treatment of the constitutional disease to be continued.

The child should remain in his tent bedstead, in a room of the temperature of 70; and the croup-kettle must be kept in action on a side table so as to moisten the air he breathes. A disinfectant should be always alded to the water in the boiler, as already directed. The kettle must not be placed too near the bed. If the air is kept constantly saturated with repour, the excess of moisture tends to depress the child. Mr. Parker's rule is a good one, viz., that we should be guided by the amount of trached secretion. If this is small, the amount of steam can be increased.

The wind-pipe and tracheotomy tube must be kept patent. Free secretion is to be desired, but this must not be allowed to accumulate so as to interfere with the passage of air. It is important to apply weak alkaline solutions, such as the bicarbonate of soda ten to twenty grains to the ounce) with a hand spray-producer at short intervals, so that the inhaled air may be saturated with the solvent. The spray at once produces free secretion into the windpipe; and the repeated use of this agent prevents the mucus from accumulating and becoming inspissated so as to block up the airpassages. It is curious to notice how the dry mucous membrane becomes almost instantly relieved by this means. After a few minutes' use of the spray, a feather soaked in the same solution must be passed into the traches through the silver tube, so as to clear away loosened membrane and mucus. The introduction of the feather causes spasmodic cough, but this is not to be regretted, as the violent expulsive action usually relieves the patient of large portions of membrane, and greatly aids in clearing the trachea. If signs of obstructed breathing are noticed at any time, we may conclude that either the traches or the tracheotomy tube is becoming obstructed, or that the latter is displaced. Measures must then be taken at once to remedy the fault.

The macr tube should be removed every hour or two and cleaned with a feather dipped in the warm alkaline solution. The outer tube will require cleaning only once in the twenty-four hours. When it is removed, advantage should be taken of the opportunity to pass the moistened feather upwards into and through the glottis, so as to clear the upper part of the windpipe. At this time, also, the wound can be examined for any unhealthy appearance. As a rule, the outer tube can be easily taken out and replaced, for the tissues around the opening soon become matted together by inflammatory exudation, and the orifice remains patent after the tube is withdrawn. After each cleaning the tube should be replaced by another of different length, so that the child may wear a short and a long tube alternately. If the tube be of silver, it should be examined for black discolourations, as these are due to morbid action at the corresponding part of the wound, and will therefore, as Mr. Parker has pointed out, be often valuable guides in indicating the parts to which our attention should be directed.

After a few days, when fresh membrane has ceased to be formed, we may make trial from time to time of the child's power of breathing through the glottis by closing the external wound with a finger. At first the

breathing is laboured, especially in inspiration, but in most cases the

Lottes soon becomes accustomed to act again as an air-passage.

While the shove treatment is being carried out, the strength of the child must be supported by judicious feeding. Strong meat assence, panieled meat, eggs, andk, strong meat broths thickened with arrowroot or eggs, and flavoured if desired with turnip, should be given at regular intervals. Sometimes there is difficulty in persuading the child willingly to take sufficient nourishment; and sometimes the power of swallowing is impaired from paresis of the muscles of the pharyux. Sometimes, also, there appears to be loss of sensibility of the glottis, so that articles of food taken appear at the wound in the air-pipe. If necessary, therefore, food must be conveyed to the stomach by an elastic tube passing through the nose (see introductory Chapter, page 15). By this means the patient can be fed efficiently every three or four hours. Internal remedies, with the exception of alcohol, are better discontinued at this time. It is wiser to hant conselves to the local measures which have been described for the relief of the local disease, and to trust to regular feeding and alcohol to support the strength of the patient and enable hum to struggle successfully against the constitutional disorder.

The trachectomy tube should not be allowed to remain in the trachea a day longer than is necessary; for besides that it is not well to allow the glottis to continue a long time inactive, too persistent retention of the tube may be followed by ulceration about the wound, necrosis of the rings of the trachea, and other accidents. In finally closing the wound certain difficulties are sometimes met with. The child having become accustomed to the use of the tube, and having a keen recollection of his sufferings before its insertion, is often nervous and apprehensive of a return of his dyspinora. The very dread may be sufficient to interfere with the normal action of the larvingeal muscles. Before removing the tube altogether many attempts should be made, by withdrawing it temporarily and closing the opening with a pad of lint, to accustom the child to breathe without its laby. He should be also in ide to articulate under the same conditions of c, while the opening is closed), so as to bring the muscles of his larying again

into action.

The accidents which often interfere seriously with the final withdrawal of the tube are: inflammatory hypertrophy of the vocal cords, adhesion between the cords, granulations growing from the tracheal wound or from the posterior wall of the windpipe, paralysis of the posterior cricoaryta nood muscles, spasm of the glottis, cicatricial narrowing of the trachea, Sometimes at is only after much difficulty that the proper function of the deutsed largus is restored. Such cases are, however, exceptional. Usually after a few days the child becomes accustomed to do without the help of the tube and all apprehensions of a return of his dyspace may be laid as de-

The chief danger and common cause of death after tracheotomy in membraneus croup is the occurrence of pneumonia. If this unfortunate complication arise, warm poultices must be kept constantly applied to the chief, and stimulants must be given freely.

If diphtheria of the external wound occur, it is best treated by a careful attention to cleanliness, and by painting the wound with a solution of

lactic acad (twenty-four grains to the ounce).

In the paraives which often follows diphtheria the child should be removed to a brazing seasade residence, and while there should be regularly shampooed and be given baths of the sea-water. If a dip in the sea is too

rigorous a shock for his weakened frame, the douche may be employed in the house after suitable preparation, as directed elsewhere (see Introductory Chapter, page 17). Quantum, iron, and strychnia are useful in these cases, and the child should pass as much time as possible out of doors. Regular faradisation is of service, especially in cases where the loss of power affects the muscles of the larynx or those employed in respiration. In cases where there is complete paralysis of the muscles of degliatition, and consequent inability to swallow, the child must be fed regularly with the stomach-tube passed through the nose. At the East London Children's Hospital many children have been saved by this means who were quite unable to take nourishment, and who without this help would certainly have died of unanition.

When a thrombus forms in the heart and gives ries to serious dyspara, the child should be kept lying down; hot bottles should be applied to a feet and if necessary to his sides; and diffusible stimulants must be given internally. Dr. Richardson speaks highly of the liq. ammonia: (P. B., of which a few drops may be given with five grains of iodide of potassum every alternate hour. If the heart's action appear to be failing, stimulants in large and repeated doses are indicated.

CHAPTER XL

ERYSIPELAS

Extractions is not often seen in childhood after the age of infancy has passed. For a short time after buth, however, there appears to be a special tendency, under favouring conditions, to suffer from this serious affection; and in lying-in hospitals the disease is a not unfamiliar one. Amongst will-to-do families crysipelas but rarely attacks the infant, and in children's hospitals, even in those where quite young infants are admitted, it

is exceptional to meet with an example of this form of illness.

derivation. Erysipelas is in all cases a general disease of which the derivation and its consequences are merely the local expression. The malaly most commonly affects new-born babies at a time when purperal fever is prevalent, and is most hable to happen during the first six weeks of life. It is then apparently the result of a similar affection to that which attacks the mother; and the illness almost invariably has a fatal issue. According to Trousseau, besides crysipelas, purulent ophthalmia and infective peritonitis are common under the same conditions, and the three diseases must be regarded as various manifestations in different subjects

of the same morbitic principle.

But besides special puerperal infection, other agencies will act as predisposing causes of the affection. Unhealthy conditions generally will do this, and the complaint has been known to follow exhausting deraugements and diseases, such as chronic digestive troubles and the acute specific fevers. In some cases, however, no such influences can be discovered to have been in operation. Such a case came under my own observation in my student days. A healthy infant of a week old had great difficulty in relieving his bladder, owing to a very narrow preputial orifice. The operation for circumcision was performed (not very wisely) by a young surgeon. Extensive eryspelas followed, starting from the wound, and in a few days resulted in the death of the patient. The child was being suckied by a healthy mother. The parents were of the poorer class, but seemed comfortably circumstanced; and their residence was clean, and certainly presented no obvious insanitary conditions. Possibly in this and similar cases the crysipelas owed its origin to the use of imperfectly cleaned instruments in the operation.

The exerting cause of the affection is usually traumatic. The crysipelus may follow the operation of vaccination, inflammation set up about the umbalicus, a burn, or the incautious application of a blister. It may develop around an intertrigio or attack a surface exceriated by the irritation of excreta. Some time ago a local outbreak of crysipelus occurring in a particular London district was traced to the use of a violet powder extensively adulterated with white argenic. Apparently idiopathic cases do, however, sometimes occur. Thus, Mr. Strugnell has reported the case of a male in-

fant, aged eight weeks, in whom a patch of ervsipelas appeared on the scalp and thence spread to the face, arms, and trunk. The child had suffered from no bruise or other injury, and nothing objectionable was decovered in the sanitary state of the house in which his parents were living.

Other cases of a similar kind are on record.

It seems possible that the milk of a mother who has lately suffered from erysipelus may communicate the disease to her sucking child. Dr Scholefield has reported a case in which a woman during a sharp attack of erysipelas of the face, neck, and scalp, gave birth to a son. As the labour progressed the crysipelas gradually faded, and when the child was born as trace of redness remained. The mother was warned not to nurse her child; but on the fourth day, as the secretion of milk was copious, he put the infant to the breast. Twelve hours afterwards a red blush appeared on the child's thumb and spread to the arm. This faded and the opposite arm became affected in the same way. Afterwards the same symptom appeared on one of the lower limbs, and in the end a large shacess formed over the sacrum and the child died. The mother had no re turn of the crysipelas after delivery.

This was not a case of puerperal crysipelas in the mother, for the disease had not only preceded labour but had completely disappeared by the time the child was born. It seems probable that the poison was communicated by the mother to the infant through the milk from her breast. At any rate, it is difficult to say in what other way the infant could have

contracted the disease.

Morbid Anatomy.—In the skin the inflamed surface is red, hard, and brawny, with a well-defined margin. The redness disappears on pressure, and the hardness is due to accumulation of scrum, lymph, and corpuscies in the substance of the cutis and tissue beneath it. If the orderna be copious, the part is dull red in colour, soft to the touch, and pits on pressure. The area of inflammation rapidly extends to neighbouring parts, and as it spreads the skin first attacked becomes less tense and browner in colour. Sometimes the skin affection disappears from one part of the body and reappears on another without spreading along the surface. Thus, it may attack one limb, then fade in its first situation and break out on the corresponding limb of the opposite half of the body.

As a result of the inflammation, abscesses may form in the subcutaneous tissue; and sometimes sloughing may occur in the skin or areolar tissue. Often vesicles or bulke form on the inflamed surface, especially in

the severe cases where there is subcutaneous sloughing.

In most instances of crysipelas in the infant, adjacent parts share in the inflammation of the skin. Peritonitis is common, even when the dermatitis does not occupy the abdominal parietes. There may be also inflammation of other serous membranes—the pleura, the pericardium, and the cerebral meninges. Sometimes the inflammation spreads from the skin to other parts by direct continuity. Thus, it may pass into the ear by the auditory means, into the nose and throat by the mouth, narcs, and lachrymal ducts. In other cases, the disease begins in these deeper parts and extends to the skin by the same channels. In addition to the above morbid appearances evidence of phlebitis, pneumonia, and enteritis is often observed. Lately micrococci, arranged in clusters, have been discovered by Fehlerson in the lymphatic vessels of the affected portions of the skin. This observer has even succeeded in artificially cultivating the organisms on gelatine, and in the course of two months reared fourteen generations of micrococci. Some of these cultivated micro-organisms he inoculated into animals and others

into the human subject. In almost all cases a typical crysipelas followed the operation in the person or animal experimented upon.

the operation in the person or animal experimented upon.

Symptoms.—The disease presents different characters according to whether it arises as a consequence of puerperal infection or is induced by

other causes.

In the first case the general symptoms are usually violent from the first. A patch of bright reduces appears on some part of the abdomen, usually about the pulses. The part looks somewhat swollen, feels hard and brawny, and has a well-defined margin. The patch may be of limited extent, but there is high fever, and the infant looks ill, is restless, cries frequently, and is evidently in great pain. By the next day the area of redness has become widened; the fever continues; the fontanelle is depressed, and the patient sleeps little and is very restless and feeble. The ervapelas continues to extend. It passes downwards to the lower limbs and upwards over the trunk; the belly usually becomes fuller and may be tympaintie; vomiting and diarrhea come on, and a jaundiced hue of the skin may be observed. After a few days, the child falls into a state of collapse and death may be preceded by convulsions and coma. In this form of the disease the duration is sometimes very short. A child who appears to be healthy and vigorous when first attacked rapidly falls into a state of prostration and may die in a few days. The illness may, however, last for a longer time. The colour of the inflamed surface then becomes deeper and more purple, bullse appear on the surface, abscesses form in the subcutaneous tissue, or gangrenous aloughs may destroy considerable portions of the skin. Infants attacked by the puerperal form of crystpelia are usually under two weeks old, and the illness is almost invariably fatal.

When crysipelas occurs as a result of other causes than puerperal infection the early symptoms are less violent. The local affection generally begins about the genitals, the pubes, the anus, or the lower part of the also ones, and spreads thence in various directions. When it extends wild by, the purts of the skin first affected become paler, but are liable at time to a return of the redness. The child has a pale pinched face, but may continue to take his food, and his digestion is often fairly good. In other cases, he refuses the bottle or breast, and may be troubled with frequent veniting or looseness of the howels. The temperature is high, at night it uses to 103° or 105°, sinking to 101° or 102° in the morning.

Complications often occur in these cases. Abscesses may form in various parts of the body; gaugernous alonghing may attack the skin; pneumonia may occur; or the inflammation may pass directly to the peritoneum through the recently healed umbilicus, or to the laryny and throat. An infant under say months old was brought to St. Thomas Hospital and a limited, under Mr. Croft, for crysipelas following vaccination. When seen, the whole cervical region and part of the chest were the seat of odematous crysipelas, and there was great dyspines without symptoms of croup. The child was placed in a warm bath and a dose of ipecacuanha wine was given to produce vomiting. These measures relieved the child for a time, but in the evening the dyspines returned with such intensity that tracheotomy was performed by the Surgical Registrar. After the operation the infant coughed up small pieces of cartilage—probably from the rings of the traches. Eventually he recovered.

Whether the disease be eliopathic or arise from traumatic causes its greaty appears to be the same. In the first case the appearance of the special symptoms is often preceded by signs of derangement or sluggishness of the digestive organs. In Mr. Strugnell's case, before referred to an infant of eight weeks old had been a fairly healthy child, but for ter days or so had been passing very firm, pale, pasty-looking motions. The child was suddenly taken with severe symptoms, and when first seen was lying with his head thrown back and his thumbs twisted inwards upon his palms, but there was no retraction of the abdomen or strabsmus The pupils were equal and acted to light, the pulse was rapid, the temperature was normal. On examination slight cedema of the scalp was noticed on the occipital bone, but there was no redness. On the next day the cedematous part was red. On the third day the cerebral symptoms had subsided; but the crysipelas had spread to the forehead and down the back of the neck. Afterwards it extended over the face, arms, and truck A vesicle the size of a filbert and filled with clear serum formed over the left elbow, and another appeared a little later on the thigh. As the disease advanced, the abdomen became distended and tympanitic, and the breathing oppressed. No mischief was discovered in the chest. The child sank and died on the seventh day.

In this case the early cerebral symptoms (retraction of the head and twisting in of the thumbs) were probably symptomatic of the general disease and not of any special intra-cranial complication. They were of short duration and quickly disappeared when the skin affection became marked. The tympanites and embarrassment of breathing were, no doubt, due to the occurrence of peritonitis. Premomtory symptoms, such as were found in the above instance, are not common. Usually the first indication of all-

health is the occurrence of the cutaneous redness and swelling.

In traumatic cases the duration of the disease is often considerable. The illness may last two or three weeks, or even longer. Recovery is not a frequent termination, and usually death is brought about by one of the many complications to which these cases are liable. If none of these occur, the case may end favourably, even although the crysipelas has spread crtensively and involved the greater part of the surface of the body. The subsidence of the cutaneous inflammation is followed by desquamation of the epithelium in the portions of skin affected.

Diagnosis.—The nature of the disease can scarcely be misupprehended. A patch on the skin of bright redness, which feels brawny to the touch and is perhaps redematous, spreads continuously over the surface, and is bounded by a well-defined margin—these local symptoms combined with the severe general disturbance and high fever, make the diagnosis of crysipelas an

easy matter.

Prognosis.—When erysipelas occurs in an infant of a week or fortnight old, as a result of puerperal infection, the prognosis is most scrious. Very few of these cases recover, although Trousseau has stated that in cases where abscesses have formed extensively, and in these cases only, he has known life to be saved. Consequently he regarded the occurrence of ab-

scesses as by no means an unfavourable symptom.

When the disease arises as a result of other causes the child's prospects are more hopeful, and are brighter in proportion to his age, his general strength, and the healthfulness of his surroundings. Of forty-three cases collected by Dr. Lewis Smith eighteen recovered; but of the cases of recovery in only one was the child younger than three months. If the disease attack an infant during the first two or three weeks after birth, death is almost certain. After the age of six months the proportion of recoveries is greater than that of the deaths.

In all cases the occurrence of a serious complication greatly reduces the

child's chances of escape, and if peritonitis occur, we can have little hope of a favourable assue.

Treatment —In cases where the disease arises from puerperal infection treatment has been found of little value. Alcoholic stimulation and the administration of ammonia and bark may be useful in supporting the strength, but local treatment of every kind appears to be useless. It would be advisable in these cases to make trial of benzoate of sodi—a salt which has been highly praised by Dr. Lehnebach for its value in puerperal fever in the adult. Two or three grains might be given to a child of a week old every four hours, and if the fever were very high, one or two grains of quipine might be added once in the day to a dose of the benzoate.

In cases where no puerperal infection is suspected, the child should be made to take the fincture of perchloride of iron in frequent doses. For an infant of three months old five drops of the remedy may be given in glycerme every four hours. At the same time the strength should be supported by a careful diet. If the child be at the breast, the mother's milk is no doubt the best food he can take. In addition, he may have a teaspsonful of the brandy-and-egg mixture two or three times a day if his fontanelle is greatly depressed. As long, however, as the strength continues good there is no necessity for stimulation. If the patient be hand-fed, care should be taken that his milk is diluted with barley-water or thickened with gelatine; and the stools must be inspected to see that undigested circl is not passing away from the bowels. If this be so, the milk should be diluted with half its bulk of barley-water or an ealers; and should be aromatised by the addition of two teaspoonsful of an aromatic water to the bottle. Mellin's food, white wine whey, etc., may also be given.

With regard to local treatment, innumerable applications have been recommended Most of these are sedative or antiseptic. Thus, the indamed part may be anointed with an ointment composed of equal parts of extract of belladonna and glycerine, and covered with cotton wool. The application of oil of turpentine has been recommended by Hastreiter. Cavazzani speaks highly of brushing the surface with a lotion composed of one part each of camphor and tannin to eight parts of ether. Painting with tineture of jodine is advocated by some, and with a solution of carbolic acid by others. Heppel states that the spread of the inflammation may be limited by painting the skin at the circumference of the patch, and for a finger's breadth on each side of it, with a ten per cent. solution of carbolic acid. The brush should be used until a distinct staining of the integument has been produced. The plan recommended by Hueter, of inje ting subcutaneously around the margin of the patch a three per cent. solution of curbolic acid, is inadmissable in the case of a young child, in whom symptoms of carbolic acid poisoning would be easily produced. Endeavors to limit the spread of the crysipelas, by a line drawn on the skin with nitrate of silver just beyond the margin of the inflamed patch, have been found to be useless. In the child such a proceeding is to be strongly deprecated, as its employment has been sometimes known to lead to the formation of troublesome sores upon the surface.

An important element in the treatment appears to be covering the indraned surface from the air. Recently, Mr. Barwell, reviving an old method, has found the utmost benefit to result from covering the affected area with a thick coating of common white lead house-paint, renewing the application as often as any crack appears on the surface of the paint. This plan of treatment seems not only to relieve the pain quickly, but also to reduce the temperature and favourably influence the general symptoms.

CHAPTER XII.

WHOOPING-COUGH.

Wиссетко-сочен, or pertussis, is an infectious disorder in which catarit of the air-развадев is combined with nervous symptoms which may assume very serious proportions. The affection occurs in epidemics and may attack the youngest infants: indeed, sometimes it appears immediately after birth. In such young children whooping-cough, even when not of a grave type, may cause serious consequences. It is principally dangerous, bowever, through its complications. These are numerous, and often appear towards the end of the disease, when the patient's strength is reduced by

the length and severity of his illness.

Causation.—The disease usually occurs in epidemics, and appears to be eminently infectious. The channel of infection is the breath and expecteration; and the virus is capable of being conveyed by the atmosphere er even by the clothes. Children of all ages are very susceptible to the infectious principle. The disease is excessively common under two years of age, very common, even, during the first twelve months. Unfortunately, I have kept no systematic record of the many cases of whooping-cough which have passed under my notice, but in eighty-nine cases of which I have preserved notes no less than twenty-four occurred in unfants during the first year of life. Even this proportion probably represents imperfectly the frequency of the disease in young babies; for in such subjects the spasmodic stage is often absent. Dr. R. J. Lee is of opinion that infants suffer from pertussis much more frequently than is supposed, and asserts that in a very young child a whoop ought rather to excite surprise than to be looked upon as an ordinary symptom. This is, perhaps, an extreme statement, but there is no doubt that in infants the disease frequently assumes the form of an obstinate pulmonary catarrh with but little laryngeal spasm. After the tenth year the disease becomes very rare; but it may be seen at any time of life, even, as is well known, quite at the close of extreme old age.

Whooping-cough seems to be more common in the spring and autumn than in the other seasons of the year, and the epidemic is often found to precede or to follow quickly upon an epidemic of measles. A patient who has passed through one attack of whooping-cough is in little danger of his illness being repeated, for a second attack in the same subject is rare. The infection, however, lasts for a considerable time after the whoop has ceased to be heard. Dr. Squire is of opinion that at least aix weeks should be allowed to elapse before the patient can be trusted to associate with

bealthy children.

Pathology. — Examination of the body in a fatal case of pertussis reveals nothing to account for the special nervous symptoms which impart its most characteristic feature to the disease. We find signs of catarrh of the air-passages, viz., congestion with hypersecretion of the mucous membrane

within the glottis, of the trachea, and of the bronchi and their ramifications. We also find certain consequences produced by violence of cough and spasm, viz, pulmonary collapse and emphysems. In addition, we usually meet with some other morbid changes due to the complication by means of which the fatal issue has been brought about. Thus, there may be serious congestion and even extravasation of blood into or upon the frain, and sometimes signs of thrombosis of the intracranial simises, shown by colourless clots of laminated structure adhering to the walls. The lungs may be the seat of catarrhal pneumonia, and occasionally small extravasations are seen here as in the brain. Moreover, there is almost invariably enlargement of the bronchial glands, and the under surface of the

tongue may be ulcerated more or less extensively.

No satisfactory explanation has yet been given of the real nature of the complaint. That the disease is due to inflammation of the pneumogastric herve has been shown to be erroneous. Pressure upon the same nerve by enlarged glands may be rejected for the same reasons which render this explanation of the phenomena of larvagismus stridulus an insufficient one. In some respects the affection resembles a zymotic disease; in others a neurosis. Some writers consider the complaint a purely catarrhal one; others by most stress upon the nervous symptoms. That the disease is something more than a mere catarrh is shown by the infectious nature of the secretion thrown off by the mucous membrane. In 1870 Letzerich believed he had discovered a species of fungus in the sputum, and supposed that this was the morbid material which, carried from one person to another, settled upon the mucous membrane of the air passages, and by its irritation gave rise to the spasmodic symptoms. Other observers, however, have not confirmed this alleged discovery. More lately Dr. turl Burger, of Bonn, has described a bacillus which he has found in the expectoration of children suffering from whooping-cough, and states that it is peculiar to this complaint.

The neurotic character of pertussis is shown not only by the laryngeal speam, but by the violent agitation into which the child is thrown during When he feels the desire to cough becoming irresistible he n parovysm. clutches at his mother's dress or the nearest object capable of giving suppart, and his whole body is agitated by a convulsive trembling. This agitation is usually attributed to terror, but it is more probably the consequence of a general nervous commotion which, carried to a higher pitch, may become a genuine convulsive seizure. A distinguished physician who was attacked by whooping-cough after middle life, in describing the neryour anitation induced by the spasm, assured me that in the paroxysm he required all his self-control to avoid beating with his feet upon the floor. It seems, therefore, that the neurotic element of the disease is something more than a mere nervous spasm of the larvny and diaphragm. There appears to be a general agritation of the whole nervous system, which may be more or less pronounced according to the severity of the attack and

the inherent susceptibility of the child.

Symptoms—The incubation period of pertussis is difficult to ascertain on account of the uncertainty as to the exact day upon which the disease can be said to be tim. It has been estimated at from two to seven days. Other observers are of opinion that it may last a fortnight.

When the disease begins we find the symptoms of cutarrh of the airpassizes. The cres are slightly injected, there is snuffling and increased secretion from the nose, and the child soon begins to cough. There is some fover, the temperature usually rising to 100°, and the pulse is

quickened. In a day or two there may be in a ldition some increased rapidity of breatling. If the catarrh affect the gastric nucous membrane, there is loss of appetite and the child may be languid and mope. The symptoms resemble those of an ordinary catarrh, but their specific character may be sometimes detected by noticing the unusual obstinacy of the cough. It is repeated at very short intervals, and sometimes is almost increasant. This catarrhal stage lasts for a variable time. It may occupy only a few days or may be continued for several weeks. The symptoms usually increase in severity as the days go by. The cough becomes nore troublesome, and is worse at night than in the day. If the child is oftenough he complains of a harassing tickling in the throat; and there is notice to the content of the cough making the content of the cough making the complains of a harassing tickling in the throat; and there is

After a time a change in the character of the cough shows that the spasmodic stage has begun. The cough occurs in paroxysus, and lassuch a distinctive character that it at once betrays the nature of the childs complaint. It consists in a number of short backs, following so rapidly upon one another as to allow of no inspiratory effort. As these continue, the child's face turns from red to purple, and seems to swell and darken at the same time. At length, when the lungs are almost exhausted of their air, and the patient seems upon the very point of suffocation, air is at last drawn in with a long, deep inspiration, accompanied by the characteristic "kink" or whoop. Immediately, however, the cough begans agan.; and in this way the long rapid expiratory cough, the signs of imminent asphysia, and the slower whooping inspiration may be repeated several times before the expulsion of a large quantity of thick tenscious phlegis from the mouth, and perhaps the ejection of food mixed with ropy mucus from the stomach, announces the end of the attack. The child, then, if an infant, sinks back exhausted and perspiring in his mother's arms, and if the cough do not return immediately, usually falls into a heavy sleep. An older child seems a little languid, but if the paroxysm has not been severe, may return quickly to his amusement. If, on the contrary, the spasm has been prolonged, he may seem dull and confused for a time, and may complain of beadache.

During the fits of coughing the pulse becomes very rapid, and is almost uncountable. If we listen to the back at this time we hear some slight wheezing in the large air-tubes during the expiratory cough, but during the long-drawn inspiration any slight vesicular sound which might be heard is covered by the noise of the whoop. In the intervals of the cough auscultation in an uncomplicated case merely reveals a few large bubbles

mixed up with dry wheezing sounds scattered about the lungs.

When the paroxysms are violent they are a cause of great distress to the patient. This is well shown by the efforts a young child will make to keep them back. He may be noticed, while on his mother's lap, to hold his breath and sit perfectly still in the hope of repressing the cough. When he feels that the impulse is getting beyond his control his face becomes a mgested, his brows contract, and sweat breaks out on his forchead; and as the convulsive expiratory efforts begin, he clutches at his mother's dress and often trembles all over with nervous agitation. During the paroxysm the straining may produce rupture in a child predisposed to herm; and his morrhage from the intense congestion induced is a common symptom. The bleeding may take place from the eyes, the ears, the nose, the mouth, and sometimes from the lungs. Cracks about the hips and sore places on the gums almost always bleed during the fits of coughing. Epistaxis is

very common. When been orrhage occurs from the nose the blood does not always flow forwards through the nostrils; often it passes backwards through the posterior narcs into the throat. It may be then swallowed and discharged as black matter by stool, or be vomited after the next attack of cough and cause great alarm. In other cases the blood irritates the glottis and induces a fresh paroxysm. It is then expelled with the

cough and is supposed to come from the lungs.

The number of paroxysms that occur in the twenty-four hours varies very much according to the severity of the attack, and partly, too, according to the number of disturbing causes to which the child is exposed. In tevere cases, where the slightest emotional or other influence will induce an attack, the number may be considerably diminished by quiet and judicious amusement. The child often coughs more in the night than during the day for the occurrence of the scizures appears to be favoured by the recumbent position. Between the paroxysms, when the spasm is violent, the child's face may remain permanently congested. The eyes are red and often bloodshot; the cyclids are heavy and swollen; the face and hips are dull red; there is a dusky tint round the mouth and under the eyes, and the vens of the neck are full.

The attacks themselves vary in character. The whoop may be entirely absent throughout the disease. This is said to be common in very young infants. The number of expiratory efforts is very variable. Usually there are only two or three, but they may be much more numerous. As a rule the coughing fits are longer at the beginning of the spasmodic stage, when secretion is thinner and less copious, than at a later period, when it becomes abundant and more tenscious. After the whoop has lasted a fortnight it grows less violent and is less frequently heard. It only occurs with the more violent fits of coughing, and in the milder ones the breath is drawn more quietly and with greater case. At the end of three weeks or a month it becomes very rare, and the complaint may then be said to have passed

The whole time occupied by an attack of whooping-cough varies from a forting ht or even less to two months or longer. The duration is often difficult to ascertain, for after the spasmodic cough has disappeared and the discuss has again come to assume an ordinary catarrhal type, trifling accidents, such as a chill or an error in diet, may set up more active symptoms, and the whole may even return for a time. In this way the com-

plaint may be prolonged for many weeks.

Completions. There are certain accidents attendant upon the complaint which may be a cause of distress or danger to the patient. Sub-highed the eration is common; hiemorrhage may be copious; the vomiting may greatly interfere with nutrition; bowel complaints may supervene; the acryous symptoms may be exaggerated; and various palmonary discrete roay ensue and, if they do not prove fatal, injuriously affect the future wilters of the child.

The sable open adveration has been before referred to. It occupies the fraction of the tengue and may extend for some distance on each side of the mobile line. The sore may vary from a mere abrasion to a deep fissure with a gray or yellowish surface. It is only seen in cases where the child has cut the lower incisors, and is the direct consequence of the scraping of these teeth against the under surface of the tongue as this organ is postruded and withdrawn during the paroxysms of cough. Blood often exists from the alem led surface towards the end of a paroxysm. The alem is not a constant symptom. It never appears before the spasmodic

stage but may then be seen as early as the fourth day of the whose is to must common in infants who have cut the two central lever in the nalto other teeth. In challern who have cut all their teeth the symptoms much less common.

Memorrhop must not be looked upon as in every case at unterest accident. When the spaces is violent and the competitive of the heal of face currence the relief of optical by a discharge of he sai from the instability resides of the none is no doubt often a saintary incident. If, however the homorrhaps occur frequently and he very copious great weatness may be accounted to the define any of nonrelineat resident by repeated which the loss of blood may be an additional reason for anisety. It quared years to also where than in the none addom occurs to any extent. Residently include from the mouth during wheopeng-cough comes almost invariant from this source. Hemophysis is rarely seen, for blood coming up that the lungs after an attack is usually swallowed by children, and is selicated ever, sufficiently considerable to be a source of danger.

He morrhage may also occur into the subcutaneous connective ties of the cycle la and that beneath the conjunctiva. The eyes are often bloodal of from small ecohymeses, and occasionally we see little extravasarius

in the thickened evelils.

Hamorrhage from the ears is the consequence of rupture of the typpanic membrane. Several instances of this accident have been recorded it is occasioned by the blast of air which is forced through the Eustachan tube during the fits of coughing, and a certain amount of blood carder from the torn surface. In two out of four cases published by Dr. 6165 the rupture occurred in both ears.

In very rare cases hismorrhage has been noticed in the brain and its

mentarines, causing death.

Certain dispessive troubles may arise. Vomiting at the end of a fit of coughing is a familiar symptom. Usually it is of little consequence. If however, the attacks of cough occur very frequently, and are followed in each case by sickness, the child's nutrition is visibly affected, for aimost all the food taken is vomited before there is time for digestion to begin Even if vomiting is not excessive, there is often considerable interference with nutrition, for the catarrhal condition of the gastrie nuccous membrane is ill adapted to further healthy digestion. In many cases, no doubt the tough nucus which coats the wall of the stomach prevents the food from bring properly mingled with the digestive juices. It is not uncommon as M. Ribact long ago pointed out, for food to be vomited little changed several hours after a meal. On account of the nucous flux in the howels worms are a frequent complication, and diarrhora is easily excited. A certain amount of looseness of the bowels is present in a large majority of the cases of pertussis, and considerable quantities of nucus are passed in the shoots.

Note one accidents form a very important class of complications. Sometimes the laryngeal spasm is exaggerated. It is not uncommon to see a child at the end of the long expiratory cough, instead of at once beginning to whoop, remain for some seconds with darkened face, staring eyes and open mouth, making agitated movements and vainly striving to overcome the spasmodic contraction which is closing the entrance to his lungs. If prolonged the spasm adds greatly to the gravity of the case, and may even determine the fatal issue. Thus is especially likely to happen if the pertussis is complicated with serious lung mischief. In a case which came

nuder my own notice—a child of seven years of age, both of whose lungs were the seat of catarrhal pneumonia—the spasms were very violent and prolonged, and in one of them the patient died. In a case recorded by Drs. Meigs and Pepper, whooping-cough complicated a case of laryngismus strictulus, and the child died in a spasm. Sometimes the patient falls into a state of syncope from which he can be roused only with the greatest

difficulty.

The semi-asphyxiated state in which the patient is often left after a severe paroxysm of cough may be a cause of general convulsions. Eclamptie attacks, indeed, often complicate pertussis; but although their occurrence should give rise to great anxiety, the seizures are not necessarily If the convulsion be the consequence merely of deficient acration of the blood, the return of free respiration removes the danger for a time; but if the same condition be frequently renewed, the child's state is a very anxious one. So, also, convulsions excited by embolisms or congestions of the cerebral vessels, thrombosis of the cranial sinuses, or diffused collapse of the lungs, are very serious. These generally occur late in the disease and are almost invariably fatal. There are two forms of eclampsia liable to happen which are less dangerous. One of these is due to an exaggeration of the nervous excitement which is an ordinary symptom of the disease. In highly sensitive children it is probably not uncommon for convulsions to take place from this cause, especially if the strength has been quickly reduced by copious epistaxis. So, also, the onset of an inflammatory complication is often indicated by a convulsive fit, and these attacks, like the preceding, are often recovered from. If, however, a convulsive lit occur late in the disease, when there is much consolidation of lung, the child seldom recovers. In connection with this subject it is well to remember that convulsions occurring in the course of whooping-cough may be due only indirectly to that disease. The tendency to eclamptic attacks which is common in early life is, no doubt, heightened by the state of neryous excitement in which the system is maintained by the illness. At any rate it is common, especially in rickety children, to find convulsions supervene in the course of whooping-cough upon very slight gastric or intestinal irritation. Convulsions occurring in pertusus without being followed by ill consequences may be, no doubt, often attributed to this cause.

Another important group of complications consists of the pulmonary lesions which may occur in the course of whooping-cough. These, on account of the nature of the complaint and the tender age of the patient, are readily excited, and often bring the illness rapidly to a close. In fact, the laddity to these accidents constitutes in most cases the chief danger of the disease.

Collapse of the lung is one of the commonest and most fatal of these complications. In a severe case of whooping-cough in a young child this accelent may happen at any time. Indeed, it may be said that at the end of every violent paroxysm of coughing the patient is threatened with collapse of the lung, for all the conditions which conduce to this disaster are present together. Thus the spasmodic cough almost empties the lungs of air; the ropy mucus in the tubes offers an obstacle to its re-entrance; and the state of exhaustion in which the patient is left weakens the force of the inspiratory act. The mechanism of collapse of the lung and the symptoms and signs which result from it are described at length in another place. It will be sufficient here to remark that the occurrence of collapse is often indicated by an attack of convulsions, and if the area of lung affected be

large, sudden death may even ensue. In the less serious cases the child lies back with his head low; his face is pale or slightly livid and covered with a cold sweat, the eyelids and lips are dull red or purple; the nares act, and the respirations are frequent and shallow. There is no fever; often the temperature is lower than natural. On examination of the chest we find a little dulness at one or both bases behind; the breathing is bronchial, and sometimes loose crackling rhonchus may be heard at the lower part of each lung. The whoop generally ceases when collapse occurs, but the fits of coughing continue, although in a modified form, and add greatly to the exhaustion of the patient. These cases almost invariably end in death. The child lies quietly, as if unwilling to stir a muscle. He takes food with difficulty and seems afraid to swallow. If lifted up suddenly he may die

from syncope : often the end is preceded by a convulsion.

Bronchitis and estarrhal pneumonia are other common consequences of whooping-cough. The pulmonary catarrh, which is one of the characteristic features of the disease, is easily aggravated, and readily invades the smaller tubes of the lung. In a young child, too, a bronchitis seidom remains a bronchitis, but the inflammation quickly travels to the fine bronchioles and air vesicles. Thus a catarrhal pneumonia is easily set up. In a severe case of pertusus the breathing becomes more and more oppressed and the face more and more livid as the catarrhal inflammation extends itself; but when the terminal tubes are reached and catarrhal pneumoma begins, the change is at once announced by new symptoms. The whoop ceases; the temperature rises to 102' or 103'; the breathing is quickened and laboured, and the pulse-respiration ratio is perverted; the face is livid; the nares are widely expanded. Although there may be no percussion dulness, a physical examination of the cliest reveals some of the signs connected with this dangerous condition. Sometimes a fit of convulsions ushers in the complication. If the pneumonia be extensive the child generally dies. If it be moderate, and the attack of whooping-cough be nearing its close, he may recover, but his life may be said to hang on a thread, for the occurrence of a little collapse, still further reducing the amount of breathing space left to him, may at once determine the fatal issue.

Emphysema of the lung, which often occurs, is a complication of little gravity. It usually occupies the upper lobes and anterior borders of the lungs. It is produced mechanically by forcible distention of the air-vesicles, air being driven from the lower parts of the lungs into the upper portions during the spasmodic cough, or rather during the violent contractions of the diaphragm which immediately precede the cough when the glottis is closed. In the severer cases there is some dilatation of the smaller brough as well as of the air-cells. The condition is an acute one, and usually subsides when the disease passes off. In scrofulous children,

however, it may remain as a permanent lesion.

Of these complications emphysema is one of early occurrence. Collapse and catarrial pneumonia occur late in the disease, as a rule, when the child's strength is reduced and his nutrition impaired.

Besides the above accidents others may occur. Laryngitis is seen sometimes, but if not severe adds little or nothing to the danger of the case. Pleurisy and pericarditis are occasionally found, but these do not, like the preceding, follow naturally from the complaint, and are not often met with.

Sequelar.—When the disease has passed off consequences, local and constitutional, may be left behind. Any diathetic taint, previously dormant, is often roused into activity. Scrofulous children may become subject

to chronic discharges, inflammations, and other signs of that constitutional condition; syphilis in babies may first manifest itself during or after an attack of whooping-cough; and acute tuberculosis is a not unfrequent sequel to the disease. Measles and pertussis seem to have a certain affinity in that they both produce an especially injurious effect upon scrofitous children. In such subjects chronic caseous enlargements of the cervical and bronchial glands are common: catarrhal inflammation of the lungs tends to pass into a chronic stage and produce serious mischief, and chronic bronchitis with emphysema may make the child a permanent invalid. Acute tuberculosis, when not the consequence of hereditary districtic tendency excited by the occurrence of whooping-cough, may be set up as a result of softening of caseous bronchial glands, and this at a considerable interval of time after the primary disease has come to an end

Besides these constitutional conditions there are other local conse-

quences of whooping-cough which it is important to be aware of.

Laryngismus stridulus is sometimes a relic of the disease, the spasm perusting although the other symptoms have ceased. This is not com-

mon, and probably only occurs in the subjects of rickets.

Cinldren who have lately passed through an attack of whooping-cough we often slow to recover their strength and healthy appearance, even although they are innocent of any disthetic taint, and have no chest affection to set up pyrexia and be a cause of weakness. A group of symptoms is often noticed in such subjects which I have elsewhere described un ler the name of "mucous disease," and which indicates a marked degree of impairment of putrition. The child is languid and pale, or has a dingy sallow complexion; he loses flesh, is easily tired, and sleeps badly at night. There is often some discolouration under the eyes, and the complexion may turn suddenly ghastly white, as if the child were going to funt. Often he does faint; and he frequently complains of a stitch in the sale and is subject to flatulent pains about the belly. The tongue presents a peculiar appearance. It has a glossy slimy look, is often conted with a thin gray fur, and the large papillæ at the sides, although not prominent, are unusually distinct. A curious irritability is a characteristic feature of the disorder. The child is capricious and fretful, and often cres without cause. He quarrels needlessly with his brothers and sisters, and is sometimes quite a forment in the nursery. At night he dreams and often wakes up in violent panie. The "night terrors" of children usually occur in the subjects of this derangement, and sometimes the child gets out of bed and wanders about in his sleep. These symptoms have no regular progression. They are better and worse. Sometimes the child seems almost well; then, in a day or two, he is as bad as ever. Tho parents are subject to what are called "bilious attacks." They are seized said baily with vomiting and purging, which lasts for twenty-four hours or a day or two, and at these times get rid of large quantities of thick mucus both from the stomach and bowels. After this relief they seem better for a time. They are less irritable and languid, their temper improves, and their rest at night is no longer disturbed. After a few days, however, the symptoms return, and continue until they are again relieved in the same way. As a rule, the bowels are rather costive, and an aperient always brings away much mucus with the stools.

These symptoms are due to a continuance of the mucous flux from the

^{&#}x27;See The Wasting Diseases of Children, 4th ed.

alimentary canal which is always present to a greater or less degree in cases of pertussis. This copious alkaline secretion acts as a ferment and causes an acid change in the more fermentable articles of food. The acid thus generated partially coagulates the mueus, so that this forms a thick coating round the interior of the digestive tube, and also covers the masses of food swallowed. Consequently a proper admixture of food with the gastric juices and other digestive fluids is interfered with, digestion is slow and imperfect, and of the food which is digested only a small part is brought into contact with the absorbent vessels. The child consequently gets thinner and paler. He is uneasy on account of flatulent pains from gases disengaged in the process of fermentation, and irritable on account of the excess of acid with which the system is charged. In bad cases the emaciation may be very great, and although the appetite may be large, the food taken seems to be, and often actually is, nearly useless for purposes of nutrition. Commonly, however, when the derangement is severe the appetite fails, and great difficulty is found in persuading the child to take any nourishment at all. Parasitic worms, which find in the alkaline mucus a congenial indus for development, frequently complicate this derangement, but it is to the digestive disorder and not to the worms that the

symptoms are really due.

Diagnoses.—It is often very difficult to say whether or not a child has got whooping-cough. At the beginning of the catarrhal stage a diagnosis is impossible. At this early period we can only detect the signs of entarrh, and unless the complaint is largely prevalent at the time, or other children in the house are suffering from pertussis, there is absolutely nothing to make us even suspect its existence. Often, towards the end of this stage, the frequency and peculiar violence of the fits of coughing may rouse our suspicions, and if a genuine paroxysm occur, doubt, of course, ceases to be possible. But although fully developed whooping-cough cannot be mistaken, the modified form of cough which is often all that we can detect may be easily misinterpreted. A more or less prolonged cough with a faint whoop from slight laryngeal spasm is not very uncommon in a child suffering from chest complaint, and an abortive pertussis may sometimes give rise to no more characteristic symptoms than these. In making the distinction no arguments drawn from the acuteness of the attack or the early period at which the cough assumed the spasmodic character can be relied upon, for modified pertussis may be as slight and transient as any mere pulmonary catarrh. It is of far greater importance to notice that in a mild form of whooping-cough the general health is good, and that an examination of the chest reveals little deviation from the normal state of things; while a chest affection sufficiently serious to produce an imitation of whooping-cough will injure the general health and modify the physical signs. It is usually in catarrhal pneumonia that this violent prolonged cough is noticed. In such cases we find the symptoms and physical signs of this disease, and we exclude pertussis by remarking that the cough did not become paroxysmal until the chest disease was well developed. In a case of real pertussis with secondary catarrhal pneumonia, the characteristic cough is very much modified immediately the complication begins. Paroxysms of violent cough with some spasm of the larynx are often noticed in cases of enlargement of the bronchial glands. But here we get other signs of pressure upon the pneumogastric nerve: the breathing is more or less oppressed and the voice is thick and house between the attacks of cough. Besides, the venous radicles of the face, neck, and chest are usually more visible than natural from pressure upon the innominate

vein there is no expectoration of ropy mucus; and the disease is not

capable of being communicated to other children.

When convulsions occur in a case of whooping-cough it is very important with a view to prognosis, to ascertain their mode of origin. If the consultant is symptometric of the onset of an inflammatory complication, it is accompanied by a rise of temperature and followed by a diminution in the spasmodic symptoms and a modification of the physical signs in the chest. If it announces the occurrence of collapse of the lung, the charac-

teristic symptoms which mark that lesion will be present.

If the convulsion arises from exaggeration of the nervous disturbance which is one of the peculiarities of the disease, it will have been preceded by signs of unusual agitation in former fits of coughing. Such seizures are only seen in children known to be nervous, sensitive, and impressionable; they follow immediately upon the cough, and between the attacks no agust of nervous disturbance remain. So also in the case of convulsions arising from partial asphyxia; the nervous attack is excited by extreme vidence of spasm, but after the fit has passed off no signs of cerebral lesion are left behind. If, after a fit, there is aquinting, drowsiness, supor, or other sign of nervous disturbance, we may fear that congestion of brain is present or that thrombosis of the cerebral sinuses has occurred, and should watch the case with grave apprehension.

Proposes -- Whatever be the age of the child, the prognosis is favourable so long as the disease remains uncomplicated; but if a complication arise the prospect is less hopeful, and in a very young child any addition to the normal course of the complaint is to be regarded with anxiety. Consulsions, bronchitis with collapse, and catarrhal pneumonia are the

principal causes of an unfavourable issue to the disease.

In the case of convulsions, if the attack can be connected with nervous attation or the onset of an inflammatory complication, or if, after the fit, the child seem bright and well, there is still room for favourable anticipation. If, however, the seizure is symptomatic of diffused pulmonary collipse; if it occur in the course of an extensive pulmonary inflammation; or if it be followed by drowsiness, squinting, or sign of cerebral lesion, there is little prospect of the child's recovery. Sometimes we can anticipate the occurrence of convulsions. If we find the child to be nervous and unpressionable, and we notice that he displays unusual agitation and extensionable, and we find that the displays unusual agitation and extensionable. So also if we find that the face becomes very blue during the cough, and that the spasm of the larynx is unusually prolonged, we may fear that an eclumptic attack may ensue. Laryngismus stribulus, as it supplies an additional obstacle to the abration of the blood and tends to prome te collapse of the lung, is an unfavourable sign. If it occur in combination with extensive lung mischief, the prospect is a very hopelies one.

If the pulmonary catarrh becomes aggravated, the presence or absence of rickets is a very important matter. Softening of ribs is a great obstacle to otherent breathing; and if the presence of thick mucus in the tubes proceeds an additional impediment to the entrance of air, the occurrence of collapse is imminent. If, with this, the spasms are violent, and the child commuch exhausted at the end of the fit of coughing, collapse of the lung may be considered inevitable. In such a case the prognosis is a very closery one.

If the extarrh pass to the small sir-tubes and vesicles, and set up catarthal pneumonia, the state of the child is serious. Still, if the patient be of healthy constitution and the pertussis of comparatively mild type, he has a chance of recovery. In a rickety child the prospect is very bad. In one of scrofulous constitution, if he do not succumb immediately, there is every likelihood that a chronic consolidation of one or both lungs will be left behind.

Treatment — The treatment of whooping-cough resolves itself into general measures for preventing complications and furthering the normal working of the animal functions; also, in special treatment for shortening

the disease and diminishing violence of spasm.

If possible, the child should be confined to two rooms opening into one another, so that he may inhabit them alternately, and get the benefit of efficient ventilation. Draughts should be avoided, and the temperature be kept as nearly as possible at 65° Fahr. If the rooms have no door of communcation, the child should be taken from one to another, wrapped from head to foot in a blanket. Next, quiet and the avoidance of all sources of exertement and irritation should be enforced. If old enough to be amused, quiet games and picture-books may be supplied; and a teachable child is not to be worried with lessons if he is disinclined for them. His dress should be suitable to the season, but bare arms and legs must be forbulden, and the chest should be covered with cotton-wadding if the weather be changeable or cold.

In regulating the diet care should be taken not to overload the stomach. Four small meals are better than three large ones, and attention must be paid to the patient's power of digesting fermentable articles of food. The mucus flux from the stomach and bowels, which is a prominent feature of the complaint, is an active agent in promoting acidity; and starches must be given, therefore, cautiously and in limited quantities. A baby does well upon milk and barley-water (equal parts), and Mellin's food, with a pinch of bicarbonate of soda to each bottle. He may also have the yolk of an egg twice a week, and, if over ten months old, weak veal or chicken broth once in the day. After eighteen months the child may have minced meat, or fish, milk, eggs, and stale bread, but potatoes and farinaceous puddings are to be avoided. Well boiled cauliflower or greens may be given if the patient will take them.

If the natural vomiting does not sufficiently unlead the stomach of mucus, nature may be aided by the occasional administration of an emetic. Sulphate of copper, as recommended by Trousseau, is very useful for this purpose, and may be given to a child of one year old in doses of half a grain every ten minutes until sickness is produced. Also, it is well to relieve the bowels by an occasional dose of castor-oil. Looseness of the bowels, such as is common in this complaint, is at once arrested in most cases

by a dose of this useful remedy.

Of special drugs for shortening the attack and relieving spasm, so many have been recommended that the mere enumeration of them would occupy many lines; but of really serviceable drugs the number is much more limited. The treatment I have myself found to be most useful, and now invariably adopt, is the following: —Directly any peculiarity in the cough or the occurrence of spasm indicates the nature of the complaint, I at once begin the administration of sulphate of zinc and atropia. From a large experience of this combination I can speak positively as to its power of reducing spasm and shortening the disease. I begin with one-sixth of a grain of sulphate of zinc and half a drop of the solution of atropine (P. B.)

¹ The quantities recommended are suitable to a child twelve months of age.

in water sweetened with glycerine, each morning and evening for two days, and then three times a day. After a week the quantity of zinc is increased to one-fourth, and still later to one-third of a grain. The atropia, however, is given in frequently increasing quantities. Children, although they vary in their insusceptibility to this drug, can all take it in large doses; and in whooping-cough where there is spasm to be overcome, the remedy is of little value unless given in doses sufficiently large to produce some of the physiological effects of the alkaloid. Excluding the belladonna rash, which is too uncertain in its appearance to be trusted, dilatation of the pupil is the earliest symptom that the system is responding to the action of the medicine. This sign is separated by a wide interval from the next earliest symptom—dryness of the throat. To be of service, the remedy stould be pushed so as to produce some effect upon the pupil. With this object the dose should be increased every two days by a quarter of a drop the atropine solution, watching the effect. In this way, with perfect mety, large quantities of the drug may be administered; and so employed, I think no doubt can be entertained as to the value of the treatment and as influence in shortening the course of the spasmodic stage and reducing be violence of the attacks. If the spasm is exceptionally severe and seems threaten partial asphyxia, it is wise to give in addition a nightly dose of be mide of potassium or ammonium (gr. iij-iv.). There is one precaution which it is well to adopt during this stage. The paroxysms are often most frequent and severe at night when the child is asleep. The slightest movement of air across the face, such as is produced by a person walking near the cot, will often exerte an attack. These night seizures can usually be really reduced in number by an expedient suggested, I believe, originally by Dr. Marshall Hall. It consists in throwing a fine mushin curtain over the cot at night-time. The simplest plan is to have a couple of hoops arranged at the ends of the cot, like the "tilts" of a wagon, so as to support the curtain at a sufficient height. This arrangement, which corresponds to the mosquito curtain used in hot climates, does not interfere with a free supply of oxygen, while it effectually stops all wandering currents of air. So protected, a child will often sleep the night through without m attack.

At the end of the spasmodic stage and during the period of decline dum is very beneficial. This remedy, first recommended by Dr. Golding Bad in 1845, has a marked influence in checking too copious secretion and inning the disease to a favourable termination. Two or three grains of slam may be substituted for the sulphate of zine in the atropia mixture, and given three times in the day. It is at this time, viz., the end of the pasmodic stage and during the period of decline, that I have found the name treatment especially useful. I have little experience of the drug at the beginning of an attack. According to Binz, Jansen, and others, who, following the suggestion of Letzerich, direct their attacks against the organism which has been supposed to cause whooping-cough, quining even at the beginning of the illness suppresses altogether the spasmodic lement, and converts the disease into a severe but manageable bronclaus. They recommend the comparatively tasteless tannate of quinine, given twice a day in doses of a grain and a half for every year of the chall's life.

There is no doubt that to be efficient in pertussis quinine should be given in full doses. I have given three times a day two grains of the sulphate of quinner to children between twelve months and two years old towards the end of the spasmodic stage, and have thought that the disease was cut

short by this means. Another combination which acts sometimes at this period of the illness with wonderful promptitude is formed by adding two drops of the tincture of cantharides to five drops each of the tincture of cinchons and paregoric, and giving this dose three times a day. Tonies generally are useful during the stage of decline. The preparations of iron are especially valuable. Thirty drops each of the compound decoction of aloes and iron wine make a good combination; iodide of iron is of service, and the citrate of iron with an alkah may be resorted to. It is a matter of great practical importance in all these cases to avoid the use of syrups in sweetening the mixture for the infant's palate. Glycerine, being nonfermentable, is far safer; or we may use a few drops of chloric ether for

this purpose.

sweetened with glycerine.

Many other drugs are used in the treatment of whooping-cough. The old treatment by dilute hydrocyanic acid and that by dilute intric acid. each of which has had its day, has now, probably, fallen into complete disuse. Opium, however, in some form has not been completely superseded by helladonna. The preparations of morphia are still relied upon by some practitioners, and the remedy is no doubt a useful one. It should be given in sufficient doses to produce slight drowsmess, and this effect should be maintained for several days. For a child of twelve months a drop of the morphia solution (P. B.) can be given every four hours. There is no doubt that the spasm can be reduced by this means; but the treatment is, in my opinion, inferior to that by atropine, and necessitates very careful watching of the patient lest the narcotic effect of the remedy be carried further than is desired. Chloral may be also employed to reduce spasm in doses of gr. ij. every four or six hours. It is sometimes used in combination with bromide of potassium, and the effect of both drugs appears to be heightened by the association. Croton chloral is a remedy greatly relied upon by some practitioners. The dose is one grain for a child of twelve months, given every four, six, or eight hours in water

Besides the above methods of treatment the topical action of drugs is largely used in the management of whooping-cough. It is now nearly thirty years since Dr. Eben Watson advocated swabbing the larynx with a solution of nitrate of silver, twenty grains to the ounce. The application was repeated every second day, and the spasm is said to have subsided at the end of the week. This heroic remedy is not now in vogue. Instead, milder applications sprayed into the throat are made use of. A two per cent, solution of salicyle acid used regularly in this manner is said to diminish rapidly the number of paroxysms. Dr. R. J. Lee is a warm advocate of carbolic acid inhalations, and claims for them that they induce a daily decrease in the violence of the cough, and promote the disappearance of the symptoms within a period varying from a fortnight to three weeks. Dr. Lee prefers long-continued inhalations of a diluted vapour, and recommends that the air of the room should be kept saturated with a weak solution of carbolic acid. As this acid does not evaporate when exposed to the air, special means have to be used for converting it into vapour. Dr Lee's "steam draft inhaler," which moistens the air as well as medicates it, is a useful and simple apparatus. A solution of one part of the acid to thirty of water is to be used for vaporisation, and by this means the child may pass a large part of his time in air kept saturated with a dilute medicated vapour. If carbolic acid be inhaled in the ordinary way from a mouth-piece, the solution should not be stronger than one part in eighty parts of water.

External applications have not been neglected in the treatment of whooping-cough Many patent remedies, such as Roche's embrocation, which is composed of the oils of cloves and amber with double their quanuty of olive-oil, belong to this class. Stimulating liminents are often useful If the catarrir of the chest is severe, and if applied along the sides of the neck, and to the spine as well as to the chest, may help to reduce the spasm. Mustard poultices to the back are favourite remedies with some practitioners, and it is said that if applied along the whole length of the spine for ax or eight minutes every night before the child is put to bed a speedy im-

provement is noticed in the symptoms.

When complications arise in the course of whooping-cough, special measures must be adopted for their relief. If the vomiting of food become ex conive, so as to interfere seriously with the child's nutrition, it may be often relieved by emetics of sulphate of copper (half a grain to the teaspoonful) given every day or on alternate days, so as to clear away tenacross mucos from the stomach. Chloral is useful in these cases by its power of dimmishing reflex action. Excessive vomiting is usually found in cases where the laryngeal spasm is extreme, and the remedies which are useful in alleviating this symptom have also a beneficial action in checking too forcible contraction of the diaphragm. Looseness of the lowels is usually easily controlled by a dose of castor-oil. In this country charrhosa seldom becomes troublesome, but in warm climates during the hot season choleraic diarrhoen may supervene. This must be treated according to the rules laid down for the management of that serious con-

If laryngismus stridulus complicate the paroxysm, bromide of ammonium or potassium (gr. iij) may be given with atropia two or three times a day; and the same treatment is useful if unwonted nervous excitement, or signs of cerebral disturbance, indicate the immunence of a convulave fit. If the spasm he prolonged and seem to threaten suffocation, slipping the child's hands into cold water will often relax the glottis at once.

Convulsions must be treated according to the special condition from which they appear to have arisen. In the more serious form of eclamptic attack, such as that induced by collapse of lung, catarrhal pneumonia, or thrombosis of intracranial sinuses and veins, the treatment must be directed against the complication by which the nervous seizure has been excited. Convulsions set up by pure nervous agitation, or by partial asphyxia from violence of laryngeal spasm, are usually to be controlled by the administration of chloral in the quantities already indicated. If the seizures occur in a rickety child, and appear to be the consequence of digestive disturbance and acidity (a not uncommon case), a dose of ipecacuanha wine, followed by an autacid and aromatic mixture, will usually put an end to them at

If the pulmonary catarrh become severe and threaten collapse of the lung, prompt steps must be taken to ward off this dangerous complication. Strambiting applications should be applied to the chest and back; occasonal emetics should be given to aid in the expulsion of mucus; and the chi dis strength must be supported by a suitable supply of alcoholic stimulant. In these cases alcohol should be given boldly. A young child in a weakly state from acute disease will respond well to such treatment, and a few timely doses of brandy-and-egg, or other powerful atunulant, will quickly give him renewed strength to struggle against his discuse. It may - necessary to give a teaspoonful every hour, or even half hour, until the

infaculty is overcome.

If catarrhal pneumonia supervene, the complication must be treated upon the principles laid down in the chapter relating to that subject.

When the disease is at an end, change of air to a dry, bracing spot or to the sea-side is of importance. Remembering the frequency of glandular enlargements and the danger of tuberculosis, we should recommend such measures as are required for restoring impaired nutrition and replacing lost strength. Cod-liver oil is very valuable, alcohol is of service, and iron is usually indicated.

The symptoms described as "mucous disease," which are often seen in children of three or four years of age or upwards after an attack of whooping-cough, are quickly removed by careful regulation of the diet. The child should be fed upon meat, eggs, fish, poultry, and milk; and potatoes, farinaceous puddings, fruit, cakes, sweets—all articles, in fact, capable of affording material for fermentation must be strictly forbidden. A mild aperient, such as the compound liquorice powder, should be given twice a week to ensure the expulsion of excess of micus from the bowels; and iron with alkalies, or iron wine with compound decoction of aloes (āā I ij for a child of five years of age), should be given two or three times a day, two hours after meals.

Part 2.

GENERAL DISEASE NOT INFECTIOUS.

CHAPTER I.

RICKETS.

Or all the chronic diseases to which young children are liable, none surpasses in interest and importance the one now to be considered. The frequency with which rickets occurs, the variety of tissues it affects, the influence it exercises upon the course and termination of intercurrent maladies, and the distressing and often fatal consequences which its presence involves

render this discuse especially deserving of careful study.

Although dissimilar in many respects from the class of so-called diathetic thee uses, viz., those which arise as a consequence of a distinct constautional predisposition, rickets is yet a general affection, for it impairs the mutation of the whole body. Under its influence growth and development are arrested, dentition is retarded, the bones soften and become deformed, the muscles and hyaments waste, and in fatal cases alterations are often noticed in the brain, liver, spleen, and lymphatic glands. The thecase usually begins in infancy. It is rare under the age of six months, for it seems very doubtful if the cases of so-called congenital rickets are true examples of the disease. At the eighth month, however, it begins to be common, and from that age until the eighteenth month may be readily set up un ler the influence of causes which interfere with digestion and impe le 'he assimilation of food. It is less common for the disease to develop in children who have been in good health up to the age of eighteen months, but it may occur at any time between that ago and the seventh year, or even in still of ter subjects. Although beginning at a very early age, the discuse often continues for several years, and may be seen existing in a marked degree in children three or four years old.

Listen. - Rickets is the direct consequence of mal-nutrition in early life. Its course must therefore be looked for in all the diverse agencies which impair the nutrition of the growing frame. The most important of these are, no doubt, faults of feeding and hygiene. Insufficient or unsuitable food starts the body of necessary nourishment, and an inadequate supply of fresh air renders assimilation defective and weakens digestive power. These two causes are most commonly found united in the poorer quarters of large cities. An infant who lives amongst other children in

one small room, where it breathes a tainted air and derives its only nearishment from the watery breast-milk of a weakly mother, with the addtion, perhaps, of a little gruel or sopped bread to quiet it when it crees, can only escape rickets by becoming tubercular. By such means an extreme degree of the malady will probably be produced. But similar agencies, although operating in a milder form, will produce rickets in any condition of life. It is not uncommon to meet with examples of the disease in wellto-do families where the child has been kept in-doors for fear of his catiking cold, and has been supplied with farinaceous compounds largely be total his powers of digestion. Over-feeding with starchy foods is a fruitful cause of rickets. The giving of farinaceous matters in excess, or at a time when the glandular secretions are insufficient for its digestion, is the conmonest fault committed in the hand-feeding of infants. Dr Buchana Baxter, who tabulated one hundred and twenty consecutive cases of rickets, found that in many of them the disease dated from the time when farmaceous food was first given. It is probable that in these cases the xcurrence of mal-nutrition and subsequent rickets is due not so much to the excess of starch as to the absence of the more nutritious fool for which the starch has been substituted. Rickety children so fed are often fat, and do not, to the inexperienced eye, convey the impression of being under-nourshed. Examination, however, discovers that they are by no means strong in proportion to their size. Although stout they are weak. often excessively feeble; and it is evident that the plumpness of the claid is due to disproportionate development of the subcutaneous fat. This tissue has been enormously over-nourished while the rest of the body has been stanted and starved.

The time of weaning is often a starting-point for rickets, for the breastmilk is usually replaced by some preparation of starch. So also longcontinued suckling may induce the disease, for the breast-milk after a time ceases to satisfy the infant's wants, and too little additional nourishment is supplied. Therefore whether the food given be insufficient in amount or indigestible in form the effect is the same: the child is starved

and rickets becomes developed.

In cases where the child lives in a good bracing air the effects of an unsuitable dietary are less painfully evident. In dry country places, where the infant spends much of his time out of doors, rickets is a more incommon disease than it is in localities where the conditions are less favourable to health. Want of sunlight, want of cleanliness, and a combination of cold and damp are other determining causes which are not without their influence in the production of rickets. All these causes must no doubt act with especial energy in the case of infants who are naturally weakly, or whose strength has been already reduced by some exhausting disease. There are, therefore, many conditions which predispose to the complaint Feebleness of constitution on the part of the parents will, no doubt, have an influence in this respect, for weakly parents are not likely to be get constitutionally healthy children. Moreover, a weakly mother is usually unable to nurse her baby; and hand-feeding, unless conducted with extreme care and discretion, is often unsatisfactory. A very large proportion of rickety infants are bottle-fed.

Hereditary tendency is considered by some observers to be an element in the etiology of the disease. In the case of so common an affection it must no doubt often happen that the father or mother of the patient has been previously affected in a similar way; but that a parent who had been rickety in childhood should give birth to a weakly infant, and that this in-

fant, brought up in violation of all the rules of health, should develope rickets as surely but stender evidence in favour of the hereditary transmission of the disease. Supporters of this theory usually point to the case of so-called 'congenital rickets" as instances of the inherited form of the disease; but, as is hereafter explained, there are reasons for exclud-

ing these cases from the class of true rickets.

The relation which exists between rickets and congenital syphilis has within the last few years been brought into great prominence. has laboured to show that rickets is always the consequence of an heredimy sophistic taint. The arguments of this observer in favour of his view are derived chiefly from morbid anatomy. He points in particular to the hastomaral changes observable in the epiphysoal ends of the long bones in the two diseases as evidence of the specific nature of rickets. But the latter is not only a disease of the bones; and although the epiphyses in the two may present a certain similarity of lesion, there are other alterations of structure in rickets which are different from those of syphilis. Morcover, The general symptoms, especially the peculiar tendency to functional neryous disorders, have no counterpart in the specific disease. Again, rickets constantly met with in cases where the most careful inquiry and most purents or sign of it in their offspring. The disease is common in localities The re-congenital syphilis is rare, and rare in places where the latter is manner. It is met with in animals as well as the human subject, and is produced in them by faulty hygiene and bad feeding as it is in the child. But it is needless to multiply arguments against the untenable hypothesis indranced by this distinguished pathologist.

Still, although it cannot be allowed that rickets is caused by syphilis, typhintic infants may become rickety; and it is probable that a parent watered by a former syphilis may, without transmitting the faint to his off-pring, beget a chill of feeble constitution in whom rickets can be easily followed. But in both these cases injudicious feeding and insanitary con-

litions must come into operation before the disease can occur.

A pronounced tubercular disposition appears to have a protective power can't rickets; for although weakly, phthisical parents may give birth to be ble infants who readily fall victims to rickets, it is rare to find the later disease in a family where other members have died of tubercular meninguis or other form of pure tuberculosas—unless, indeed, the tubercular numbers has occurred secondarily to rickets. The reason of this immunity was to be that the causes which are capable of setting up rickets will induce tube readesis in a child predisposed to this form of illness and very

quells bring his life to a close.

How it is that these causes give rise to rickets is still undecided. It has been shown by the experiments of Friedleben that a diet deficient in plantic acid and the line salts is not capable, as was at one time supposed, of inducing rickets; indeed, it seems probable that the essence of the process is not a more deficiency of lime in the bones, but an irritation of the bone-making tissue. It is asserted by Heitzman that lactic acid excesses an irritating influence upon the osteoplastic tissue, and that it is influence, combined with a deficiency in time salts, which induces the limits. There is little doubt that factic acid is abundantly generated in the demogral digestive organs of rickety children, for this acid has been betieved in their name. If Heitzman's theory be correct, the acid excites tritation in the osteoplastic tissue, and at the same time dissolves and acips to climinate the calcarcous matter deposited in the bones. If, in ad-

dition, the supply of lime salts be actually reduced, rickets is set up with

still greater certainty.

Morbid Anatomy. - In looking at a case of well-marked rickets the ere is at once arrested by the enlargement of the epiphyseal ends of the long bones and the deformities of the skeleton which result from softening of the osseous framework. In rickets the bones are affected in three ways Growth, although not completely arrested, is retarded and rendered irregular; ossification of parts still remaining cartilagmous is interfered with, and bone already ossified is softened. When a longitudinal section is made of one of the long bones the whole structure appears deeply reldened from intense congestion. The epiphysis is very large, and the incrosse in size is due chiefly to an enormous development of the earthage, which is preparing for the reception of the calcareous selts. The laver of cartilage into which the new bone is advancing is called the zone of col the cation. That next in order, in which the corpuscular elements arrange themselves in vertical columns in preparation for the approach of the carthy deposit, is called the zone of proliferation. These two zones are greatly thekened and are not separated, as would be the case in the bone of a healthy child, by a well-defined straight line of demarcation. In the rickety emphysis the new bony tissue, justead of advancing by regular steps into the zone of calcification, no one point being in advance of another, shoots up irregularly, so that lines or little islets of calcification are seen far up in the proliferating zone, while on the other hand specks and streaks of uncalcified cartilage are left far below the line of earthy deposit completely surrounded by bone. Moreover, medullary spaces are formed in unusual places, and appear even in the proliferating rone of cartilage far in advance of the margin of ossification. The cartilage cells become the seat of calcareous impregnation,' and are in many cases converted intebone corpuscles Small isolated masses of time can also often be seen scattered through the matrix -enough in many cases to give a dotted appearance to a section of the cartilage

Changes similar to those described in the epiphyses take place at the surface of the shaft of the long bones and in the flat bones. The periosteum becomes excessively thick and very vascular, and is connected so firmly with the bone beneath that it cannot be detached without fragments of the latter being stripped away with it. Its connective-tissue corpuscles undergo rapid proliferation and become transformed directly into bone corpuscles. The calcifying process is irregular here as it is in the epiphyses, so that layers of firm bony tissue are interspersed with others composed of a fibrous matrix containing connective tissue or bone corpuscles and medullary spaces. In the flat bones, especially those of the skull, the irregularity with which calcareous matter is deposited is well seen. The new porous bone occupies chiefly the surface and edges. In the cranial bones a special change is often found. In certain spots the bone becomes excessively thin and transparent (cranio-tabes). This condition is due to deficient deposit of lime salts in the external layers and absorption of the soft tissue in places, here and there, from the pressure of

the brain.

Bores in which ossification is thus delayed and perverted are usually soft. The softening is the consequence of the smaller proportion of earthy

It has been doubted whether this change occurs in healthy ossileation for in the normal process the calculation of the intercellular matrix which surrounds the caritiage coils conesals the latter from view. In rickety beneather all dying granules are deposited first in the cells, so that the changes in them can be distinctly seen.

mits they contain and the larger percentage of organic matter. deficiency of lime salts is due not to their removal after deposition, but to the sluggishness with which they are deposited. The corpuscular elements of the periosteum are proliferated in large quantities, and the new matter is but slowly and imperfectly converted into bone. The circumference of the shuft, therefore, consists in great measure of spongy lamelle which are only partially ossified. All this time in the interior of the bone the normal eniar gement of the medullary canal by absorption still continues, so that as long as the rickety process is active the proportion of properly constructed osseous matter containing its due percentage of earthy silts is continually diminishing. Such a bone must necessarily be, yielding and subject to ready distortion. This, however, is not the only cause of the hone deformities. According to Strelzoff, the osseous trabecula have an abnormed arrangement in rickety bone. They are disposed radially instead of concentrically. He maintains that this irregularity further dimusics their power of resistance to external pressure and is an additional source of weakness.

At the height of the disease the bones, besides being softer, are specifically lighter than natural, and contain an undue proportion of fatty matter. Moreover, the cartilage contains a high percentage of water. The bone on analysis has been shown to consist of 33 to 52 per cent. of earthy salts, instead of 63 to 65 as in health, and its animal matter is said to yield no gelatine on boiling.

When the disease becomes arrested, ossification in the soft, newly torined tissue takes place rapidly. The loose spongy structure closes up and becomes thick and hard, and the whole bone is heavy and dense.

The morbid changes in the osseous system form, no doubt, the most characteristic feature of the rickety state: but rickets is not merely a disease of the bones. In addition, various pathological changes are discovered in the bodies of children who have died while suffering from this affection. In some the liver, spleen, and lymphatic glands are found diseased, the muscular structure is altered in bad cases, the brain may be affected, and

the urme almost invariably exhibits pathological characters.

The alterations in the liver, spleen, and lymphatic glands are by no means present in every case, or even in every marked case of the disease. The affected organs are cularged, tough, and solid to the touch, and heavy out of proportion to their size. The change is usually most marked in the spicen Dr. Dickinson considers it to be due to no "new growth or intiltrated deposit,' but to a hyperplasia of the normal tissue of the organ, and chiefly of the interstitial connective tissue. The fibrous and epithelial elements are hypertrophied, and at the same time their earthy salts are debe sent in quantity. In the liver the fibroid sheath within the smaller portal canals is twice its natural size, and in the glandular structure the yellowish acini are bounded by a thin pinkish or gravish line. In the sphen the interstitud connective tissue may become so hypertrophied that the trabeculae are as thick as the spaces they enclose. In the meshes the corpuscles are seen by the microscope to be crowded together. The organ is hard and resistant, so that it can be cut with the utmost ease into tinn sections. Its surface is deep red or purple in colour, with smooth white spots from enlarged Walpughian corpuscies. Its section is deep red mottled with pale but colour. But little blood can be squeezed from the cut surface. applicate glouds are sometimes also enlarged and hard. They are white and opaque on section from accumulation of their cellular contents.

Enlargement of the liver in rickets is not always the consequence of the

pathological condition described. If a rickety child be much wasted from intestinal catarrh or other digestive trouble, the liver may be swollen from fatty infiltration. If he have been subject to repeated pulmonary catarrhs with great interference with the respiratory function, the organ may be enlarged from chronic congestion. So also turgescence of the spleen may be found unaccompanied by any appreciable lesion of the liver or lying lattic glands. In some cases the increase in size of the organ appears to be dee, as in the case of the liver, to a chronic congestive process which causes a large development of hyaline fibroid material. In others the spleen seems to be the seat merely of simple hyperplasia and presents the ordinary characters of hypertrophy, such as are seen in some cases of inherited syphilis and in the ague cachexia. This form of enlargement is referred to elsewhere (see page 238).

The muscles have been noticed by Sir William Jenner to be small, pale, flabby, and soft. Their fibres under the microscope are softer and pale than natural, with the strise very indistinctly marked. The brain is sometimes small and shrunken, so that fluid is thrown out to fill up the space left vacant in the skull cavity. It is also sometimes enlarged, so much so in some cases, as to cause distention of the cranium. Dr Hilton Fagge has referred to a case which was taken to be one of advanced hydrocephalm until an examination of the body after death showed that the brain filled up the cranial cavity completely. In such cases the organ, although enlarged, has a healthy appearance and is of natural consistence. The hypertrophy is said to be in the neuroglia without any increase in the nerve-

The urine contains an increased proportion of phosphate of lime, and lactic acid has been found in it by some observers. The secretion is pale in colour and often deposits crystals of oxalate of lime. Often, also, as is so commonly the case in children in whom acid is largely generated from fermentation of food, crystals of uric acid and even considerable quantities of red sand may be passed from the kidneys.

In addition to the above pathological conditions, which may be considered to arise directly from the general disease, there are others which may be looked upon as accidental since they are induced mechanically by the deformities of the thorax resulting from the softening of the ribs. In all cases of distortion of the framework of the chest two pulmonary lesions are invariably present. These are emphysema and collapse. The emphysema is seated at the anterior borders of the lungs, and extends backwards for about three-quarters of an inch from their free margins. Immediately outside this line of dilated lung tissue is a line of collapse which separates it from the healthy pulmonary substance beyond. These lesions occur together and, although not dependent one upon another, are produced by the same mechanical means. During the act of inspiration the softened ribs ank in, and the pressure of the enlarged ends of the ribs compresses the lung tissue with which they are in contact so as to prevent its expansion by the air which inflates the remainder of the lung. While, however, the diameter of the chest is narrowed laterally, its antere-posterior diameter is increased by the protrusion of the sternum. Consequently the alveon of the anterior borders, immediately behind the breast-hone, are ditended by the air which is forced into this part to fill up the resulting

Pulmonary collapse is not always limited to the parts of the lung corresponding to the ends of the ribs. There is often to be seen, in addition, a certain amount of atelectasis at the bases of the lungs behind. Collapse

at this part of the lung is due to pulmonary catarrh and plugging of an air-tube with mucus. Its mechanism is described elsewhere (see p. 465). The enlarged epiphyses of the ribs, besides their effect upon the lung listue, are also the cause of the patches of circumscribed opacity seen on the visceral surface of the pericardium and on the spleen. That on the pricardium is situated on the left ventricle a little above the apex of the heart. At this point the heart at each beat comes into contact with the nodule of the fifth rib. That on the spleen is produced in the same

way by attrition, the organ as it rises and falls in respiration being rubbed against a similar costal projection. In each case the white patch is

limited to the fibrous laver.

I rom a consideration of the morbid changes discovered in the bodies of rickety children, it is evident that the disease is a very special one, mvolving very wide spread lesions of structure. Attention has lately been breeted to the whole subject of bone changes in the young subject, and it is asserted that many cases in which bone softening has been pronounced are not real examples of rickets, but ought rather to fall under the heading of osteo-malacia; the osseous changes resembling closely those observalle in cases of osteo-malacia in the adult. The question is of importance, for the pathology of the two conditions is essentially dissundar. In osteoashe is softening is the consequence of a removal of the earthy constitutous from perfectly formed bone. In rickets ossification is incomplete, and much new maternal is thrown out which undergoes very imperfect extendention. The question can only be decided by a careful study of the morbid appearances. In the case of a rickety little girl, aged eighteen mouths, described by Dr. Rehn of Frankfort, there was marked distortion at i softening of many of the long bones, with other signs usually considand characteristic of rickets. The disease, however, was judged to be esteo-malacia on the ground that although softening was a marked feature in the bones, the epophysesi ends were only moderately swollen, and in the banes of the lower extremities were hardly swollen at all. Moreover, the whole skeleton was excessively thin and the lower extremities were quite straight. There was, however, a considerable formation of soft periby al deposit; and a rickety element in the case was admitted. It is pospible that true estee-malacia may be grafted on a case of rickets, as is supposed by Dr Rehn to have happened in the instance referred to, but further observations are to be desired before any definite conclusion in the matter can be arrived at.

Before closing the subject of the pathology of rickets a few words may be said with regard to the cases of so-called "congenital rickets." This term is applied to a condition in which the limbs of a new-born child are found to present peculiar characters. The shafts of the bones are short in it thickened, and may be found bent or even broken. At the same time the epiphyses are swellen, soft, and quite cartilagmous. The condition, however, differs materially from true rickets, and has been compared by Eterth to that found in cretinous children. In all recorded cases where the pest-morten appearances have been noted the shafts of the bones have been found much ossified and remarkably thick and stunted. This pulsarity gives, of course, a curious shortness to the limbs. The diaphyses, instead of being imperfectly ossified as in rickets, with great porcenty of the medullary parts of the bone and thickness of the percos-

^{&#}x27; in a case described by Dr. Barlow the upper limbs reached only to the umbili-

teum, are excessively hard and compact. Fibrous tissue derived from the inferior layers of the periosteum intrudes between the epiphysis and the shaft. The epiphyses, also, are enlarged generally and not only at the line of calcification, as in rickets; and their microscopical characters present sensible differences. In a case recorded by Urtel the cartilage cells in the epiphyses were found lying confusedly together. As they approached the disphysis they were seen to become flatter, especially in the peripheral portions, and finally passed into the layer of connective tossee which separated the greater part of the epiphysis from the shaft of the bone. The resemblance between these cases and cretmism is displayed not only by the stunting and firm ossification of the diaphyses. There is the same tendency to early union by ossification of the basi-occipital and post-sphenoidal bones. Some specimens of "congenital rickets" preserved in the Museum of the Royal College of Surgeons exhibit this peculiarity, and in others, where the soft parts remain intact, many of the facial characteristics of the cretin are also to be observed.

Symptoms.—As might be expected in a disease which arises as a direct consequence of faulty nutrition, the symptoms proper to rickets are usually preceded by others indicating a general interference with the nutritive processes. Digestive derangements are common, but these comparatively seldom consist in attacks of severe or repeated vomiting or diarrhea. In most cases the derangement is limited to a lessening of digestive power, so that the motions, without being actually loose, are more frequent than natural. They are large, pasty-looking, and offensive from the quantity of farinaceous and curdy matters which are passing undigested out of the body. At this time the child is often irritable and fretful. His belly may be swollen from flatulent distention, and he frequently cries with pains in the abdomen. For this reason he may be often found asleep in his cot. resting on his chest, or supported on his knees and elbows with his head buried in the pillow. The urine is often very acid and causes uneasiness in micturition. If the child perspires copiously the renal secretion may contain considerable quantities of uric acid sand.

Unless by judicious treatment and diet the alimentary canal be restored to a healthy state the child, although often still plump to the eve, becomes pale and flabby. Then, after an interval which varies in duration according to the natural strength of the patient and the more or less wholesomeness of his surroundings, the early symptoms are noticed. The onset of the disease is announced by three special symptoms. The child begins to sweat about the head and neck; he throws off his coverings at night and lies naked in his cot; and begins shortly afterwards to exhibit uneasiness if much danced about in his nurse's arms or handled without the utmost

gentleness.

The sweating is profuse and occurs principally during sleep. At night beads of moisture may be seen standing on his brows, and the sweat trickles off his head on to the pillow, which is often saturated by the secretion. If the child fall asleep in the day-time, or even if he exert himself much while awake, the same phenomenon may be noticed. The irritation of this perspiration often gives rise to a crop of miliaria about the neck, behind the ears, and on the forehead. The superficial veins of the temples are full, the jugular veins are unusually visible, and the carotid arteries may be felt to pulsate strongly.

The desire of the child to lie cool at night comes on almost at the same time with the preceding, and may be observed in the coldest weather. It is, indeed, a frequent cause of catarrh in these patients, and I have seen many cases in which continued looseness of the bowels was apparently muntained by repeated chills so contracted. For the same reason a fre-

quent cough from pulmonary catarrh is a common symptom.

General tenderness usually begins to be notice I at a certain interval after the two other symptoms which have been mentioned. It is shown by unusual sensitiveness to even slight pressure, and appears to be scated in the muscles as well as the bones. The child cries if lifted up at all abruptly or subjected to any jolt or jar, and prefers to lie quietly in his cot or on the lap of his nurse. This symptom seldom occurs until the esseous changes are well marked. It is accompanied by uncasmoss or pun about the head, which is indicated by a monotonous movement of the head from side to side upon the pillow. The hear covering the occupit is eften worm tway by this constant movement, and the bareness of the back of the scalp from this cause is a very characteristic symptom. Tenderness is not always noticed. It is usually confined to cases where the disease is avere. In the mild cases, which are shown merely by a slight enlargement of the wrists and ankles, without any apparent softening of the bones,

the symptom is usually absent.

The hone changes consist in an enlargement of the apiphyseal ends of the long bones, in a thickening of the flat bones, and in a general softening of all. The enlargement of the ends of the bones occupies the point of junction of the shaft with the ejaphysis. Both extremities of the bone may suffer, but the change is naturally most obvious in the part which is nearest to the surface. The ribs at their sternal en Is are usually the first to be affected; then the hones of the wrists. As a rule, the epiphyseal swelling is more marked in the bones of the upper extremities than it is in those of the lower. The thickening of the flit bones is well seen in the bones of the cramum, and the softening of all the bones is one of the causes of the deformities of the trunk an I limbs which are so common in early life. It must not, however, be supposed that every case of rickets ends in softening and distortion. All degrees of severity of the disease may be met with, and in middleases softening and the consequent deformities of bone are antirely absent. Even in more severe cases we must not expect in every instance to find all the symptoms to be enumerated. In one child the epiphyseal swellings attract most attention; in another the softening of the bones. In some the chest is excessively distorted and the bones of the limbs are comparatively straight. In others the limbs are greatly twisted while the thorax is but little altered from the normal shape. These differences are said by Baginsky to be determined by the part of the skeleton in which growth happens to be most active at the time of the attack.

In a pronounced case of rickets the effect of the bone lesions is very

striking and peculiar:

The stall is large with a long antero-posterior diameter, and often, on account of the comparatively small size of the face, looks larger than it really is. The forehead is square from exaggeration of the bosses of the frontal bones, and is sometimes very prominent from the development in the bone of cellular cavities. The fontanelle is large and remains open long after the end of the second year. Sometimes, if the size of the brain is increased, or there is excess of fluid in the skull cavity, the sutures in connection with the fontanelle can be felt to be more or less distinctly gaping. On account of the thickening of the edges of the flat bones the margins of the sutures and fontanelle are elevated, so that the latter feel depressed and the sutures are indicated by furrows. The posterior fon-

tanelle has usually disappeared before the beginning of the illness, but in extreme cases, where the disease began early and the symptoms are pro-

nounced, it may be felt to be still unclosed.

In every case of rickets the condition known as "cranio-tabes" and described by Elsasser should be searched for. It is best detected by pressing gently with the tips of the fingers on the posterior surface of the head. If cranio-tabes be present, spots will be felt where the bone is this soft, and clastic, as if at this point it had been converted into tightly stretched purchanent. The spots are seldom larger than the diameter of a good-sized pea, and are usually confined to the occipital bone. They are caused by absorption of the imperfectly ossified bone from its compression between the pillow and the brain as the child lies in his cot. They may be met with as soon as the third month of life, and are said to be the ear-

hest sum of the disease.

A rickety child's hair is usually thin, and is often kept moist by the copious perspirations to which the head is subject whenever the patient falls asleep. In most rickety children a systolic murmur of variable intersity can be heard with the stethoscope applied over the fontancile. According to Senator, the symptom merely shows that an ossified membrane is better fitted than the cranial bones to transmit to the car sounds generated in the cerebral vessels. There is no doubt that it is rarely heard in children in whom the fontanelle has closed. The murmur is sometimes curiously loud. Not long ago a pallid, flabby little girl, between two and three years old, the subject of rickets, was brought to me from the country on account of a strange noise which was beard at times to proceed from her head. The child had cut all her teeth, but was very weak on her legs. She was subject to attacks of stridulous laryngitis. The fontanells was not quite closed. Her beart and lungs were healthy. It was said that in this child a noise like "the purring of a kitten," not continuous, but distinctly intermittent, "like a pulsation," could be heard at times. It was loudest at the right side of the head. It was not especially loud after exertion, and was only occasionally audible. It was heard best immediately the child awoke in the morning, and was then distinctly perceptible several yards from her cot. During the child's visit to me no cerebral or other murmur could be heard with the stethoscope. Still, I had no reason to doubt the good faith of the relatives. The mother, who gave me the account, told her tale in a straightforward manner, with the air of one who was eager to receive an explanation of a mystery which had puzzled her and made her anxious.

The chief cause of the smallness of the face is the imperfect development of the jaws. Fleischmann has drawn attention to the angularity, and flatness anteriorly, of the lower jaw. It has lost its normal curve. The incisors are quite in a straight line; then at the situation of the eye-teeth the jaw forms a sharp angle and bends abruptly backwards. This is due to imperfect growth of the middle pertion of the jaw. Baginsky describes in addition an occasional want of symmetry between the two balves of the bone, which gives the appearance of one side being ligher than the other. The effect of this delayed development of the jaw upon dentition is very important. Rickety children are late in teething. At whatever age before the completion of dentition the disease may begin, directly the cranad or facial bones become affected there is complete arrest in dental development. Thus, if the disease occurs before any teeth have been cut, their appearance may be indefinitely delayed. If several teeth have already pierced the gum the process stops there, and months may elapse before

others are seen. When, however, the teeth do come they are usually cut without much trouble; but they are in most cases of bad quality from imperfect development of the dental enamel, and quickly blacken and decay.

The chart is deformed in a very characteristic manner on account of the inability of the softened ribs to resist the pressure of the atmosphere. Under normal conditions, when the ribs rise and the chest expands in the act of inspiration, the solid framework of the thorax is able to withstand the pre-sure of the expired air, and the chest easily enlarges to allow of inflation of the lungs. Air rushes through the wind-pipe to dilate the pulmonary tissue in proportion as the chest walls expand. In the rickety chest, on the contrary, the ribs are not firm but yielding. Consequently the framework of the thorax is not rigid enough to resist the pressure of the air from without, and when the effort is made to expand the chest the softened ribs are forced in at the sides—the parts where they are least supported. This sinking in of the ribs throws the sternum forwards. We therefore find the chest grooved laterally and the breast-bone prominent and sharp. The groove is broad and shallow, and reaches from the second or third rib to the hypochondrium. The bottom of the depression is formed by the ribs outside their junction with the cartilages. Therefore along the inner side of the groove the swollen ends of the ribs can be seen, looking like a row of large beads under the skin. The groove is deepest in children who have suffered much from pulmonary catarrh. In such subjects the impediment to the entrance of air, already existing, is increased by the narrowing in the calibre of the smaller tubes in luced by the derangement; and the softened ribs receive still less support from the lung tissue beneath them. In a chest so deformed each inspiration increases the depth of the lateral groove, and at the same time produces a deep furrow which passes horizontally across the chest at the level of the epigastrium. This furrowing of the surface has been shown by Sir Wilham Jenner to be due not to the traction of the diaphragin, as was taught by Rokitansky, but like the lateral grooves of the chest to atmospheric pressure. The liver, stomach, and spleen support the parietes under which they he, and prevent the wall at these points from falling in.

The spine is often bent. In an infant the cervical curve is increased that the head is supported with difficulty and falls backwards upon the shoulders, producing a very characteristic attitude. Also, the weight of the head and shoulders, as the child sits bending forwards, causes a projection backwards of the dorsal and lumbar spines, which is sometimes so sharp as to give the appearance of vertebral caries. The deformity, however, subsides completely when the child is taken up under the arms and the spine is drawn upon by the weight of the limbs and pelvis. If the patient is able to walk, there is an increase in the lumbar and dorsal curves. The curvature may be lateral. If the child is earried habitually on his nurse's left arm, the trunk sways over to the right; if on the right arm, the largy leans to the left. In all these cases the deformity is due to weak-

ness of the ligaments and muscles.

The bones forming the pelcis may be also deformed, and sometimes, like the chest, are greatly distorted. The shape assumed by this framework is very various, for as it is due in all cases to compression of the yabling bones, it will be determined partly by the age at which the disease begins, and the degree to which ossification has advanced. It is therefore different, according to the usual attitude of the child, and to the carcumstance of his being able or not to walk about. Its most ordinary shape is an irregular triangle. Distortion of the pelvis is of great impor-

timee in its influence upon child-bearing in the adult female; but even a early life it may have grave consequences. The operation of lithetomy a the young subject has been attended with serious difficulties, and even

been followed by fatal results, on account of this deformity.

In the bones of the limbs the articular ends are nodular from enlargement, but the shafts themselves have often an unnatural shape. In the arm the humerus is often curved at the insertion of the deltoid mucle by the weight of the forearm and hand when the arm is raised. The redius and alna are curved outwards and twisted, for a rickety child often rests his hands on the bed or floor to assist his feeble spane in supportant the weight of his trunk. In the femur the head of the bone may be lent at an angle with the shaft. The body of the bone is curved forwards if the child cannot walk; for as he sits on his mother's lap the weight of the leg drags upon the lower part of the thigh. If he can walk, the current an exaggeration of the natural curve-forwards and outwards. The thu is curved outwards if the child is unable to walk, so that when the patient is held upright the knees are widely apart. The deformity is due in the case to the position commonly assumed by the infant, who is addicted to sitting cross-legged on his bed, so as to make pressure upon the outside of his ankle. In children who can walk an abrupt curve, having its convexty forwards and outwards, is seen in the lower third of the bone. The lower limbs are not distorted in the infant so frequently as the arms. If the child cannot stand, these extremities, although small and feeble, are often perfectly straight. In cases where the deformity of the long bones is exfreme, the slaft is not only bent but broken, for a partial ("green-stack) fracture is generally present. The same thing is often seen in the claveles which bave their normal curves very greatly exaggerated.

Besides the softening and deformity of the bones there is another consequence of the disease which is of great importance. This is the arrest of growth and development of bone which can be noticed in all cases of severe rickets. Rickety children are short for their age, and remain undersized after the disease has passed away. The arrest of growth is most marked in the bones of the juws, of the fower limbs, and of the pelvis. As it affects the pelvis, this feature is of especial importance on account of its influence upon parturition in after life; for if the capacity of the pelvic framework be not only diminished by distortion, but also relatively small from arrest of development and growth, the difficulties in the way of suc-

cessful delivery may be insuperable.

The weakness in the lower limbs, which is a marked feature in rickets, is due not alone to feebleness of the muscles combined with the general debility of the child. There is also great weakness and looseness of the ligaments of the joints. This weakness is more pronounced in cases where the disease begins after the end of the second year. In such cases of late rickets softening and deformity of bone are less common features of the disease, while the looseness of the joints from marked relaxation of the ligaments may reach a very high degree. In such cases, too, the disease having begun after the completion of dentition, the teeth are often white and sound.

During the progress of the bone-changes which have been described, the general symptoms continue and become more severe. The head perspirations are profuse; the child can hardly be kept covered in his bad, but whether it be night or day pushes off the bed-clothes and exposes his naked limbs to the air. In bad cases his tenderness and dishke to movement are extreme. So long as he is left alone he is patient and still, but

when approached or noticed be at once becomes fretful and apprehensive of disturbance. He will sit for hours together, heedless of his toys, crenched up in his cot; his legs doubled beneath him, his spine bowed, and his head thrown back; supporting his body upon his hands placed before him on the bed. On account of the softened ribs and his consequent difficulty in expanding the lungs, his breathing is rapid, and his whole attention seems concentrated upon the efficient discharge of this function. He appetite varies. Sometimes it is poor, but more often it is good and may be ravenous. If attention has not been paid to his diet, and the child continues to pass large quantities of pale, putty-like matter, he will usually swillow almost anything that is given to him. Sickness is not common, and severe distributes is only occasionally met with; but moderate attacks of puriting are frequently seen, the stools being green, show, and offensive.

The belly in rickety children is always large, even in cases where no disease of the liver or spleen can be detected. The swelling is principally due to feebleness of the muscular walls, allowing of accumulation of flatus, and to the shallowness of the pelvis, which throws all the abdominal viscera above the level of the pelvic brim. If the spleen is very large it may cause a special swelling on the left side of the belly, sometimes reaching below the unbilities. It may be remarked here that in cases where the liver and spleen can be felt below the level of the ribs we must not at once conclude that their size is abnormal. The organs may be merely pushed down by the depression of the disphragm and diminished capacity of the thorax. Therefore, after ascertaining the position of the lower edge the upper limit of the organs should be estimated by careful percussion. In addition to enlargement of the liver and spleen the superficial lymphatic glands are sometimes swellen, and can be distinctly felt larger than natural in the artille and grouns.

Rickets is not a cause of pyrexia. If the temperature rise above the normal level a complication may be at once suspected. If fever occur during the stage of improvement it often announces the return of dentition, and shows that a tooth is pressing through the gum. The degree of wasting varies. If the disease he mild the child, although pale, is often exceptionally plump from over-nourishment of the subcutaneous fat; but unless recovery take place shortly the limbs quackly begin to feel soft, and soon the child can be seen to be evidently wasting. The complexion is always pale, the lower exclid is frequently discoloured, and the borders of the mouth have a bluish tint. If great enlargement of spleen be present the fint of the face becomes peculiarly bloodless and the mucous membranes are very pale. Rickety children are backward in every way, both in mind and body. Their intellect seems to grow as slowly as their bones. On account of their inability to join in ordinary children games they are much in the society of older persons, and therefore acquire an unchildish way of expressing themselves; but they talk very late and are dall at picking up new words and phrases.

The progress of the disease is slow, and unless the insunitary conditions which have led to it be removed, it goes on from had to worse. These children often die from some catarrhal complication. A had diarrhora is very dangerous on account of their general weakness, and a comparatively mild pulmonary catarrh may prove fatal through the softening of the ribs. Death rarely takes place from the intensity of the general discase. When improvement begins under judicious treatment, the general ten lerness is usually the first symptom to subside. The child is less fretful when noticed and takes more interest in what passes around his bed. At the same time the softening of the bones diminishes, and as the ribe regain their firmness the marked improvement in breathing which results from the greater rigidity of the chest-wall cannot oscape notice. Teeting also begins again; the wasting ceases; the belly is less distended; the sweats diminish and all the symptoms undergo great imprevement. These children often become very sturdy and strong, but usually remain short in stature even when their full growth has been attained.

A form of the disease has been described which has been called "acut rickets." In this variety the articular ends of the long bones undergo rapid enlargement and become tender on pressure. Secondary cybin-ired swellings are also seen about the limbs. The temperature is high. It seems probable, from the investigations of Drs. Cheadle and Barlow, that these cases are instances of scurvy grafted on to rickets. They are referred

to more fully in the chapter treating of the former disease.

Complications. It is not often that a case of rickets remains uncourtcated by some intercurrent complaint. The subject of a pronounced form of rickets has but little resisting power, and is readily affected by any kind of injurious influence. But he is in addition peculiarly hable to certain forms of derangement on account of the special tendencies of this phase of mal-nutrition. The sensitiveness to chills manifested by a rickety child has been already remarked upon. This proneness to cotarrh may be the consequence of the profuse and ready action of the sweat glands, and it is no doubt encouraged by the child's practice, when his perspirations began of throwing off the coverings of his bed. The various forms of catarrh and therefore especially liable to occur, and pulmonary and intestinal catarris are the most frequent of these derangements. Few rickety clobben are without a cough, and this symptom, on account of the unnatural flexibility of their chest walls, must be always regarded with anxiety. The danger of even a hald pulmonary catarrh in these patients, and the readiness with which this derangement gives rise to collapse of the lung, is referred to elsewhere (see p. 467). To this cause a large proportion of deaths is due. Again, more or less intestinal catarrh is a common derangement in this disease, and after any unusual exposure the looseness of the bowls may pass into a severe attack of purging. Diarrhea, on account of the great general weakness, is a source of extreme danger, and during the changeable seasons of the year many children are carried off by this com-

Another peculiarity of the rickety state is the curious impressibility of the nervous system which manufests itself by the ready occurrence of various forms of spasm. Itellex conculsions are common, and largunizous studyins is practically confined to the subjects of rickets. Catarrh of the largunx is also hable to be accompanied by spasm, and therefore entervial croup (largunities stridulosa), as is elsewhere stated, is a frequent cause of anxiety. These subjects need not be further referred to in this place, as

they all receive consideration in special chapters.

One other not uncommon complication is chronic hydrocephalus. On account of the small size of the brain in many cases of rickets, fluid is effused into the crunial cavity to fill up the resulting space. The amount of serosity is, however, seldom large and rarely comes to be a source of danger.

An occasional complication, although not a common one, is acute tuberculosis. The disease is probably in all cases the result of an acquired tendency due to the presence in the body of a softening cheesy deposit. It certainly is proportionately less frequent in rickety subjects than in children tree from this disorder of nutrition; but it is necessary to be aware that nekets these not exclude tuberculosis.

Piagnosis.—In a mild case of rickets the prominent features are the swelling of the epiphyseal ends of the long hones, the tardy eruption of the teeth, and the backwardness in learning to walk. If we notice the wrists to be large in a young child, we should at once count the number of his teeth and ask if he is able to stand alone. If a child ten months ald shows no sign of a tooth, if his wrists are large, and if when held upon his feet his limbs double up helplessly beneath him, there can be little doubt that he is the subject of rickets. Even before the swelling of the articular ends of the bones has come on the onset of the disease may be suspected. Big, fat, flabby infants are generally slightly rickety and if a child sweats profusely about the head, and is kept covered at night only with great difficulty, we can have little doubt that the characteristic signs of rickets are about to appear. In such a case attention should be at once directed to the child's diet, the regularity with which he is taken out of doors, and the state as to ventilation of his sleeping-room, so that any errors in management may be promptly corrected.

In a marked case of rickets the deformity of the chest, the bending of the bones, the enlargement of the joints and beading of the ribs are sufficiently characteristic. Even the position of the patient as he sits with his legs crossed and his head fallen back between his shoulders, supporting his feeble spine by his hands placed before him on the floor, enables us at

once to recognize the case as one of well-defined rickets.

The complete uselessness of the lower limbs in many of these cases is often a serious anxiety even to parents who regard the other symptoms with comparative indifference, for they fear lest the child should be "going to be paralysed." But although the patient has no idea of even placing his feet upon the ground, and cries bitterly when any attempt is made to persuade him to do so, power of movement of the legs is unimpaired. If the skin of the legs be pinched or gently pricked he at once draws his limbs out of the way. Of other local symptoms: The nature of the antero-posterior spinal curvature is readily shown by lifting the child up un ler the arms, when the weight of the pelvis and legs at once causes the spinal distortion to disappear. A lateral curvature is distinguished from the effects of plenrisy by noting the presence of signs of rickets and the absence of these of efficient into the chest cavity. The rickety head differs from a skull dilated by excess of fluid by its shape. Instead of being globular it is elongated from before backwards, with a characteristic squareness of the for head, and moreover this shape of head is associated with other well marked signs of rickets. The fontanelle does not always furnish trustworthy evidence; for although often depressed in rickets and raised in hydrocephabis, these conditions may be reversed. Certainly a depressed fontanelle is compatible with a fairly copious effusion of intra-cranial fluid.

In the present state of our knowledge no differential diagnosis can be made, during life at any rate, between rickets and osteo malacia. Cases where softening and deformity of bone are present must be assumed to be rickets. Fortunately, for all practical purposes, a distinction in any individual case is unnecessary, as the measures to be adopted for the relief of the patient are the same whatever be the correct pathology of the osseous kenons.

Progress: Rickets is not a fatal disease in itself unless the bony change be far advanced, nor even in such a case does death often ensue except as a

consequence of some catarrhal complication. As a rule, improvement begins directly measures are taken to amend the unwholesome conditions a which the patient is living. The dangers of pulmonary catarrh and attestasis in a child with great deformity of chest are elsewhere referred to; and the serious consequences which may result from diarrhosa in an unfut reduced to a state of serious weakness by chronic and nutration need not be insisted upon. Of the nervous complications, laryngusmus stridulus is sometimes a cause of sudden death, but reflex convulsions excited by some

trifling irritant rarely have any ill results.

Enlargement of the spleen, liver, and lymphatic glands generally a very rare, but if present should excite great anxiety. It is more common to find enlargement of the spleen alone without any affection of other internal organs. In rickets, as has been said, the spleen is often the seat of simple hyperplasia. This lesion, as it is an additional cause of anama, no doubt introduces into the case a further element of danger, but the danger is dependent more upon the intensity of the rickety process than upon the degree of splenic swelling. If the symptoms of rickets are comparatively mild, and due care be taken to shield the child from catarrial complications, the presence of a big spleen does not indicate the probability of a fatal termination to the illness.

Age has no influence upon the prognosis of rickets, and when the disease occurs as a sequel of inherited syphilis, it presents no special diffi-

culties in its treatment.

With regard to the permanence of the unsightly deformities of bone, it is often astonishing to note the improvement which takes place after recovery from rickets in the deformities which seemed the most unlikely to be reduced. Large joints grow smaller, crooked bones become almost straight, and a distorted chest will recover itself in a surprising manner. In some children, however, improvement goes on farther than it does in others, and therefore, while encouraging the parents to believe that there will be considerable improvement, we must not be too sanguine as to the

complete disappearance of all distigurement,

Treatment—In every case of rickets our first care should be not to give cod-liver oil or tonics, but to inquire into the conditions in which the child is living; to ask about the food he is taking, the quantity allowed for each meal, the frequency with which the meals are repeated, and the degree of chanliness of the feeding apparatus. We should then turn to the subject of his clothing, the ventilation of his bedroom, and the number of hours he is passing out of doors. The real treatment consists in attention to all these important matters, and not solely in the administration of any particular drug. Medicines are no doubt useful as helps in the treatment, but their importance is trifling as compared with that of a reformation of the unwholesome conditions under which the failure in nutrition has taken place. The reader is referred to the chapter on the treatment of infantle atrophy for general directions with regard to the feeding and management of young children.

Almost all cases of rickets have been preceded by symptoms of digestive derangement or bowel complaint, and unless improvement has already begun we often find signs of looseness or intestinal derangement still persisting. This should at once he remedied. The belly should be kept warm with an ample flannel binder, and the child should take a drop of laudanum to control the undue peristaltic action of the bowels, with a few grains of the bicarbonate of soda to correct acidity, in an aromatic water awestened with a few drops of spirits of chloroform three times a day. In

many cases there is a special difficulty in digesting starch. In almost all instances we find that this variety of food has been given in great excess. The quantity must be therefore considerably reduced, and that taken should be guarded with malt, as in Mellin's food. Hoff's extract of malt, in doses of two or three teaspoonfuls three times a day, is of great service in these cases. If the child be no longer an infant, the diet should be arranged as directed under the heading of "Chronic Diarrhoa" (see page 640).

Plenty of fresh air should be insisted upon. The child, warmly clad, should be sent out in all suitable weathers, and if care be taken that his feet are well warmed before he leaves the house, there will be little danger of his catching cold. If the patient have reached the age of eight or ten months he should be carefully packed with cushions in a perambulator, and in cold weather should always have a hot bottle to his feet while out of doors. The ventilation of his sleeping-room must be attended to. A small fire in the winter, and a lamp placed in the fender during the summer months, will insure a sufficient circulation of air through the bedchamber. Both the patient and his immediate surroundings must be kept scrupibously clean. Every morning the whole body should receive a thorough washing with soap and water, and be well sponged in the evening before the child is put into his cot. On account of the copious perspirations his body linen, as well as that belonging to his cot, soon becomes attracted with monsture. His underclothing should therefore be changed as often as is necessary. Every morning, too, his mattress and bed-coverings must be thoroughly exposed to the air. The sheets also should be changed frequently and be carefully aired.

If the above measures are properly attended to improvement will quickly begun. Directly the bowels have been got into a healthy state cod-liver oil should be given. A quantity much less than that usually prescribed is, however, sufficient; for children, infants especially, have comparatively small power of digesting fats. It is best to begin with ten drops of the light brown oil, and during its administration the stools must be carefully watched for any appearance of undigested oil. The quantity can be gradonly increwed by a few drops at a time as long as none of the oil is seen to pass undigested from the bowels. Iron is also useful. Iron wine (M xx xl.), the exsecuted sulphate of iron (gr ij. iv.), or the fincture of the perchlorale (1 v -xv.)-all these are useful, and are to be preferred to any of the syrupy preparations. The latter are not fitted for rickety subjects, as the large quantity of sugar they contain encourages fermentation and sendity, and often, indeed, by the disturbance it sets up in the bowels, makes each dose of the medicine decidedly prejudicial to the patient. If quinne be given, the tannate is the most suitable preparation. One or two grains should be suspended in glycerine and given two or three times a day. If there is any tendency to acidity left after rearrangement of the thet, the ammonio-citrate of iron may be given in a draught with a few grains of bicarbonate of soda and one drop of the tincture of nux vomica between meals.

The salts of lime were at one time recommended in the treatment of rickets, as it was supposed that the bone-softening was due to a deficiency of lime in the system. In practice, however, the use of these drugs has not been found of value; indeed, the remedy, for any special benefit it produces, may as well not be given at all.

The copous perspirations from the head and neck are always a source of great manety to the mother. They can be controlled by applying belladonna humaent to the parts where secretion is copious before the child

is put to bed. He may also take one drop of liq atropic every night. Directly the tenderness has subsided steady frictions with the hand alone, or with objectly, all over the body, especially along the spine, are of great service and do much to strengthen the muscles. The nurse should be directed to rub the child steadily for a quarter of an hour immediately after his bath. In the morning the open hand or a flesh glove may be used; in the evening it is advisable to employ warm olive-oil for the frictions. As the child improves and his strength begins to return, a cold or tepid saline douche, given as he sits in the warm water of his bath, will be of service.

Care must be taken to prevent the child's getting on his feet before his bones are sufficiently solid to bear his weight. As his strength improves he seizes every opportunity of practising his newly acquired power of standing, and very marked deformaties of the tibia may be produced by this means. In such cases support may be given to the himbs by the use of light, padded splints, and if the ligaments of the joints are much relaxed

a firmly applied elastic bandage can be made use of.

The treatment of any deformities which may remain after the complete cossition of the disease falls rather under the department of the surgeon. For the treatment of the various complications of rickets the reader is referred to the special chapters treating on these subjects.

CHAPTER II.

AGUR.

CHILDREY who live in malarious districts are not exempt from ague; indeed, in early life the system is said to be particularly susceptible to the action of the malarious poison. During infancy and up to the age of five or aix years, the fever may assume peculiar characters, and unless detected early, and promptly treated, may even prove fatal. In more advanced childhood the symptoms present little variety from those met with in adult life.

Consistion.—Ague is an endemic disease, which is excited by residence in a malurious neighbourhood. An ague-breeding district is usually lowlying, marshy or ill-drained, and has a more or less porous soil, composed largely of rolling vegetable matter. Still, these conditions are not always found united in places where ague abounds. A disintegrated rocky soil, which is very porous, and is saturated with water to within a few inches of the surface, may largely generate the malarious poison, although decaying vegetable matter is entirely absent. A soil thus deleterious is rendered doubly noxious by digging below the surface. Indeed, in some cases a spot previously healthy has been known to become malarious after disturbance of the soil for building or other purposes. Even a malarious district is only personous at certain seasons. In temperate climates the spring and nutumn are the agueish periods of the year. In the tropics the miasma is evalved in the dry hot season which succeeds to the periodic rains. The mularia is thrown out from the soil, especially at night-time, and rises to a certain distance from the ground. It is always more intense near the surface, being apparently more diluted or rarified as the distance from the earth mereases. It may be carried by the wind to a considerable distance from the spot where it has been generated, but appears to be incapable of passing a broad sheet of water, and even a band of trees is found to arrest the progress of the miasma.

Amongst the residents of a malarious neighbourhood the disease is very common. The children hving in the district are said rarely to escape; for even if considered healthy they will be found, according to Steiner, to have the splicen enlarged. Even the new-born infants of mothers who suffer from intermittent fever may be found at birth to present the enlarged splicen, the bronzed skin, and all the other signs of a pronounced malarious cachexia. It has even been affirmed that the milk of a cachectic woman is capable of communicating the disease; but this statement requires

further proof

Mortad Anatomy.—When children who have been subject to ague die, the only constant lesion discovered is an enlargement of the spleen. During an acute attack, and for some time afterwards, the organ is engaged with blood so as to be several times its natural size. It afterwards duminates in bulk, but if the child remain in the malarious district it continues to be harder and larger than natural. The cut surface is then pale

and dryish, with white strice from thickened trabeculæ, and sometimes it has a gray tint or even a speckled appearance from dark gray spots. The capsule is thickened and often adherent. Besides the spleen, the liver a also congested during an acute attack, and afterwards may remain more of

less enlarged.

Symptoms.—In early life ague may occur either in the intermittent or remittent form. Both are common; for although in the adult the number tent form is rarely seen, except in the more serious variety of the disase, which occurs in tropical climates, in the young child a comparatively feeble dose of the poison may produce a profound effect upon the constitution, and excite fever of the remittent type even in a temperate zone in most cases the fever is quotidian, but it may be tertian and even, although rarely, quartan. The three stages of the attack are usually to be recignised; but they are less perfectly marked than in the adult, and are often characterised by peculiar features not found in after-life.

As often happens in the case of the adult, the attack may not come of for some considerable time after exposure to the malarious influence. Indeed, cases are sometimes met with in which a child, who is free from four while he lives in the agueish district, only begins to suffer after be is re-

moved to a more healthy situation.

The cold stage may begin with very violent symptoms or may give only trifling indications of its presence. The child may have a severe rigor like an adult, or may be taken suddenly with a convulsive seizure. If the latter the fit is rarely repeated, but is followed almost immediately by heat of skin and all the symptoms of the second stage. In infants nature rigours nor convulsions may be seen. Instead, the baby seems drown; frequently yawns; sometimes stretches itself; is peevish and fretful refusing the bottle; and looks pale and prostrate, with perhaps some lively of the lips and finger-nails. In rare cases the hands and feet are cold to the touch. This stage is usually short. The temperature rises progressively throughout, and even at the beginning, when the child feels colder actually shivers, is above the normal level. Towards the end of the stage the mercury may register between 103 and 104 degrees of heat.

The hot stage is usually better marked. In this the skin is distinctly februle; the child is drowsy and looks ill; if not flushed, the face is precipil and pale; and the head is said to be tender. The tongue is covered with a yellowish fur, and according to Dr Fruitnight it is not uncommon for the throat to be congested with a whitish deposit on the tonsils. The child is usually thirsty and drinks greedily; he often coughs indeed, a cough it said by Dr. Fruitnight to be a constant symptom of the attack; the pulse is rapid, feeble, and compressable. Pressure on the liver and spleen clust signs of discomfort, and both these organs on palpation are found to be enlarged. The child often vomits, sometimes bringing up bile; and the bowels may be relaxed. Occasionally an icteric tinge is noticed on the There is one symptom sometimes met with in a marked case which must not be omitted. This is a general bright redness of the surface. Such a rash, accompanied by a high temperature, and following rapidly upon a rigour or an attack of convulsions, would strongly suggest scurlatura, especially if at the same time some redness of the throat could be detected Through this stage the temperature continues to rise progressively, and towards the end has reached its maximum, which may be 105 or higher.

The third or sweating stage is very imperfectly developed in the it fast. Obler children may burst out into a profuse perspiration like the adult. Still, whether the disease end in sweating or not, there is a remarkable

fall of temperature at the end of the hot stage, and the thermometer will often mark 100° or 101 where a very short time before the pyrexia had been as high as 106° or 107°. At the same time that this diminution in the bodily heat is noticed there is usually a profuse secretion from the Libreys, and the child passes a large quantity of impid urine. According to Dr. Gice's observations, the proportion of urea and chloride of sodium are greatly increased during the hot stage, while the phosphates are diminished. As the temperature falls the amount of urea and of chloride of sodium diminish, while the proportion of phosphates is augmented

The duration of the attack varies. The hot stage, which lasts the longest, may occupy six or eight hours. After the attack is over, the child, if he is suffering from the intermittent form of the disease, seems quite well until the next attack begins. If the fever is of the remittent type, the putient remains more or less feverish in the interval. He is thirsty, has little appetite, is languard, pecvish, and restless; looks pinched and ill, and usually loses flesh. The wasting is sometimes increased by a troublesome harrhea. Often the fever, at first intermittent, may pass into the remittent form; and then, again, in its progress towards recovery return to the intermittent type. In many cases of the remittent form of the disease the fever runs a less acute course, and the temperature, although persistently elevated, does not reach the high level common in the shorter and sharper attacks. Thus during the paroxysms at may rise no higher than 102° or 103°, and during the remissions may be little over 100°.

In children of feeble constitution or reduced by chronic disease, the fever may assume very mahgnant characters. When the attack comes on the patient becomes stupid and drowsy, and then quickly passes into a state of come from which he never revives. Such cases are never seen in England. Dr. Lewis Smith states that he has twice met with this form

of the disease, and that in each instance the attack proved fatal.

Criticism who live in malarious districts often exhibit signs of ill-health without suffering from actual attacks of fever. Such patients are thin and weakly; the skin is of a peculiar pale bistre tint; the mucous membranes are pallid; the appetite is poor, and the bowels are costive or relaxed. The spleen is permanently enlarged and hard. If the ansemin is extreme, a tema of the legs and ankles may be noticed. Sometimes, however, colema in these cases is due to disease of the kidneys; for humaturia and albuminum are said to be not uncommon symptoms in children living in agne-breeding neighbourhoods. Indeed, in countries where malarious fever is prevalent the origin of Bright's disease in the child is frequently attributed to a previous attack of ague. Catarrhal pneumonia is said sometimes to complicate the illness and may even pass into confirmed pitthesis.

The more obscure forms of malarious fever, which are not uncommon to the adult, in the child are very rare. Brow ague is unknown. Bolin, however, states that he has met with an intermittent torticollis which he is level to be referable to a missmatic cause, and Dr. Gibney has de-

scribed an intermittent spinal paralysis also of malarious origin.

It across see When the disease assumes the ordinary form met with in the adult it is easily recognised; but when, as often happens, especially in infinits and the younger children, the stages are imperfectly marked and the samptoms indefinite, there is much difficulty in the diagnosis. If the case occur in an ague-breeding district, sudden illness and prostration with a high temperature should always excite our suspicious, especially if no system cause, such as counting or districts, exists to explain the alumning

symptoms. Afterwards the sudden fall in the temperature which occurs at the end of the hot stage, and the rapid return of apparent health as the attack passes off—these symptoms, combined with enlargement of the spleen, are very suggestive of malarious origin—When on the next day, or the day after, the same phenomena recur, ending as before in apparent recovery, the nature of the illness can no longer be misapprehended.

Fits of ague sometimes occur in children who are not at the time living in a malarious district. If we were suddenly called to a child of whom we had no previous knowledge, and found him looking ill with a very high temperature and signs of severe general weakness, we should be justified in regarding his condition with grave apprehension; for the fact of his having been lately exposed to the ague poison would probably not be referred to. In such a case, after a careful examination of the patient, we should be able to come to no conclusion, and might probably suspect the onset of one of the exanthemata. It would be only on the next visit, on finding the patient whom we had left in so apparently scrious a state looking and feeling well, with a normal temperature, that the nature of the

illness would suggest itself to our minds.

If, during the hot stage, the body becomes covered with a bright red rash, this symptom, combined with the high temperature and perhaps siight redness of the throat, may raise strong suspicions of scarlating. If, however, we are aware that the phenomenon may occur, and find that the rash subsides and the temperature falls completely in the course of a few hours, we should reserve a positive opinion as to the real nature of the eruption. When, later, the same phenomena are exactly reproduced, the nature of the case can be no longer doubtful. Dr. Cheadle has reported two such cases. In one a child aged two years and nine months-the illness began at 9 a.m. with a sharp rigour. A hot bath which was immediately given brought out a bright red rash all over the body. At the same time the skin was dry and burning, the temperature 102, and the pulse 110. There was no soreness of the throat. At the end of three hours the rash faded, and the next day the child was playing about as usual. On the following day-the third an exactly similar attack took place; and later the phenomena were again repeated a third time. Quinine was then given, and the ague fits quickly came to an end. In a case such as the above, if there is no reduces of the throat the resemblance to scarlatma is less close. Even if the throat is sore, the peculiar punctiform redness of the soft palate which is so common in scarlating is wanting; and, moreover, the redness in the fances is less generally diffused.

When ague assumes the remittent type, as it is apt to do in feeble, badly nourished children, the diagnosis is less obvious. In malarious districts it is well to suspect ague in all cases where pyrexia appears in a young child without evident cause. Still, the sources of error are numerous, for a probable cause of elevation of temperature, such as dentition, may be present in a child who is suffering from a real agueish attack. Perhaps the best rule in doubtful cases is to prescribe quinne. We can do bitle harm by this practice, and may do great good by putting a stop at once to attacks which in weakly subjects, if not arrested early, may pro-

duce very serious consequences.

Promosts.—If the disease be recognised and treated promptly it can usually be controlled with ease. The fatal cases are those in which the real nature of the illness has been misapprehended and specific treatment consequently withheld. Also, the exceptional cases where the child appears to be overwhelmed by the violence of the malarious poison, and

sees rapidly into a state of come, are said rarely to end in recovery. See even in these cases, if the cause of the symptoms were recognised a line, it is possible that energetic stimulation and the use of quinine in age doses by enema or hypodermic injection might be successful in recting a futal issue. It must not be forgotten that in malarious district the specific fevers, and indeed acute illnesses generally, tend to run increase course than in healthier neighbourhoods, and that as a rule ensures have a high rate of mortality. Children who suffer from the late cackerin are bad subjects for the eruptive fevers; and in all such cases we should speak with considerable caution as to the patient's chances of provers.

Townent.—Directly the existence of ague is recognised in a child specific treatment should be had recourse to without unnecessary delay. Children lear quinine well. A child of twelve months old will take a grain policial of the sulphate of quinine three times a day, and the fever will quint weld to this treatment. The best way of administering the remedy a touch it up with glycerine and give it either in a spoon or in a wine-partitud of milk, for milk helps to conceal the bitterness of the drug. It tankenne should be continued for a few weeks after the attacks have coincident in the given in diminished quantity or less frequent doses. At the same time it is desirable to remove the child from the malarious neighborhood. If this be impossible, it is well to give a dose of quinine twice

two for a cousi lerable time after the subsidence of the seizures.

lacus where the child vomits the quinine, or where from other reasee it is not desired to administer the remedy by the mouth, it may be the map the bowel suspended in a small quantity of mucilage, or may by ten by hypo lermic injection. In the former case the dose must be deal, that previously recommended for administration by the mouth. If is reme by is administered subcutaneously, Dr. Ranking recommends and the neutral sulphrate of quinne be used freshly dissolved in warm mer, that the syringe and solution be both warmed before use; and that is rejection be made very slowly, distributing the fluid at the same time to the interstices of the cellular tissue by the foreinger of the left ball so that no lump is left to mark the site of the puncture. It is found that warning the solution and the syringe not only lessens the pain of the proton, but also reduces the tendency of the quinine to deposit itself was in the cellular tissue. If used cold the quimne is almost always "Parted at once in a solid mass before absorption of the solution can pace. This is, however, not injurious, but it retards the beneficial elet of the operation. The quantity of the drug thus administered be a lifth of that given by the mouth. For an adult the dose is half Probably one-sixth of a grain would be a suitable quantity for a five or three years old. In order to prevent corrosion of the on to us a lyis able directly after the operation to wash the instrument 4 st water and stry it carefully, and afterwards to oil the screw well. Essel of the sulphate the kinate of quinine may be used. Mr. H. Colher as recommended this salt as the more suitable on account of its solubility for lypedermic administration.

It some cases, especially in the older children, where there is much active chargement of the liver and spleen, quinne seems to be useless. In the case it is of great importance to reduce the congestion of the liver of my beginning the quinine treatment. The child should take at night a live of gray powder (gr. iv) with jalapine or compound scammony powder, will the action of the bowels should be kept up for a week or two by doses

of some aperient saline. Sulphate of magnesia is very useful for this purpose, given with dilute sulphuric acid and half a grain of quinine for the doe. The medicine can be made palatable with spirits of chloroform, glyceine, and tincture of orange peel. After the liver has been unloaded, the quinine treatment in full doses can be returned to, or the child can take arenis (m. v.-x. of the solution three times a day for a child ten years of age), with or without quinine, directly after meals.

In the more chronic cases, a combination of quinine and arsenic with iron is very useful. It is also of great importance that the child be removed from the malarious district to a bracing seaside air. Moreover, he should be dressed from head to foot in flannel or some woollen material.

CHAPTER III.

ACUTE RHEUMATISM.

Reconstruction in the fibrous tissues is a common affliction in early life. In childhood, indeed, there appears to be a peculiar tendency to rheumatism; and in young people the disease may assume very special characters. The joints are generally affected, but other fibrous structures suffer as well. More often than in the adult the articular inflammation is absent, and not infrequently it is very partial and takes an insignificant share in the illness.

The great importance of rheumatism in children is due to the inflammation in and around the heart, of which it is so frequently the cause. The large majority of cases of heart disease are the consequence of rheumatic endocarditis occurring in early life. But besides the heart other fibrous structures may be attacked. The pleura may be affected; the meninges of the brain and spinal cord may suffer; and sometimes fibrous tissues in other situations may be implicated, as will be afterwards described.

Acute rheumatism is said to be uncommon under five years of age; but the accuracy of this assertion is open to question. Infants and young this literature may not suffer from much articular swelling and pain, but it is a common experience to detect a cardiac murmur at the mitral orifice in a young child, and to discover, on inquiry, that the patient had some weeks or months previously been feverish, with a little stiffness and tenderness of one or more joints, symptoms amply sufficient to establish the rheumatic origin of the cardiac disease.

thusation.—The principal cause of rheumatism is exposure to cold, or to cold and dump. In young children and infants a very slight impression of cold may suffice to set up the disease. Thus, I have known a young child exposed to draught from the nursery door, while being dried, after a bath, before the fire, suffer shortly afterwards from stiffness and pain in the knees and endocarditis. Sudden changes of temperature are favourable to the production of rheumatism. In England the disease is much more rife during the spring and the autumn, when the evenings suddenly turn chilly and damp, than in the winter months when the temperature is more uniform.

Many influences favour the action of cold and moisture in producing rheumatism. Family tendency will do this. A large proportion of rheumatic children come of rheumatic parents. Again, previous illness of the same kind predisposes to fresh attacks. When a child has once suffered from rheumatism, he is very likely to suffer from it a second time. The state of the health at the time of the exposure exerts some influence. The existence of catarrh of any mucous membrane renders the patient very sensible to child, and makes exposure very dangerous to a child of rheu-

matic tendencies. Lastly, scarlatina predisposes with peculiar force to

rheumatism or to a disease indistinguishable from it.

Morbal Androng. — When a joint becomes the seat of rheumatic inflammation, there is reddening of the synovial membrane lining the joint, the synovial fluid is increased in quantity and often nilky, and there is some effusion of fluid into the surrounding tissues. Supportation in the

joint is very rare.

In percentures the pericardium is reddened and softened, exudation of lymph occurs on the serous surface, and fluid is effused into the cavity. The serous fluid and the more solid lymph vary greatly in amount, and either may be in excess. The quantity of fluid thrown out is sometimes enormous. It may be clear or opalescent, or tinted red from blood. Sometimes, as in pleurisy, although far less frequently than in that disease, the fluid is purulent. The layer of lymph, also, may reach a great thickness. It may be smooth, or pitted with holes like a honeycomb, or ribbed like the seas-sand. Sometimes the visceral and parietal Liyers are united by soft thick bands of lymph. If the inflammatory process in the pericardium is severe, the heart substance towards the surface is generally softened to a certain extent and weakened. If much lymph has been thrown out, more or less complete adhesion is likely to take place, after absorption of the fluid, between the opposed surfaces of the serous membrane.

In endocarditis the morbid appearances, when not congental, are limited almost invariably to the left side of the heart. The valves become thickened and softened, and very soon granular on the surface. The granulations enlarge and develop into the so-called vegetations outgrowths from the fibrous tissue of the valve which may vary greatly in shape and size. They consist of connective tissue more or less perfectly organised. They are usually limited to the auricular surface of the valve, and are often partially covered by fibrinous deposits. Granulations may also develop on the chordæ tendineæ. The softened tissue of the valve may tear, or the chordæ tendineæ may rupture; and the tension of the valve and the closure of the oritice may be seriously interfered with. After a time the valves may become thickened, contracted, and hardened. Sometimes they adhere to one another or to the wall of the ventricle. In this way, also, the proper closure of the opening may be impossible, and the opening itself may be narrowed and altered in shape.

Ulceration may take place, seriously affecting the valve itself, and tending to produce other grave consequences. It is the washing into the circulation of fibrinous deposits and particles of disintegrated tissue from the ulcerated surface that produces embolism in distant organs—the brain, the

kidney, or the spleen.

Symptoms. The disease begins suddenly. The child, if old enough, complains of cold, and sits over the fire. He is unwilling to move about, sometimes vomits, and may feel some stiffness of the articulations. Soon, pain is complained of in one or more joints, and the child takes to his bed. When the patient comes under observation his temperature is moderately high—102 or 103. His skin is generally most with a sour-smelling perspiration, and on inspection we find the affected joints tender, swollen, and suffused with a pink blush. The child is thirsty, has little appetite, and his tongue is furred. The urine is high-coloured and scanty, and is often thick with lithates. The bowels are confined. The patient may wander at night; he sleeps badly on account of the pain; and for these reasons (pain and want of sleep) his face is often haggard-looking, and his expression distressed.

The pain is at first of only moderate severity, but gradually grows As long as the child is quiet and undisturbed he may not make complaint: but if the limb is touched, or the bed is shaken, he at me shows signs of distress. The degree of pain and the amount of swellat an affected are usually the larger ones—the laps, the knees, elbows, and wrists. It is exceptional for the small joints of the fingers at test to be painful and swellen. Usually one or two joints are first succel; these recover, and others become inflamed. The whole illness as as a variable time, but the duration of the inflammation in each patadar joint is comparatively short. It may pass away in a few hours, and rundy lasts longer than a day or two. Sometimes, after leaving a joint and possing to another, the inflammation returns to the joint first affected; and in this way, if the illness be a long one, the same joint may be attwid again and again before the energy of the disease is exhausted. has when the attack appears to be at an end, a sudden return of the symptax may distress and disappoint the patient and his friends. Relapses are ter common in rheumatic fever, and the symptoms may return, after a max has complete subsidence, two, three, four, or even five times.

The articular inflammation, although the part of the disease which case the greatest discomfort to the patient, is yet, as it seldom produces the illumination of comparatively traffing moment. A far more imported feature is the heart affection, which is so common an expression of the malady. Inflammation of the fibrous structures in and around the best of an essential part of the disease, as it attacks young persons, and make not be regarded as a mere casual complication. In exceptional case melecular child may have rheumatic fever and the heart may escape; and rheumatism all the fibrous structures of the body need not be affected at once. The patient may have inflammation of one joint and tot of another: the right wrist, for instance, may be affected and the left are example; one leg may be crippled and the other sound. So the disease the thick the joints and leave the heart alone, as it may attack the heart in space the joints. The younger the child the more likely is it that the leave will fasten upon the heart to the exclusion of the articulations.

The occurrence of rheumatic inflammation of the heart and perceardium and at once an nonced by any striking change in the symptoms, or even also aspect of the patient. Indeed, it is matter for surprise how complete a rost rises is the absence of all external indications that so important an allow has been made to his illness. Often the only sign of implication of these organs is derived from physical examination of the chest.

Is the unsatte inflammation of the pericardium there is in ordinary cases maker pun nor tenderness, we notice no special hurry of breathing or of piec, the heart's action may be irregular, but there are no palpitations; there is little change of colour in the face; and, unless the joint affection be see, the temperature may be only moderately raised, or may even be small. In spite, however, of the absence of symptoms, the child looks be and while up and about—as he usually is before coming under the notice of the method attendant, if the articular inflammation is not severe—the manner wears an expression of distress which quickly attracts the stantage of his friends.

Local aged three years and a half, was admitted into the East Local Children's Hospital. She had had a slight cough for a fortuight, was said to have looked ill. On examination, there was found dubband pyramidal shape in the pracordial region reaching upwards to the

left sterno-chondral clavicular, and to the right as far as one finger'sbreadth beyond the right edge of the sternum. The apex-beat of the heart was behind the fifth rib, slightly to the inner side of the nipple line. A faint impulse was felt all over the precordium. The heart-sounds were muflled, and a soft double friction-sound was heard at the base. The child complained of no pain. There was no affection of the joints. The other organs were healthy and the temperature was normal. A week afterwards it was noted: "The cardiac dulness is as at last report, and there' is the same friction to be heard over the precordial region. Since admission the child has had no symptoms, and the temperature has been generally subnormal. Still the patient looks ill, and there is a distressed expression on the face even during sleep. Is now (3 F M.) lying asleep on her back, inclining to the left side. Pulse 88, regular; respiration 28, nares not acting. Some slight lividity about the mouth and under the eyes. General pullor of face, with a faint tinge of pank on her cheeks. Lips rather pale. The superficial veins are visible over the sides of the neck and the backs of the hands, although not greatly enlarged." After a few weeks the physical signs of the heart became normal, and the child's health was perfeetly restored.

The above illustrates very well the general appearance of a child who is the subject of pericarditis. In the large majority of cases, although he may look ill and be languid, yet if there be no joint affection, he makes no special complaint. An examination of the chest at once reveals the cause of

the indisposition.

Still, it is right to say that in exceptional cases much more serious symptoms may be noticed. There may be tumultuous action of the heart, with great dyspneas or even orthopnea, and lividity of the face. The countenance may express the utmost anxiety, and the restlessness may be extreme. There is usually, also, some puffiness of the face, and slight but general cedema. The gravity of these cases is probably owing to the participation of the heart substance in the inflammation. Again, in still other cases we find symptoms all pointing to the brain. There is high fever, with headache and delirium (see page 159). Such cases are, however, chiefly interesting from their rarity. They occur very seldom even in hospital practice, and are chiical curiosities which for practical purposes may be put on one side.

The beginning of pericardial inflammation is indicated by a more or less loud rub of friction accompanying the sounds of the heart. The rub is best heard at the base, and is double, the systole and diastole being accompanied by a distinct catch or scrape, which is very superficial, and conveys the impression of being generated at a point nearer to the ear than the sounds of the heart themselves. Even if there be at the same time an endocardial murmur, the friction sound can be in most cases readily separated by the practised ear, through its higher pitch and more superficial character, from the lower pitched and more deeply sounding muruur generated by the inflamed valve. A percardial friction-sound is not, however, always high pitched, and even its superficial character may not be so decidedly marked as would be expected. In certain cases a loud blowing sound is heard, which is indistinguishable by the ear alone from a similar sound of endocardial origin. Its mechanism must be then decided by other considerations.

At first there is no alteration in the precordial deluces, but in a day or two, as fluid is poured out from the inflamed serous membrane, the limits of the heart's dulness are extended. At the same time the position of the apex-bent of the heart is raised, and the cardiac impulse is feebler

Altile girl, aged seven years, had a mild attack of rheumatism follow! by cherca. Six months afterwards the choreic movements returned,
at the was admitted into the East London Children's Hospital. At this
tage the heart's apex was noted to be beating between the lifth and sixth
not em fourth of an inch outside the nipple line; and a soft systolic
moment was heard at this spot. After being a few days in the hospital,
the rad's temperature rose from normal to 103.8, and a double rub was
becard over the prescondal region. There was also a patch of pucumotage the base of the right lung. Some days afterwards effusion was
tage to have occurred in the pericardium, the limits of the heart's dulness
were extended, and the heart's apex was raised to between the fourth and
the right at the level of the third left sterno-chondral articulation.

If such lymph and little fluid be thrown out, the hand placed upon the partial region can often detect a distinct fremitus with each beat it is seril. When a considerable quantity of fluid is effused into the partial, the resulting area of dulness takes the shape of the containing me. It becomes triangular or "pyramidal" in form, with the apex direct appears towards the top of the sternum. A moderate effusion does not present the friction-sound from being heard, but the rub becomes less these and less crisp than before, and the heart-sounds are muffled and that In great effusion the chest-wall in the cardiac region may be back and on careful inspection the eye can often detect a distinct unitatively movement with each beat of the heart in the intercostal

HALLIER.

As important distinguishing mark of pericardial friction is, besides its saperical character, the arregularity of distribution of the sound. Endocarried along with the blood-current. Pericardial In a may be himted to a small area, or heard equally loudly over the the pracordial region; in either case they do not follow the rules The regulate the transmission of heart-murmurs. Further, a pericardial tel contensated by pressure, and is heard better during expiration than the lungs are expande l. As the fluid and lymph become absorbed, the mails of dalness gradually return to their former dimensions; and the b. t a after a time becomes fainter and fainter and gradually disappears. I to kmph has been exuled in large quantity, adhesion of the pericar-Lay take place. Unless there be also adhesion between the pericarand the alprent plears, there are no physical signs by which this Caltion can be detected. If the pleura and pericardium be adherent, the attract d space corresponding to the apex of the heart is depressed who impulse. Adherent pericardium is generally followed by hypertophr of the heart.

The fluid in pericarditis sometimes becomes purulent. The supposition of pericarditis is more common in cases where the inflammation has evended to the pericardium from the pleura; although it may not also occur without the pleura having been previously affected. In the cases of this form of pericardial influmnation which have come under to take, the patients have complained of pains in the chest or epigistrate the temperature has been high at night (103 to 104), with a paragonary remission; pericarchal friction has disappeared early; about if the effusion, if it had begun at all, has been slow and incompate, and towards the end of the disease slight but general ordems has been

noticed without any albumen being discovered in the urine. These cases almost always end fatally.

When endocarditis occurs, the valvular lesion is indicated at first by no external signs, and can only be discovered by physical examination. With the stethoscope we hear a low-pitched soft murmur at some point of the præcordial surface, indicating, according to its site and rhythm, obstruction or incompetence of one or another of the cardiac valves. The affection of the valve may be accompanied by increased frequency of the pulse and some palpitation; but while the patient is at rest in bed these symptoms are very exceptional. Tenderness is never present, and it is rare for the chill to complain of pain or uneasiness about the chest. The valve affected is most commonly the mitral, although the nortic semilunar valves are sometimes inflamed alone, or in conjunction with it. The lesions are almost invariably limited to the left side of the heart.

Endocarditis may occur without implication of the pericardium, or the two lesions may be combined. In the latter case the endocardial murmur may be completely masked by the external friction-sound, and may only be discovered as the latter subsides. If unaccompanied by inflammation of the pericardium, endocarditis, although a very serious misfortune as regards the future of the patient, adds little, if anything, to the numediate

danger.

There is one accident which sometimes occurs as a direct result of endocarditis. The vegetations on the inflamed valve may undergo disintegration, and minute particles swept away into the general circulation may become arrested in the small arteries of a distant organ. Ulcerative endocarditis is not a common disease in children, but it is occasionally met with. This complication gives rise to symptoms which may be mistaken for those of pyramia or of continued fever, so close sometimes is the re-semblance. They are partly constitutional, owing to admixture with the blood of decaying atoms of organic matter from the disintegrating valve; partly local, from embolisms which interfere with the function of special organs. Thus there is high fever with marked remissions; great weakness and prostration; a furred dry tongue; often sickness, and perhaps diarrhoa, thirst, and anorexia. The pulse is small, rapid, and weak, the breathing hurried; and the child gradually becomes restless and delirious, or drowsy and comatose. The local symptoms are derived from the organ or organs, whose function is interfered with by arrest of emboli in their minute arteries or capillaries. Thus, embolisms in the skin produce petechic from minute extravasations; in the liver, swelling and perhaps jaundice; in the kidney, albumen and blood in the water; in the spleen, swelling and tenderness; in the brain, paralysis; or if from small disseminated emboli, headache, delirium, and coms, without special interference with motor function. In all these cases examination of the heart reveals the signs of valvular disease. The cases generally end fatally.

The pleura is often affected in rheumatism, alone or in conjunction with the pericardium. Pleurisy and pericarditis may occur simultaneously, or the inflammation may spread from one membrane to the other. When the two diseases are present together, the inflammatory processes in the two situations may be perfectly independent the one of the other. The effusion in the pleura may be purulent, and that in the pericardium serous;

or the pericardium may contain pus, and the pleura pure serum.

A little hoy, aged six years, died in the East London Children's Hospital of pleurisy and pericarditis. On examination the right lung was found adherent to the pericardium, and partially to the chest wall. It was

condensed and tough from pressure, and the pleura of that side contained a large quantity of clear fluid. The pericardium was adherent to the heart in places, and in the sac were about two ounces of thick pas. In this case the illness had begun with sickness and pain in the side, followed by cough—symptoms which pointed to pleurisy, and three weeks afterwards, when the child first came under observation, there was slight but distinct contraction of the right side, shown by lowering of the shoulder and angle of the scapula, with distinct curving of the spine—the convexity to the left. These signs, taken in conjunction with the history, seemed to indicate that the pleurisy had dated from the beginning of the illness, and that the refore, if it did not give rise to the pericarditis, was not, at any rate,

secondary to it.

Presumona is not rare in rheumatic fever, and may occur in conjunction with pleurisy or independently of it. A much rarer lesion is meningates affecting the membranes at the convexity of the brain and those of the spine. These cases are characterised by high fever, headache, and dehmum. Still, we must not suppose that in every instance where such symptoms occur in the course of acute rheumatism they are due to inflammation of the cerebral meninges. Many cases are now on record in which these symptoms have been present, with others-all pointing to the head as the seat of the lesion, and yet on dissection of the dead body no s. In of disease have been discovered within the cranium. Dr. Latham less described a case of this kind which occurred in a little scholar at Christ's The boy had high fever, headache, delirium, and convulsions; and died in spite of energetic treatment directed against a supposed menmentis. Examination of the body disclosed no disease of the brain or its membranes, instead, there were all the signs of a severe pericarditis-a herase which had not been so much as suspected during life. Troussau believed this form of "cerebral rheumatism," which leaves no trace d intracranal inflammation behind it, to be a neurosis depending upon some such invaterious modification of nerve-substance as is believed to occur in hysteria and tetanus. The symptoms may, however, be explained more simply by attributing them merely to the effects of hyperpyrexia; and this is the view commonly accepted in the present day. Such a case has never come under my observation; nor have I ever seen a case of rheumatic intis in the child, nor of peritoritis occurring in the course of acute rheumatism.

Peritonitis may, however, be simulated by rheumatism of the abdominal muscles which sometimes occurs in children. If this be severe, there is tendern as on pressure of the abdominal wall, the child may have an appearance of great distress, and may lie in bed with his knees flexed on his abdomen, as if he were really suffering from inflammation of the peritoricum. The bowels are usually confined. These cases may be readily distinguished by careful examination. The face, although often distressed, has not the haggard look which is so characteristic of peritonitis; there is little or no tension of the abdominal wall; the natural markings are not lost; the tenderness is not extreme; the pulse is soft, compressible, and of moderate quickness, not rapid and hard; and the temperature is normal or only slightly elevated. There is generally great accusty of urme; it is scanty and high coloured, and its passage may cause some scalding.

Tortwolls estiff neck) is sometimes a consequence of rheumatism. The disease may affect the muscles, especially the sterno-mastoid; or may attack the fibrous ligaments uniting the vertebra. The nervous system, too, may suffer. Neuralgia has been noticed in some children; and paralysis

of the muscles of one side of the face may be produced by rheumatic inthammation of the sheath of the facial nerve at its point of exit from the bone. Moreover, there is an evident connection between rheumatism and chorea. This important subject will be considered elsewhere see Chora).

A peculiar manifestation of rheumatism is sometimes found in cl., dren. This was first noticed by Meynet, and is characterized by swellings varying in number and size which appear in the tendons and their sheatist, and in other fibrous structures which he close under the skin. Thus they are seen around the patella and the malleoli; on the spinous processes; on the temporal ridge, and on the superior curved line of the occiput. They are very hard; are accompanied by no redness, tenderness, or pain, are sometimes movable; and disappear after a time spontaneously. They are composed of small masses of loose fibrous bundles, and are very tascular.

A little girl, nearly ten years old, was under my care in the East London Children's Hospital for an attack of rheumatic fever complicated with chorea. She had a harsh systohe murmur at the apex of her heart, which evidently dated from a previous attack of endocarditis; but the apex-heat was not displaced, nor were the normal limits of the heart's duliness extended. In this child fibrous nodules were found on the spinous processes of the vertebre, the prominences of the scapula, the head of the radia, the tendons in front of the right ankle, and the back of the right hand. The nodules varied in size from a split pea to a large marble; they were not tender, and the skin over them was not adherent. While the child remained in the hospital her temperature never at any time rose above 100. The swellings gradually diminished in size, and by the end of the month

had almost completely disappeared.

The duration of the rheumatic attack is much longer in some children than in others. It may be variously estimated according to the method upon which the reckoning is conducted. If we take into account merely the joint affection and the general symptoms, the disease may be considered over in a few days. A child may be taken with high fever, and complete of pain in one or other of his joints, which is found to be red, swollen, and tender. In twenty-four or forty-eight hours the articular inflammat. may be at an end and the temperature normal. But it does not follow that the disease is over; and if we at once begin to treat the child as a convalescent, we may find reason to regret our precipitation. Serious taflammation of the pericardium and lining membrane of the heart is quite compatible with a normal temperature; and these internal lesions may be only beginning when the external signs of the disease are on the wane. As it is only in exceptional cases of rheumatic fever that the heart does not suffer, and as the mildest attack of percarditis is seldom over before week has gone by, eight or ten days must be considered the earliest period at which convalescence can be said to begin.

In other cases, if there are frequent relapses, the disease may be prolonged for many weeks, the inflammation leaving joints and returning to their with wearisome repetition, and the pericardial inflammation waving and waning with similar persistency. In this way an attack may be now to last six weeks or two months. It is, however, only right to say that since the introduction of the salicylates these cases are much current than

they used to be.

Although the joint affection in rheumatism is usually an acute discuss and ceases when the attack is at an end, yet this is not always the cost Children with strong rheumatic tendencies, and who have had several at

acks of rheumatic fever, may complain of wandering poins in the back, much and forms, and of transient discomfort and stiffness in a joint from take to time, especially in the variable seasons of the year, without having to take to their beds. In such patients there is general impairment of balth, appetite is poor, and nutrition is unsatisfactory. The child is oftoner ressively nervous, sleeps badly at night, and is changeable in temper. Dr West has connected these symptoms with the lithic acid diathers. There is no doubt that such children are subject to sandy deposits

in their urine, and to abundant secretion of urea.

Diguous - When the joint affection is well marked it can scarcely be metaken. An acute articular inflammation which flies from joint to yart expreciously, is accompanied by redness, swelling, and extreme tenderives, and in a day or a couple of days has passed completely away from the joint first attacked, to run the same rapid course in another act a disease can only be rheumatism. Real rheumatic joint affections we very transitory. If redness, pain, and swelling persist in a joint supposed to be rheumatic, we may suspect strongly that the true cause of the lesion ess ret to be discovered. It is often difficult to decide the nature of the were pains and stiffnesses from which some children suffer. The socaled "growing pains" are often rheumatic in their origin; and if they over in children of decided rheumatic family tendency, should be reguled with extreme suspicion. A careful examination of the cliest will dearlear up obscurity, and it is unfortunately too common to find serious white or pericardial mischief associated with a very trifling amount of whether or even muscular pain in young subjects. A to-and-fro friction exad over the pracordial region, if decided, is very suspicious in itself of percaptual influentation. If the child look ill, and especially if there be the acresse of the heart's dulness, the evidence in its favour is complete. A fust double rub at the base of the heart is not in itself sufficient to eswhich this conclusion; for such a friction may be produced by slight regimess of the perseardisl surface, from prominent vessels or other cause, *bet the membrane is quite free from inflammation.

Dulness of pyramulal shape in the precordial region, although very measures of pericardial effusion, is not conclusive; such a dulness may be trained by a mass of enlarged glands in the anterior mediastinum. Extension of dulness to the left, beyond the point at which the apex beats, and to be a positive sign of effusion. The increase in the dull area the patient is placed in the erect position is often absent; when present, it is, no doubt, an additional proof of fluid accumulation in the

or of the heart.

When the fluid becomes purulent, as it may do at an early date, the moure of the contents of the sac may be inferred from the variable imperature, the mercury rising every night to 104° or 105°, and ainking the morning to the normal level, or even below it; the early subsidence of the friction, although the amount of the effusion remains unchanged; in stationary character of the dulness, showing want of absorption of the fall, and the appearance, after a time, of more or less general codema without all and the appearance.

On account of the frequency with which pericarditis and pleurisy are continued in young children, we should never neglect to make a careful turnation of the heart in every case in which we have ascertained the theorem of pleural inflammation. Pericarditis, under these circumstances, and easy to diffect, as the dulness in the precordial region is attributed to be effection in the chest cavity. Unless, however, the pleural effusion

be very great, the percussion note in the infra-clavicular region is very different from that obtained in the precordia. If, therefore, we find complete duluess towards the upper part of the sternum, and a fairly resonant or wooden note below the clavicle near the acromial angle, we may strongly suspect accumulation in the pericardial sac. Friction over the heart uny

then be generally heard on careful auscultation.

A difficulty sometimes arises in these cases from a pleural friction of cardine rhythm being heard at the limits of the pericardina. The isomorphist to the action of the heart causing a movement between the adjusted pleural surfaces. In these cases if the child be old enough, or sufficiently while the breath is held after forced expiration, and if the rub cease or he has a only at this spot, it is probably due to the cause referred to. It is not

always possible, however, positively to exclude pericurditis

If we hear a blowing murmur at the apex of the heart, the question of valvular competence has to be considered. All blowing nurmurs at the apex must not be taken to indicate regargitation, nor, indeed, are they as positive sign that the endocardium is inflamed at all. The murnur may be the consequence of regurgitation, of roughness of the valve or cardialining, of anamic dilatation of the ventricle, or of mere abnormal tensi a of a healthy valve, and there is nothing in the quality of the sound to show to which of these causes it may be properly assigned. If, however, the second sound is evidently intensified over the pulmonary artery; if the murmur is heard at the angle of the scapula; and if, with a full contraction of the left ventricle, the pulse is feeble, small, and irregular, we can confidently pronounce the mitral valve to be insufficient. Still, regulartation may take place without giving rise to these signs. Therefore in most cases we must reserve a positive opinion, and wait until suffrant time has clapsed to allow of nutritive changes taking place in the wall of the heart. If there be no displacement of the apex-best at the end of twelve months, we may be satisfied that the cause of the murmur is not regurgitation.

A recent murmur is very soft in quality and of low pitch. After long in existence for some months it becomes harsher and its pitch rises. If a case of acute rheumatism we hear a barsh and loud er docard. I name at the apex, we may be sure, whatever its mechanism, that it is not of re-

cent origin, but is a relic of some former attack.

The diagnosis of ulcerative endocarditis has been already sufficiently explained. If we find that a child, who has lately suffered from an attack of acute rheumatism with endocarditis, remains feverish, with rapid elevative and depressions of temperature, such as are characteristic of supportation if he pass quickly into a typhoid state with dry brown tongue, how of appetite, hurried breathing, and signs of great prostration, we should support the presence of this complication; and if we find evidence of embodies.

isms in special organs, our suspicions are sufficiently confirmed

Progress.—The immediate prognosis of acute the unation is sell a otherwise than favourable. Even the existence of endocarduts and not a mation of the pericardium cannot often be regarded as giving rise to a fear of immediate danger. Still, it is well not to speak too positively in predicting a favourable issue to the illness. In acute the amatism—even at the mildest cases—there is a tendency to hyperinosis, and the rapid from tion of a clot in the right ventricle of the heart or in the puln may artery may be a cause of sudden death. In some instances this distressing accident happens quite unexpectedly in a case which is running a fa-

countle course, and may even occur at a late period of the disease after consistence has seemed to be established. Again, in rare cases, pericarlines a reases of death. When the effused fluid is or becomes purulent,

the duger is great; and few such cases recover.

The ultimate consequences of an attack of rheumatic fever may be very see as, for the large majority of cases of heart disease can be referred to the case. But, as already remarked, the mechanism of heart-marmura to example, that the mere existence of a blowing sound at the apex of the heart is no in lication in itself that serious consequences are to be appared to the child be seen during an attack, or while the murmurant lication is impossible to speak with certainty as to the gravity to be unched to the phenomenon. If, after a time, we discover signs of distant typertraphy of either ventricle, with displacement of the heart spectral accentuation of the second sound at the pulmonary cartilage.

to locardial murmurs arising during an attack of rheumatism in children sometimes disappear. It is probable that in all these cases the morbid and was generated by other mechanism than valvular incompetence, for I have never known the auscultatory sounds to become healthy except

us make where the heart's apex has retained its normal situation.

t little lov, uged eighteen months, with sixteen teeth, was brought to me is N vember, 1874. A few months previously he had seemed to have parant stiffness in some of his joints, and had been a little feverish, a that time he had been subject to pulpitations which were sometimes "Lt. On examination I found a loud basic systolic murmur conducted bette second right cartilage, and at the apex a less loud mitral murwar. The apex-beat was normal. In March, 1875, I saw the child again. To apex-best was still in normal site. The heart-sounds were a little male I to the ear, although no murmur could be heard at either the base or to spor; but on this occasion no attempt was made to excite the heart's The patient was seen for the third time in March, 1881. He was 10 x searly eight years old, and of average height for that age. Although rather than, he was stated to enjoy good health, and never complained of printains or of breathlessness. The position of the apex-beat remained saltered. The first sonn I was muffled, and after the boy had been made to run round the room, a faint systolic murmur was developed at the apex. hord I not be heard at the angle of the scapula.

In this case the basic murmur disappeared, and that at the aper become so indistinct that it could only be detected by exciting the heart's stron. Whatever may have been the cause of the abnormal sounds first send, they were apparently the consequence of rheumatism. Still, it sends certain that there could have been no organic lesion of valve, for in the course of nearly seven years no alteration in the nutrition of the heart

hal triken place.

Trestment.—A child the subject of acute rheumatism must be kept in bed, the influent joints must be wrapped in cotton wood, kept in place by a tirruly up plot dannel bandage, and the chest should be also enveloped in the same material. A mercural purge should be given to produce free action of the bowels; and subcylite of soda should be administered without unnecessary delay. Children, as a rule, bear this remedy well. It is constituted to find any ill effects resulting from its employment. For a child of five years of I, ten grains of the salt may be given every two or three hours with uncture of orange peel and glycerine. Within two

or three days, sometimes within a few hours of beginning the treatment the temperature falls, the pulse becomes less frequent, and the joint symptoms are moderated. The pulse usually loses in strength as well as m frequency; and the depression induced by the action of the drug upon the muscular fibres of the heart is sometimes so great that its administration has to be supplemented by the free use of stimulants. This effect of the remedy is, however, less common in children than it is in the adult, and I have rarely been obliged to discontinue its use for this reason. It sometimes causes distressing vomiting, and occasionally excites epistans which may be obstimate. If, on account of any of these accidents the treatment has to be suspended before the disease is completely subdued, the temperature often rises again, and the joint affection may return.

In a small minority of the cases the medicine, although well borne uppears to exercise no influence upon the disease, and even when it lowers the temperature and subdues the joint affection, it seldom prevents the occurrence of cardiac or pleural inflammation. The first signs of percarditis may be noticed when the patient appears to be under the influence of the remedy; and I cannot say that in any case the course of the percardial disease has appeared to me to be shortened by the use of the salecylate. Still, if only for its influence in reducing temperature and checking articular inflammation, the drug would be a most valuable one, and we should not be doing our duty to the patient if we neglected to employ it.

In cases where the salicylate cannot be used, we may adopt the alkaline treatment, giving bicarbonate of potash in ten-grain doses every three or four hours. If thought advisable, the bicarbonate may be combined with quinine; or we may prescribe a mixture of quinine with iochde of potassium, as recommended by Dr. Greenhow. The objection to the alkaline plan of treatment is that it encourages the tending to anomia. It should therefore be supplemented by the early administration of iron when the joint pains have subsided. The method of treatment advocated by Dr. H. Davis, which consists in encircling the affected joint with a thin have a blistering fluid is a painful proceeding and ill-suited to young patients. The best local application is a thick layer of cotton wool, with a firmly applied flauncel binder.

If there be much pain in the joints, a small dose of Dover's powder can be given at night (gr. ij.-iij. to a child of four or five years olds. Chloral must not be used during the administration of the salicylate, as it also has

a depressing effect upon the heart.

Hyperpyrevia is not common in cases of rheumatic fever in children and, indeed, it is difficult to say what degree of elevation of temperature con in an ordinary case be accounted hyperpyrevia in a child. An injurious amount of fever is usually accompanied by symptoms of mental disturbance such as are characteristic of the so-called "cerebral rheumatism." If these are absent, it is unnecessary to attempt to reduce the temperature by boths: unless, indeed, the pyrexia persist and seem to be injuriously affecting the patient's strength. I have never seen a case of rheumatic fever in a child in which I have felt it necessary to employ cold.

The dict in acute rheumatism must be simple. While the fever persists the child should take nothing but milk and fresh-meat broths, with a little dry toost. When the temperature falls, a more generous dict may be allowed; but for some time attention should be paid to the quantity of fermentable matter, such as starches and sweets, taken by the child. The appearance of lithates in his water is a sure sign that some modification in

his diet is required.

Directly the existence of pericarditis is ascertained, a blister should be applied over the pracordial region without loss of time. I prefer the blistering fluid for this purpose as most certain in its action, and use it to quite young children. It is of extreme importance to check the pericardial inflammation early, and there are no means at our command so efficacions for this purpose as a blister. In many cases the effusion begins to disappear as the blister rises. If there be much effusion, and the joint affection have subsided, I am in the habit of giving large doses of the iodide of potassium, alone, or with the tartrate of iron. The iodide is in my opinion of great value in removing scrous effusions, if given in full doses. To a child of five or six years of age I give ten grains of the iodide three times a day, and have never seen ill effects follow its employment. On the contrary, its value in causing absorption and restoring the natural state of the membrane has appeared to me to be very decided.

In endocarditis, also, bistering should be employed; and if the temperature has fallen, iron and quinine should be prescribed. The same tome treatment can be adopted in cases of pericarditis after absorption of the effusion, for the patient is usually left amenic and weak from the attack, especially if he have been treated with the salicylate of soda. In all cases where the disease has been complicated with endocarditis it is advisable to keep the child in bed as long as possible; and even when he is altowed to get up it is wise to enforce the utmost attainable quiet. In these cases the heart is more likely to recover itself if its action be not excited; and, indeed, judicious care during convalescence may largely influence the future well-being of the patient. Complete rest moderates the heart's action, and allows time for the healthy removal of inflammatory products from the valves. If such products become organized, they contract the tissues and cause puckering of the valves, with all the evils which the resulting lamiliance to the circulation must inevitably entail.

If suppuration in the pericardium is suspected, the sac should be carefully punctured with a hypoderime syringe in the fourth or fifth interspace, near the left edge of the sternum, to make sure that the fluid is purulent. If it prove to be so, the question of evacuating the contents of the pericardium must be considered. Professor Rosenstein has reported an interesting case, in a boy of ten years of age, in whom recovery took place after the sac had been emptied. The pericardium was opened by incision in the fourth space, near the stornum, and after the pus had escaped, two drainage-tubes were passed into the wound, and antiseptic dressings were employed. This form of pericarditis is so fatal that the operation should be decided upon if the state of the patient offer the slightest prospect of its

success.

Muscular rheumatism, whether it affects the abdominal wall or the muscles of the neck, must be treated with stimulating applications and with wurmth. A good mercurial purge to relieve the bowels is useful.

In cases of chronic joint pains affecting children who are old sufferers from rheumatism, it will be often necessary to change the conditions under which the patient has been hving. Removal to a warm dry air will often do wonders. Great attention should be paid to the action of the skin and kilneys. Five or six grains of bicarbonate of potash, with an equal quantity of curate of iron, given three times a day, will be found of service. Fermentable matters and acid-making articles of diet should be taken with moderation.

CHAPTER IV.

SPONTANEOUS GANGRENE.

Anonour the non-infectious general diseases may be included the curious condition in which apparently spontaneous gangrene becomes developed in various parts of the body. The lesions are often symmetrical, but are not so in every case. Sometimes the lower limbs are the parts affected; but portions of the face and trunk may be also attacked. Children, the subjects of this tendency, are not always cachectic or otherwise enfectled; although in many cases the gangrenous process occurs in convalescents from acute or depressing disease. After measles a special disposition to gangrene is occasionally discovered. The same tendency is displayed, but less frequently, after other acute specific diseases, as scarlatina, variola, varicella, and enteric fever; and insanitary conditions generally, combined with poor food, have been cited as predisposing causes of the gangrenous lesions. It is said to be more common in cold than in warm weather; and some observers are disposed to look upon a low temperature of the air as

one of the causes of the mischief.

In the case where the disease appears in a well nourished child who has not previously been subject to any enfeebling influence, the etiology of the lesion is obscure. Raymand, who was the first to describe a "symmetrical gangrene of the extrematics," attributes the affection to a spasm of the arterioles, followed by a impration of blood-corpuscles and transudation into the skin. He states that he has noticed, with the ophthalmoscope, spasm of the arterioles of the fundus occuli in these cases. The disease is sometimes associated with intermittent humaturia; and Dr. Gee has reported the case of a little girl, aged five years, in whom gangrene of the vulva was combined with embolism of the kidney and the brain. Still, in many cases no lesion of the viscera or arterial system is discoverable on the closest investigation; and no evidence has yet been brought forward pointing to any centric or nervous defect capable of exciting mortification of the tisanca, although the symmetrical distribution of the lesions is suggestive in many cases of some such mode of origin. Dr. Nedopil, in explaining the mechanism by which spontaneous gangrene is produced, assumes the existence of a functional nervous derangement. This writer agrees with Raymand in ascribing the arrest of circulation to a spasm of the walls of the arterioles in the part affected. He supposes that owing to irritation of sensory and centripetal nerves the reflex centre of the vaso-constructors which control the circulation at the extremutes of the limbs is excited. If the spasm be prolonged and be sufficiently intense to close the arterial channels, gangrene of the part may be induced.

Children of all ages may suffer from the disease. It may occur immediately after birth, or may appear in later childhood. It is not always fatal; but if the gangrene is extensive and penetrates deeply through the

skin, it seldom terminates otherwise than unfavourably,

Gangrene as it affects the mouth and the lung is described elsewhere. In the present chapter gangrene of the skin and underlying tissues will above be considered.

Mr. I bedony -Gangrene may affect the healthy skin or may attack a bistered surface. In the first case the skin becomes dark blue in colour, it has almost black. Its consistence varies. Sometimes it is hardened and feels dry like parchment, in others it is softer and moist. At the markets of the gangrenous patch the skin is residented and inflamed. Instead the skin is patched to patches the gangrene may assume the form of ulcers limited access. These ulcoss are circular in shape, with abrupt, clean-cut edges, at their depressed floor is formed of a gray or blackash slough. They have tracted completely through the skin.

When gangrene attacks a blistered surface the lesion is usually more special than in the former case. It appears in the form of a lightish

gas wayle, marbled here and there with a violet tint.

Sometimes the gangrene penetrates completely through the skin and substancous tissues. It may then be found in two forms: a moist and a dispersity. In the moist form the gangrenous patch is black, softened, all calculated with a dirty, reddish fluid. Its odour is excessively offensive, addit tessue, affected appear to be completely converted into a putrescript. Often it begins as a small pumple, which changes into a bleb of the gather than purulent matter. As the process continues, more and have skin becomes involved, and a considerable extent of surface may be a techniques, and beggy to the touch. The centre is usually pumple. On this surface blebs form and burst, leaving spots of gangrene. The detrie units, and if the patient survive may become limited. The gangren is then thrown off, leaving the under muscles exposed.

When the gaugeene assumes the dry form its anatomical characters are at the total of sends gaugeene. MM. Rilhet and Barthez describe a send which the skin of one leg was completely mortified. On the toes are sure the translational blackish. Elsewhere it was transparent, hard, redds, and elistic like a piece of parchment. The dried skin was so transparent that the injected venous radicles could be seen ramifying on the other surface, and it had a currous resemblance to the rind of bacon.

In some cases ante-mortem clots have been found in the arteries leading to the affected part, but in not a few cases no embolus is to be found

is the femoral or other arteries of the diseased limb.

A constituent sent for this spontaneous gangrene is the vulva in the female child. Here the gangrene usually begins on the labia, and may spead thence to the interior of the vulva, to the anus and the sacrum. The affected parts are dry and blackish-brown, and may slough off, leaving the muscles exposed. In mode infants the scrotum is sometimes attacked. Often the piches of gangrene are not limited to one region or to one land, but occur in scattered spots of various sizes situated on the legs, the arms, the buttocks, or other parts of the body. The lexious are then often symmetrical, attacking corresponding parts of the surface on the two sales.

Some time. Children the subjects of this tendency to spontaneous mortuniation are hable to attacks of what has been called "local asphyxia." Some part of the body—usually a finger, a toe, or the whole of a hand, a feet, or even a limb—becomes excessively painful, and is noticed to be purple in colour. It feets cold to the touch. The tint may deepen to a dull leaden have. After three or four hours, during which the greatest anxiety has been excited, the pain subsides; the colour of the part grows

lighter and then becomes normal, and the natural warmth returns to the skin. These attacks are sometimes accompanied by severe abdominal pain. Occasionally, too, they are followed by hæmatura of a distinctly intermittent character, the water being normal at some times, red with blood at others. The attacks of local asphyxia do not always subside harmlessly. In some cases the symptoms grow slowly worse, and the affected part becomes gangrenous.

Gaugrene occurs in two principal forms: disseminated and more or less symmetrical gaugrene, and gaugrene limited to the extremities, the

vulva, or the serotum.

In the disseminated variety the disease begins in scattered nodules or patches. The child for some days appears to be unusually drowsy, and then, if old enough to speak, complains of pain in some part of the body—the thighs, legs, buttocks, or arms—and livid patches make their appearance, which grow rapidly darker in colour. The patches are hard and tough to the touch, and seem to be tender, for pressure elicits signs of suffering. If the patches are few and small, the general health may be little affected; but if they are large or numerous, there may be vomiting.

headache, and general malaise.

Dr. Southey has reported the case of a little girl, two and half years of age, who had a feverish attack accompanied by purpuric spots on the limbs. She soon recovered, but some months afterwards had a second attack which lasted three days. About a fortnight later the child complained of headache, and said she had hurt her legs. The pain was increased by friction of the limbs. In rubbing them it was noticed that the skin on the backs of the calves was livid. Soon afterwards the child vomited, complained of headache, and was feverish. Towards the evening the patches were seen to have extended up and down the calves and to be darker in colour. A similar appearance was noticed at the backs of the arms, and on the following morning the buttocks had become hvid.

When admitted into the hospital on the second day the child was moribund. The pulse at the wrist was feeble and somewhat wiry, but could still be counted. The tibial pulse could not be detected. The patches of lividity felt hard and tough. The lungs and heart appeared to be quite healthy. Brandy and milk were given, and two doses of nitro-glycerine, but all were vomited. Intelligence was preserved until evening. Convulsions then occurred, and were frequently repeated until the child's death at 11 r.m. The illness altogether lasted only thirty-two hours. A post-mortem examination of the body discovered no coarse lesion of the viscera, nor could any embolus be detected in the femoral or other arteries of the

left lower limb, which was the only one examined.

Mr. Astley Bloxam has kindly communicated to me the particulars of a case of spontaneous gangrene which was under his care in the Charing Cross Hospital. The child—a little girl of ten months old—had been aling for eight weeks. A small pumple then appeared on the region of the inferior angle of the scapuls. The next day a head formed on the pimple, and became filled with purulent fluid. When the child was admitted a day or two afterwards (on August 19th) she was seen to be pale and thin, and was said to be wasting. The whole of the scapular region on the right side was a dematous, red, boggy, and hot. In the centre was a purpuric patch an inch and a half long by three-quarters of an inch broad, the borders of which were quite purple. On palpation the patch gave a boggy sensation to the finger, as if from fluid underneath the skin. The temperature on the first evening was 101.8°.

On August 20th the patch had slightly enlarged. Temperature: in the morning, 100.6; in the evening, 101.2. Pulse, 96; respirations, 60.

On August 21st the patch was much larger, measuring three and threequarter inches long by two and one-half inches broad. Some bulke had appeared on the surface, and one of these had burst, leaving a small slough. There was no tenderness at the gangrenous part; indeed the opposite appeared to be the case, and the part seemed to be unusually devoid of sensibility. Temperature: in the morning, 98°; in the evening, 99.6°. Pulse, 120°, respirations, 60°. An ammonia and bark mixture was ordered, and in the evening the part was well painted with strong nitric acid. The application caused no pain. Thirty drops of brandy were ordered every three hours.

After this the slough did not further increase. On the contrary, it began to separate, and the surrounding cedema to subside. There was a little diarrheea. On August 24th part of the slough came away and exposed the mascles. The child became very fretful and weak, and died rather sud-

denly on August 29th.

When the gangrone attacks the extremities, it may be seen in the fingers and toes, or may spread to the hands and feet, or even higher up in the limb. Children so affected are usually pale, under-nourished, and cachectic in appearance. After a few days of more or less irritability, loss of appetite, headache, sleepiness, and general malaise, the patient begins to complain of severe pains in the toes, which may extend for some distance up the legs. At the same time the ends of the toes are noticed to be dull red or purple, and their sensibility is found to be blunted. The pains continue. There may be some fever at night, and in the morning the hvidity of the ends of the toes is seen to have extended to the circumference of the nail. At this point the symptoms may subside, the pains becoming moderate, and the hvidity fading and disappearing; or, on the contrary, the disease may go on to complete sphacelus, and extend to the whole of the foot or even of the limb. Thus, François records the case of a child, three years of age, makem the gangrene involved the whole of the foot and lower part of the

This form of gangrene may be dry or moist. If the former, it assumes the characters of semile gangrene, becoming separated by a line of demarcation, and subsequently detached. Raynaud reports the case of a little girl, aged eight years, of good constitution and healthy appearance, who began to complain of severe pains in the feet and lower halves of the legs. It the same time the ends of the toes were noticed to be blue. The pains increased and the child was a little feverish. The fourth toe on each foot became date-coloured, and the other toes showed spots of livid red. The mortified parts were insensible to the touch, but the pains continued and were worse at night. The appetite remained good, and there was no diarriced. After a few days the pains ceased, and the gangrenous patches became limited by a well-defined line. In about a fortnight the toes desquamated. Dry brown scabs became detached, and left the skin beneath them unted of a pale violet colour. On the fourth toe of the right foot, the one which had exhibited the largest patch of gangrene, a black crust was thrown

off, and a suppurating surface was left which quickly healed.

A very similar case has been published by Dr. Southey. In this the spots of gangrene were accompanied by subcutaneous mottlings of the trunk and limbs. These mottlings developed into a raised rash like crythema tuberculatum. The cruption at first itched, then became tender and painful, but eventually subsided, leaving merely a discolouration of the

skin. Recovery in such cases is sometimes followed by an attack of parexysmal ha maturia, in which large quantities of crystals of oxalate of hime

are passed with the urine.

In the moist gaugeene of the extremities the affected part—which is commonly the end of a finger or toe—is swollen, and the epidermis is raised up by red serous effusion. As the destruction of the tosues of the part proceeds, the articulation may be laid open. Sometimes moist gaugeene of the extremities is combined with disseminated spots of a kind similar to those previously described. Thus, MM. Rilliet and Barthez refer to the case of a little garl, aged four years, who was under the care of Legendre. In this child moist gaugeene attacked the ungual phalanges of the right thumb and middle finger—in the latter laying open the second articulation—and the ungual phalanx of the left forefinger. Moreover, gaugeenous blebs filled with bloody serum formed at the back of the shoulder, in the lower part of the dorsal region, and in other parts of the body. At last a double pneumonia declared itself, and the child died on the ninth day

from the beginning of the illness.

When the gangrenous process attacks the vulva, the lesion is usually seen in a cachectic or weakly child, who has lately passed through an exhausting illness. Severe measles occurring in a scrofulous subject is sometimes followed by this dangerous sequels. As in gangrene of other parts the earliest symptoms are usually loss of appetite, headache, and nausea. Then the child complains of severe burning pains in the gentrals; and a light red circumscribed patch is seen on one of the labas, often on its internal aspect. Around it the tissues are dense and swollen for some distance. The patient cries frequently with the pain, and seems to suffer great distress in passing her water. After a day or two ashy gray spots appear. These are circumscribed and limited by a light red ring. Soon their colour changes to a dark brown or black, and the gangrene spreads to the upper part of the vulva, the perimeum, and the anus. Often there is a purulent, offensive discharge from the diseased surface. The general symptoms also become more pronounced. The pulse is small and rapid; the features are pinehed, and the face is very pale. The child lies meaning in her hed, and complains of pains not only in the diseased parts, but also in the limbs and body. Sometimes a watery diarrhoa comes on, and in that case the child soon dies exhausted. If by energetic treatment the gangrenous process can be arrested before it is too late, the sloughs separate, the swelling and darkness subside, and a granulating surface is left which quickly heals.

The gangrenous patch is sometimes single and of limited extent. Often the case is first seen when the separation has partially occurred, and a sloughy-looking ulcer is found on one of the labia. Still, however small the local lesion may be, the general symptoms are severe, and on account of the exhausted state of the patient the danger is very great. At the beginning of the disease a slight febrile movement is sometimes noticed, and the temperature may reach 100° or 101; but the pyrexia usually quickly subsides, and the temperature for the remainder of the illness is below the level of health. Death in cases of gangrene may occur from exhaustion. Sometimes it is ushered in by a series of convulsive attacks. In Dr. Gee's case of gangrenous ulcer of the vulva an extensive embolism was

found in the cerebral arteries.

Diagnosis.—The diagnosis of spontaneous gangrene in the child presents little difficulty. The only case in which a mistake is likely to be made is that in which the disease attacks the extremities of the tingers or

to a luthat case the pricking pain, combined with the livid line of the are, to suggestive of childrens; and, indeed, according to Raymaud, case of this variety of gangrene have been often confounded at the beginning with this common and insignificant disease. In most cases of gangrene however, the puns are far more severe, the occurrence of the local lightness is more abrupt, and several fingers and toes are attacked simultaneously. Moreover, the gangrenous lesion is often found at a season area the common children is not usually suffered from.

improved—In every case of gaugeene, whatever part of the surface be recied, the prognosis is most unfavourable. The patient, indeed, does not take the but instances of recovery are rare. If the patient be a new-bandant, or a child of weakly constitution, he may be considered to have still fewer chances of passing safely through so formidable an illness. The nest favourable cases are those in which the gaugeene is of the dry take and remains limited to a finger or toe. If the gaugeenous process the successively in several parts of the body, little hope of recovery

ca be entertained.

In all cases where a cachectic child is attacked with gangers, every effort should be made to support the strength of the patient, and approve the state of his nutrition. He should be supplied with as the marishing food as he can digest. Meat—pounded if necessary, and event through a fine sieve—eggs, milk, well cooked vegetables, and a proper quantity of farmaceous matter must form his diet. Stimulants are anylys required, and the child may take half an ounce of port wine, or to be hapfined tanning wine, diluted with an equal proportion of water, whereach quantity of food.

If the patient be an infant at the breast, we should inquire if the supple of rolk is indequate to his necessities. If the breast milk is poor and wall roll, additional food must be given as directed elsewhere (see page Winter wine whey is very suitable in these cases. Tomas are always are 1. Quinine can be given in full closes (two grains for a child of two years old, three times a day), or the ammonia and bark mixture can be given. Mr. Cripps speaks highly of opium given frequently in small.

drawe

It eases of disseminated moist gangrene the heat of the part should be and all the lat applications; and directly a slough is noticed on the under its further extension should be prevented by the free application of I jewerful escharotic. Strong nitrie send should be applied once thorand the part must be then kept covered with hot poultices. When be sough separates, the resulting sore or sores can be dressed with a are located lotton live drops to the ounce of water), or a solution of boacid (twenty grains to the ounce). In all cases of gangrene of the has method of treatment is useful; and the local measures employed it is treatment of gaugrenous stomatitis are equally serviceable when becalm is the purt affected. Parrot advocates the use of powder of blum, especially in cases of gangrene of the vulva. The ulcers must first carefully cleaned. Then they must be completely filled with the I war, no part of the raw surface being left uncovered. If the ulcer is mask it ought to be dressed twice a day. This method of treatment planiess, and is said to arrest the progress of the uleer in three or four das A! the same time the surrounding cedema rapidly diminishes.

When the gangrene is limited to the extremities, the affected part should be wrapped in cotton wool, and gentle frictions with a piece of function with causele-Cologne are recommended by Raynaud. This

author disapproves of the use of energetic local stimulants, and state that he has seen very disastrous results follow quickly upon undue local irritation. Directly a line of demarcation forms, hot dry applications, such as bags of heated bran or sand, should be kept applied to the seat of the lesion, so as to preserve the dryness of the tissues and hasten the separation of the sphacelated part. In extensive gangrene amputation has been sometimes performed, but without saving the life of the patient. Indeed MM. Rilliet and Barthez are of opinion that the removal of the diseased member only hastens the fatal termination.

Part 3.

THE DIATHETIC DISEASES.

CHAPTER I.

SCROFULA

In scrofulous diathesis is one of the most common of the morbid types of constitution which we meet with in the child. It is found in all ranks of life, and in almost all parts of the world. It is, however, especially frequent in the temperate zones, being far less common in very cold or in topical climates. This vice of constitution is often hereditary, and is then banded down with singular persistence from generation to generation. Sometimes, indeed, it is seen to pass over certain members of a family, but even those who escape may not transmit complete immunity to their offspring.

A child who has the misfortune to be born with this unhappy predisposition is liable to very widespread evidences of the constitutional fault with which he is burdened. His skin, his mucous membranes, his bones, joints, organs of special sense, lungs and lymphatic system are all exceptionally sensitive to the ordinary causes of disturbance, and may all or any of them become the seat of obstinate derangement or even of incurable disease. These manifestations of the constitutional tendency usually take place early, so that scrofula is especially a disease of childhood. Infants, indeed, are in great measure exempt from its attacks; but after the third year it begins to be common, and from that age until the fourteenth or fifteenth year the disthesis is most active. At puberty its energy sensibly abutes, and strumous disorders are less and less frequently met with as the advances towards middle life.

Causation.—One of the most important of the causes of scrofula is hereditary influence. When the parents are actually suffering from the cachesis, or have suffered from it, the child is hardly likely to escape a share in the constitutional predisposition; but when no such manifestation of the tendency has been seen in the father or mother, there is a hope that by careful management and attention to the laws of health the same freedom may be extended to their offspring. But besides actual scrofulous disease, other debulating influences in the parents may determine the strumous constitution in their children. Thus, the cancerous and tubercular ca-

chevize will do this. Syphilis in the third generation is apt to manifest itself by scrofulous disorders; and age in the father, or insperfect nutrition in the mother during her period of gestation, are also held to be determining causes of a congenital tendency to strumous complaints. Whether there nearness of relationship on the part of the parents will exercise the same influence is a question which has been often debated, and many writers hold that it can do so. I do not think, however, there is any satisfactory proof that such a result can follow in cases where there is not already a tendency to scrofula in the family.

Besides being hereditary, the diathesis, it is commonly held, may be acquired under conditions favourable to its development. It is true that we frequently see patients who exhibit all the signs of a scrofulous lesion without any discoverable family history of scrofulous disease; but it is often difficult to trace out hereditary taints, especially when the transmitted tendency has been mild in its manifestations, or has skipped over one or two generations. It is more probable that in such cases latent scrofula is developed by debilitating influences in children, who, under more favoura-

ble circumstances, would have escaped altogether.

The causes which are thus capable of developing the cachexia in children whose constitutional tendency is comparatively feeble, are all the various agents which impair the nutrition of the body by weakening digestion, checking assimilation, and interfering with the escape of waste matters from the system. Repeated exposure to cold and damp; an habitval coarse and indigestible duet; absence of fresh air, and confinement to close, ill-ventilated rooms; deprivation of sunlight and want of exercise -the continued operation of these causes, if it cannot set up the disease where no predisposition exists, has at any rate a powerful influence in exciting the cachexia in children who have been born the subjects of the duathesis. Even grown up persons exposed to such unhealthy conditions are often found to become scrofulous. Therefore causes which are capable of reawakening the cachexia in the adult, after the age most prone to it has passed by, must act with still greater energy in the child. Certain fevers have the power of developing or re-instating the disease in suitable subjects. Measles and whooping-cough have a wonderful influence in this respect. Unmodified small-pox used frequently to be followed by obstinate scrofulous disorders; and scarlatina can count the same complaints amongst its sequelæ. Where the predisposition is strong, it is probable that any disease of a lowering tendency may suffice to develop it.

Scrofula, like other complaints, has been said to have been communicated by vaccination; but that the disease possesses any specific morbid matter which is capable of being conveyed from one child to another by inoculation is a doctrine which has now been proved to be destitute of any foun-

dation.

Morbid Anatomy.—The structural lesions induced by the scrofulous diathesis consist in various chronic inflammations with their consequences. These have nothing special in their anatomical characters to distinguish them from the same lesions occurring in non-scrofulous children. They

need not, therefore, be further referred to in this place.

The affection of the lymphatic glands, which is so characteristic a part of the disease, differs from the ordinary hyperplasia induced in a healthy child by neighbouring inflammation in the fact that the swelling does not subside when the irritant which has given rise to it has passed away, but continues as a chronic condition. In the case of a healthy child the gland becomes more vascular, and swells up by an increase in its corpuscular elements.

Two mpilly increase, multiply, and enlarge, and acquire many nuclei and all their interior. This is the first step. In the second, one of two the place. If the irritation subsides and cell-production is cheroi before the nutrition of the gland is interfered with, a fatty degenthe place in the new cells which reduces them to a milky fluid, The are then absorbed and the gland resumes its former size. If, on the controy, the arritation persist, the proliferation of cells centinues; they could together, destroying the reticulum and the capillary network of the chal arrest nutrition by their pressure, and lead to rapid disintegration and appair thon. This, then, is an active process conducted reputly. In the sections child the course is much more protracted. The glands are at to take on a chronic inflammatory process. They increase slowly in the same as indolent lumps, apparently incapal le of fartarrelange; or, if the swelling have been originally acute, no diminution it are takes place when the influentatory process is at an end. In either the gland is filled with proliferating cells, which by their pressure laber nutrition, and induce an imperfect fatty degeneration, so that the game is converted either wholly or in part into a mass of cheesy matter.

clands so affected have a spongy feel, unless there is much hypertrophy of the connective tissue, in which case they become hard. Their section is pile a l. pussing into a dirty white or vellowish colour. After a time the wave gland becomes thick, tough, ancient-looking, and dry, and is then taken converted into an opaque, yellow, caseous mass. Disease in the fact is unequally distributed. Some are unaltered, and even of these field there is great variety in the degree to which the process extends, for some remain small while others enlarge considerably. After remaining for their inactive one of two changes may take place. Either the late, seltens, sets up inflammation around, and evacuates its contents; in the faul part of the gland is absorbed, and the gland dwindles into a fibrus mass, or is hardened by the deposition of earthy salts. The cervice, has soften supportate; the bronchild glands occasionally do so, but in

to meanteric glands such a termination is very rare.

Stering and suppuration constitute a chief danger of caseous glands. It is glands of the neck this is of less moment than in those of the closed less for their contents are discharged externally, and are thus removed less the body. Farm in these cases secondary consequences may ensue. It is is tence of a chronic discharging sore, such as often results from the effection of these glands, is very upt to induce amyloid degeneration of a hier, kulney, and spleen. Therefore these organs are frequently because in scrofulous children. Besides, there is always danger that softential entire in any give rise to an explosion of acute tuberculosis; and the effections children fall victims to this fatal disorder. In the case of the effection of a content of the effect upon neighbouring organs. This per will be referred to afterwards.

Simplimis.—In a well-marked example of the scrofulous diathesis the matter tendency often expresses itself in an unmistakable manner of a billiant pareral appearance of the child. He is stout and heavy, and links as a rule older than his age. The subcutaneous fat is usually the belonged, and in places remarkably so. His face is broad and fut, with thick to the bosses, and the absolute is mediated to be large. But although the dispose the rule is relatively increased, there is a want of firmness about the said's flesh, and his himbs feel soft and flabby. Such children are not

necessarily ill-favoured. The general want of delicacy and refinement in the features is often redeemed by the large size and dreamy expression of the eye, by the high colour in the checks, and by the redness and fulness

of the lips.

Such characteristics are, however, seen only in pronounced cases of the diathesis, and even then are not always to be found. All the tendencies of the scrofulous constitution may be active in a child without his presenting any such peculiarities of face or figure. Indeed, in many strumous cases the child is seen to have a spare frame, with delicate features and a thin transparent skin—a type which conforms more to the tubercular variety of constitution to be afterwards described. But whether he be stout and coarsely built, or thin and delicately framed, there is one indication of the diathetic state which is seldom absent in a strumous subject. This is the singular activity of all the epithelial structures. The hair is soft, thick, and luxuriant; the eyelashes and eyebrows are well marked; and in many cases there is a remarkable development of fine down covering the ears, cheeks, shoulders, and spine. The skin, moreover, is apt to be rough and scaly, and the nails grow fast. This peculiarity marks one of the essential features of the scrofulous diathesis, viz.: a tendency to rapid pro-

liferation of all the epithelial and cellular elements of the body.

It has been said that the scrofulous diathesis is not in itself a disease. It is a tendency to disease—a tendency to derangements of structure or of function which finds expression under suitable conditions in a variety of lesions. All these bear a common character, and vary in gravity according to the tissue or organ affected. The lesions are inflammatory in their nature, and are characterized by rapid cell-growth and rapid decay of the newly formed elements. They are not distinguished by any special anatomical characters which stamp them at once as of scrofulous origin. In appearance they do not differ from similar derangements occurring in children of a healthy habit of body. Their constitutional origin is shown by their tedious course, for if not stopped at once they soon pass into a chronic state; by their sluggish response to treatment; and by their proneness to relapse when apparently cured. The disturbance originates under the influence of some trifling and temporarily exciting cause; and the length of its course is often dependent upon the hygienic conditions surrounding the child at the time of the attack. If these are satisfactory, the derangement may be quickly recovered from, although it readily recurs when a similar cause is again in operation. If they are unsatisfactory, as is usually the case amongst the poor, the derangement becomes a chronic disorder, and increases in severity and obstinacy as the days go by.

The parts which are prone to suffer in this disthesis are: the mucous membranes, the skin, the bones and joints, the organs of special sense, and above all the lymphatic glands. In whatever tissue the lesion is seated, the neighbouring lymphatic glands are hable to suffer; and this is a fact so generally recognized that amongst the public the term "scrofula" is understood to mean simply a chronic enlargement, with tendency to

suppuration, of the glands.

The nucous membranes in all strumous children are especially sensitive and subject to catarrh. Gastric and intestinal catarrhs are very common; and we find besides, coryza, ophthalmia, catarrhs of the throat, ear, and air-passages, and in girls of the vulva. All these, beginning as catarrhs, pass quickly into chronic inflammations very difficult of cure.

The affections of the gastric and intestinal mucous membranes will be considered in another place. They do not differ from the same derangements as they occur in healthy subjects except in the fact—and it is a very important one—that in scrofulous children such entarrhs are always accompanied by fever. This is seldom the case with healthy children. If pyrexis be present with a simple gastric catarrh, it affords a strong presemption that the patient is of a scrofulous constitution. Catarrhs of the intestine in these children often set up ulceration of the mucous membrane. This is an obstinate lesion and may lead to serious consequences (see Ulceration of the Bowels).

Charries of the nasal passages leading to ozena, and even destruction of bone, may be seen. Obstinate discharge from the nose in a boby is generally of syphilitic origin; in a child of two and a half years and upwards it is much more commonly due to the scrofulous cachesia. It is very obstinate, gives rise to a distressing and perhaps unavoidable habit of smulling, imparts a nasal character to the voice, and leads to cracking

and excornation of the upper lip.

The eyelids and eyes may be affected with tinea tarsi, pustular ophthal-

mia, and keratitis, with intense lachrymation and photophobia.

Pharyngeal catarrh is a very common affection. It is also a very important one, for it is accompanied by some enlargement of the tonsils, and considerable swelling and thickening of the posterior nares and back of the fauces. Consequently there is occlusion of the Eustachian tubes and deafness. On inspecting the back of the fauces in such cases we find the mucous membrane of a deep red colour. It is swellen and velvety, and is covered with a thick muco-purulent secretion. The closure of the Eustachian tube is not due to enlargement of the tonsils, but to the swelling of the mucous membrane. Clubbren so affected present a peculiar appearance. They have a vacant look, hold their mouths half open, and, hearing but imperfectly what is said to them, heartate and are confused when spoken to They are not really wanting in intelligence, but on account of their deafness appear to be so. On examination of the ear the tympanum a seen to be drawn in, but it retains its translucency, and there is no tunitus.

(Borrheea is very often met with in acrofulous children from catarrhal inflammation of the meatus. The inflammation may spread to the inner car, in which case perforation of the membrane always takes place. Severe primary otitis may also occur as a result of cold or injury, or as a sequence of scarlatina, measles, and small-pox.

Pulmonary catarrhs in strumous subjects may become chronic and give rise to winter cough, with emphysema of the lungs and persistent hypersecretion; or the catarrh may spread to the air-cells, inducing chronic

catarrhal pneumonia with all its possible consequences.

Various skin affections occur in subjects of this diathesis, and are generally the earliest manifestation of the constitutional tendency. Acute ecommon are common, and slight depressing causes may give rise to an outbreak of impetiginous or ecthymatous pustules. Little scratches are apt to run into festering sores which may be slow to heal. Occasionally we find rupus, pemphigus or lupus, but these are rare in childhood. A not uncommon form of affection of the skin is seen in babies and children under two years of age. This begins as a small lump—hard, painless, and of the size of a pea or a small nut. It is seated in the subcutaneous tissue, and the skin over it is at first freely movable and is natural in colour. Gradually an adhesion forms between the little mass and the integument. The skin gets red, and after a variable time gives way, and the cheesy contents of the abscess are evacuated wholly or in part. After discharging

for a longer or shorter period, the sore heals; its hard base becomes absorbed; and a deep cicatrix is left at the site of the abscess. Sevent of these abscesses are usually seen at the same time in various stages of pagrees. They are seated on the arms, legs, or abdominal wall, and run a protracted course, passing very slowly through their several stages. The seldom occur except in children of pronounced strumous tendences. When seated on parts where the skin is in close contact with the bops, we on the fingers, periositits may be set up with exfoliation of bone bar.

elsewhere they have no injurious local consequences.

Disease of the bones and joints is a very common consequence of the scrofulous diathesis. These affections enter more particularly into the department of the surgeon. Still, there is one form of hone disease which a brought so frequently under the notice of the physician that it marks properly considered in connection with this subject. This is carres of le bodies of the vertebræ, in its early stage, before it has led to curvatured the spine. The reason why we so often see such cases is that the prewhich is one of the earliest symptoms of the malady, may, by its seat me by the cramp-like character it sometimes assumes, give little indication of its being generated in the spine. Like the pain of pleurisy, the pain of vetebral caries is often referred to a region far distant from the seat of the disease. When the atlas and axis are affected, the pain is referred to the occipital region. In the case of the lower corvical vertebrie, it is felt in the shoulders, down the arms, or even in the upper part of the breastlone. If the caries occupy the dorsal spine, the only discomfort complained of may be in the sides of the thorax, the middle line of the chest in frent, or the epigastrium. In disease of the lumbar vertebræ the pain is reflected to the pelvis, or to the lower limbs as far as the knees, or even to the feet-But wherever the pain is felt, and whatever may be its degree of seventy. its cause may usually be distinguished by noting the increase to the claid discomfort when he moves about, and the relief he experiences when he lies down. Sometimes, however, slow cautious movement may be mad without uneasiness; for if the spine be braced up and steaded by the surrounding muscles, the patient may be able to move carefully about without communicating any jar to the vertebral segments. But movemen # when the child is taken at a disadvantage, with the spinal muscles relaxed. is always distressing, and therefore it is important to inquire as to the effect of coughing, sneezing, riding in a carriage, or making a false step in walking.

Besides pain, another important indication is obtained by noticing the degree of mobility retained by the spinal segments. The child holds had back stiffly, and avoids all movements which necessitate bending of the spine. Thus, when laid down on his back and told to get up, he does so by turning slowly upon his hands and knees, keeping his back straight and then getting carefully on to his feet. If required to pick up a small article from the floor, he turns sideways to the object and lowers and ruse himself by bending and straightening his knees, keeping the spine straight and almost erect. Movements such as these are of great value, and to doubtful cases the child should be put through a series of exercises, so to test thoroughly the mobility of his vertebral column. He should be required to turn round quickly as he walks, to climb a chair, or to touch his

toes with outstretched fingers while his knees are straight.

Another important symptom is the attitude assumed by the patent when at rest. If there be much disease of the bones, the child will endeavour to relieve the spine by supporting his head or diverting the weight of the body from his back to his arms. Thus the favourite attitude of a child whese cervical vertebre are affected is to sit with his elbows on the table supporting his head with his hands. In other cases of the disease the weight of the body is transmitted through the arms. Mr. Howard Marsh, who has devoted much attention to this subject, describes two characteristic attitudes assumed by a child the subject of caries of the dorsal and lumbar spines. In one of these he places the palms of his hands on a chair, and leans over forwards with his arms straight and shoulders raised. By this means weight is taken off the spine and transmitted through the arms. Another position is equally characteristic. The child rests his weight on one toe, with the heef slightly raised and the knee fiered, and placing his hand on the middle of the thigh, leans over, so as to convey weight from the shoulder down the arm to the limb.

Attention to the above points will give very valuable information. Other symptoms are less trustworthy. Thus tenderness on pressure over the spines of the diseased vertebric is sometimes present; but it is not characteristic of caries. Striking with the knuckles down the centre of the back is a very fallacious test. In cases of undoubted caries there may be no response; and a child may shrink when the spine is tapped even though the bones are sound. In the same way the application of a Lot sponge to the spine as a test of tenderness is unsatisfactory, and in the

case of a child little information is to be gained by this means.

Whenever spinal caries is suspected we should never forget to look for iline or psoas abscess; for in cases where the ulceration is limited to the surface of the bodies of the vertebre, an abscess may form before any

curvature can be detected in the spine.

Creaton of tibrids. - One of the most familiar consequences of the scrofulous diathesis is a chronic enlargement of the lymphatic glands. In all young subjects these glands are liable to enlarge upon slight uritation; but in a healthy constitution the swelling subsides when the cause which gave rise to it has passed away. In the child of scrofulous tendencies the cause exciting the morbid process may be so feeble and transient as to cape notice. But, the unhealthy action once set up runs a protracted course, and the enlargement continues until some further change takes place which causes it to disappear. The steps by which the affected gland becomes converted into a cheesy mass have already been described. The process is a purely local one, and does not necessarily produce any ill effect upon the patient. It is evidence, no doubt, of a constitutional tendency, and as such may excite apprehensions of other and more formidable manifestations of the diathetic state. Of itself, however, unless the swellen glands be so situated as to press injuriously upon parts in the neighbourhood, or to threaten by setting up inflammation around to injure a vital organ, it is seldom attended with danger.

The glands most commonly affected are the cervical, the bronchial, and

the mesenteric.

Chrome enlargement of the cervical glands is excessively common, on account of the many scrofulous lesions to which the head and face are limble. But these lesions do not all act with equal energy in promoting the glandular swelling. Inflammation of the pharyngeal mucous membrane is found to produce this result far more frequently and readily than an unitant occupying any other part of the head and face. A skin affection may exist for a long time without causing enlargement of the glands, but a pharyngitis causes them to enlarge very quickly. Chronic glandular swellings are seen as round or oval masses, firm to the touch, and usually

freely movable. The skin over them retains its normal colour and is of adherent. They are generally to be seen behind the ear, beneath the lower jaw, and sometimes extending down the neck to the collar less. The masses may be formed of single glands; but more often several of these unite and are bound together by thickened and condensed cilled tissue. Such swellings may reach the size of a small apple. Usual after a time, tenderness begins to be noticed; the skin becomes adherent and red; fluctuation is felt; and eventually the abscesse bursts and incharges its contents externally. Scrotulous abscesses are slow to bed Often a discharging cavity is left from which a thin pure escapes; or the opening enlarges, and we see a sluggish ulcer with thickened undermated edges. In bad cases several of these may be seen at the same time at each side of the neck.

Enlarged cervical glands do not always supporte. Sometimes the remaining a variable time as a chain of indolent swellings, they beging gradually to diminish in size and return alowly to their normal dimensions.

Cascation of the bronchial glands is little less common than the same condition in those of the neck. The effect, however, of such disease a very different. Swelling of the superficial glands of the neck, although unsightly enough, is yet in itself a complaint of comparatively little moment. But when the glands of the mediastinum become enlarged the consequences may be serious. The glands are seated at the bifurcation of the tracken, behind the upper bone of the sternum, and a little below a They also accompany the bronchi into the interior of the lung. When swellen, they must therefore encroach upon neighbouring parts, and use produce considerable disturbance by pressing upon the blood-vessels, the

an -passages, and the nerves of the cliest, Before describing the symptoms produced by this means, it may be remarked that enlargement of the bronchial glands does not necessari, imply the existence of chronic lung disease. A child is not to be onsidered consumptive because his mediastinal glands are bigger than the ought to be. The term "bronchial phthisis," which has been applied to this condition, is very misleading, and was given at a time when all chronic changes in the glands were attributed to tubercle. Scrofulous children, who are so prone to suffer from pulmopary catarrh, will generally be found, on careful examination, to have some swellings of the glands behind the sternum; but if no dulness or bronchial breathing can be detected over either lung, we have no reason to infer the existence of pulmonary disease. Like the same affection in the neck, cascation of the glands below the trachea is often a purely local process, induced in a screulous child by some passing irritation. It is more serious than a smith condition in other parts only because the glands are shut up in a closed cavity, in the immediate neighbourhood of large vessels and vital organs, which may be affected injuriously by their pressure, or by pathological changes occurring in them.

It is possible that the bronchial glands may be, as most authorities hold, occasionally the seat of tubercle, although arguments in favour of this view, drawn exclusively from morbid anatomy, are of only secondary value. But there is little doubt that the ordinary form of glandular enlargement is due to a very different cause. It is true that children who suffer from this form of scrofula are frequently feverish, and that they are often thin and under-nourished; but these phenomena are not necessarily the result of tubercle. It will be generally found that the pyrexix is not a constant feature in the case. It occurs now and again, the child's ten-

perature in the interval being normal, and lasts on each occasion for a week or ten days. While the feverishness continues, the child is languid and mopes, eats little or nothing, and is generally troubled with cough. The explanation is that a child suffering from this cachexia is excessively sensitive to changes of temperature and readily takes cold. While the catarrh lasts he is feverish; and as all the muccus membranes are equally ensitive, the stomach sympathizes in the general derangement. For the time, then, nutrition is in abeyance, and he loses flesh. Even when the atta k is at an end, and appetite returns, the stomach does not all at once recover its power. The patient's digestion continues weak and cannot fully satisfy the requirements of his system, so that he regains flesh but slowly. If the catarrhs recur at short intervals, the child is kept thin ind weak, but he is not therefore tubercular, and if he die, he dies usually from a simple bronclutis or pneumonia, and not from any tubercular complant. But such children, if in a position to receive all the care they require, soldom do die. In my experience such a termination is rare in cases where the lungs are unaffected. When due precautions are taken, they often become fat and strong, and the signs of glandular enlargement dis-

In many cases the disease in the glands is associated with pulmonary phthous; but this is more often than not of the non-tubercular variety. When death takes place in such cases it results from the lung disease, and the glandular swelling contributes little, if at all, to the fatal issue. Death, however, does sometimes occur as a consequence of the scrofulous swelling. The mass may cause such disturbance by pressure upon neighbouring parts that inflammation and ulceration are set up, and the child sinks from exhaustion. Thus the assophagus or an air-tube may be perforated, as in a case published by Dr. Chee, without any softening having occurred in the gland. In other cases the gland softens and becomes converted into a mass of pus. Here there is hectic fever, general and perastent wasting, and loss of strength. Eventually the abscess discharges itself into the plantal cavity, into a bronchus, or into a large vessel, causing fatal harmorrhage. A common termination when softening takes place in the gland is by scute tuberculosis. This, however, may occur in the case of any other softening cheesy mass wherever situated. It is no proof that the gland

was originally the scat of tubercle.

The special symptoms produced by enlargement of the mediastinal glands are the consequence of pressure—the glands by their unwoated size

encrosehing upon the parts around.

Pressure upon the superior vena cava, or either innominate vein, interferes with the return of blood to the heart. There is a certain degree of lividity of the face, the skin around the mouth has a bluish tint, and the hips look puffy and dark. The superficial veins also are unusually visible in the temples, the neck, and over the front of the chest and shoulders. A small amount of pressure is sufficient in children to cause dilatation of the venous ratheles of the chest, and the symptom is one of the earliest indications that the bronchial glands are larger than they ought to be. If there be great obstruction to the return of blood from the head, wdema of the face and puffiness of the eyelids may be seen; and this, when one innominate vein only is pressed upon, is limited to one side of the face. On account of the congestion of the venous system, constants is common, and hiemorphise may even occur from the lungs. But haemoptysis in children is difficult to detect, for blood coming up from the air-tubes is almost invariably swallowed, while a discharge of blood from the mouth is

usually the consequence of epistaxis, the blood escaping backwards at

the throat from the posterior mares.

Pressure on the nerves of the chest causes hourseness of the voice and paroxysmal cough which may be mustaken for whooping-cough. It cores in violent fits, and sometimes ends in a crowing inspiration. It is how ever, seldom followed by vomiting. When the pressure affects also the lower end of the traches at its bifurcation there may be, in addition, attack of dyspacea. These are the ordinary "asthmatic attacks" of young childra Sometimes laryngeal spasm is induced, and long-continued spasm may so interfere with the entrance of air into the lungs that the antero-postence diameter of the chest becomes diminished, the weight of the atmosphin forcing the sternum backwards below the level of the ribs. All these presure symptoms become greatly aggravated by an attack of pulmonary atarrh. In ordinary cases severe symptoms are only seen when the chil extches cold. If this happen, the condition of the patient becomes alarming. His face is livid; his dyspacea distressing; his voice hourse; his cough violent and spasmodic. Even then the attack is often not continuous. It occurs in sudden seizures which come on once, or more often a the day, or only at night. The attacks last a variable time and costs much alarm. In most instances their violence abstes after a few dry, and in the course of a week or so the child seems restored to his order r health, although he is left languid and more feeble than before his illness In other cases the symptoms increase in severity instead of diminishing The child starts up suddenly in his bed with staring eyes and a du-ly, frightened face; his respiratory muscles work violently, and his agranta and distress are painful to see. After several repetitions of these attacks death may take place either suddenly, or after a fit of convulsions.

The physical signs afforded by examination of the chest are of importance. In marked cases we find dulness on the first bone of the sternes. which may extend for some distance on each side and below. Sometimes it is found to reach as far downwards as the base of the heart. I have never succeeded in detecting any dulness in the back between the scornic. Indeed, the results of percussion even in front are often misleading. There may be very considerable and extensive disease in the glands, and miles the mass is in actual contact with the wall of the chest no duli esa may be discovered at the spot. The signs afforded by the stethoscope are much more trustworthy. Pressure upon the lower part of the trachea product a respiratory stridor which is sometimes so loud as to be heard at a distance from the chest. It is generally intermittent. In either bronchus markel pressure may interfere with the entrance of air into the corresponding loss. and lead to a certain amount of collapse at the base. Pressure such as the however, is exceptional, and is only seen in cases where the enlarge ment is great. The most common auscultatory sign connected with the breathing is produced by conduction, the glands forming an artificial medius of communication by which sound is conveyed from the air-tubes to the class wall. This gives to the breathing a loud blowing character which is very characteristic. It is less high pitched and metallic than the ordinary lawing and cavernous breathing heard in cases of pulmonary consolidation ad excavation; and is most marked at the spaces of the lung, especially at the supra-spinous fosse. Sometimes it is heard loudly over the whole of one or both sides of the chest. Opening the mouth generally modifies could erably the intensity of this blowing quality, and may even make it case altogether.

Pressure upon the descending vena cava or the left innominate ven

gives rise to a hum, and on the pulmonary artery to a systolic murmur heard best at the second left interspace. But long before the ordinary signs of pressure on the vessels can be detected, we can induce pressure on the vern if the bronchial glands are enlarged. This sign is one of the earliest indications of disease in these glands.' Thus, if the child be directed to hend his head backwards upon his shoulders so that his face is turned upwards to the ceiling above him, a venous hum, which varies in intensity according to the size and position of the swollen glands, may be he and with the stethoscope placed upon the upper bone of the sternum. As the chin is slowly depressed again the hum becomes less distinctly audible, and ceases shortly before the head reaches its ordinary position. The explanation of this phenomenon appears to be that the retraction of the head this forward the lower end of the trachea. This carries with it the glands lying in its bifurcation, and the left innominate vein is compressed where it passes behind the first hone of the sternum. I believe this explauntion to be the correct one, for in cases of merely flat chest, where there is no reason to suspect enlargement of the glands, the experiment fails. Nor, again, can the hum be produced in a healthy child by the thymus gland. This gland has in front of the vein immediately behind the sternum. Enlarged bronchial glands lie behind the vessels in the bifurcation of the truches. A swelling in front of the vessels does not appear to be able to set up pressure upon the vein when the head is bent backwards in the position described. Again, in order that the experiment should succeed, the lower end of the truches must not be fixed, and the glands lying below its bifurcation must be movable, otherwise no hum is heard when the head is retracted. Thus a child was admitted into the East London Children's Hospital for lymphadenoma. There was dulness at the upper part of the sternum, and downwards as far as the base of the heart. In this case, to my great surprise, no venous hum could be heard. The child died, and on examination of the body, yellow, flattened, cheesy masses were found atherent to the inner side of the sternum, and others, very large and immorable, were seen filling up the interval between the bifurcations of the trachea. The lower end of the air-tube was held firmly down by the mass, consequently pressure could not be brought to bear upon the vein by bending of the head, as the glands, being fixed, could not be brought forwards against the vessel. The experiment may sometimes fail even in cases where the lower end of the traches with its caseous glands is free to move, for the relative position of the glands and the vein may not correspond; but as a rule it will succeed, and a venous hum, so induced, is, I believe, a certain wars that the glands of the mediastinum are not healthy.

The nesenteric glands are, perhaps, less commonly affected than those of the neck or the chest; but disease in them is far from rare, although it cannot always be detected during life. The affected glands may be separate, or they may unite as in other situations into masses bound together by thickened cellular tissue. In this way a mass the size of an apple, and more or less movable may be felt on manipulation of the abdomen.

The old name for disease of the mesenteric glands was table mesenterical, and very serious consequences were described as resulting from the glandular enlargement. It is now known that these symptoms are due, not to the mesenteric swellings, but to the lesion of which they are the consequence; and that the caseous glands form a part—and often only a very

¹ See a paper by the writer, "On the Early Diagnosis of Enlarged Bronchial Glands." Lancet, August 14, 1875.

insignificant part—of the disease from which the patient is suffering. Like the lymphatic glands in other situations, those of the mesentery swell up as a result of irritation or inflammation in the parts from which the imphatic vessels passing through them take their origin. In strumous subjects they have the same proneness as the others to become caseons. Uf themselves they form a strong argument against the tubercular theory of scrofulous glandular enlargement; for cascation of the mesenteric glands unless their size be such that they press upon neighbouring purts is a itself a by no means serious matter. In ordinary cases, where there a no accompanying lesion of the bowels, the child's nutrition is good, he spirits and appetite are satisfactory; his temperature is normal, and except, perhaps, for some slight pallor of face, he may show no sign of ilhealth. In most cases, however, swelling of the glands, if at all considerble, is combined with scrofulous ulceration of the bowels; but even been the consequences are not always as serious as might be expected. Much depends upon whether or not the ulceration of the intestine is accompanied by a catarrhal condition of the mucous membrane. If this be present, there is diarrhose with marked disturbance of nutrition. The child green thinner, paler, and weaker; his expression is distressed; he sleeps hadly at night, often asking for drink, and is disturbed by wandering abdomad pains. The temperature may rise slightly in the evening, but there is seldom marked pyrexia.

If there be no intestinal catarrh, the bowels may be confined, and the effect upon the child's general health is much less pronounced. He still looks ill, is troubled by flatulent pains, and is pale and weakly; but nutrition may be fairly performed, and the child may even appear stout, although to the touch his limbs feel soft and flabby (see Liceration of

Bowelsi.

When caseation of the glands is associated with tubercular peritomus—and it is to this combination that all old descriptions of takes mesent-nea apply—the symptoms are those of the peritoneal disease, and the case is a

very serious one.

Scrofulous mesenteric glands are not always easy to detect. The belly is so often distended in children, with flatulent accumulations, that it may be difficult to force the parietes sufficiently inwards to reach the swellen bodies. Moreover, a certain tension of the abdominal wall, more or less voluntary, may still further increase the difficulty. The enlarged glands he about the middle of the abdominal wall directly inwards will usually detect the swelling at once. In cases where the increase in size of the glands is inconsiderable, it is better to make pressure laterally, bringing the hands together from the sides towards the centre, so as to catch the little mass between the fingers.

If the glands are large enough to press upon the parts around, there may be ordens of the legs and scrotum from pressure upon the vena cava. This, however, is exceptional. A very small amount of pressure will be sufficient to cause dilatation of the superficial veins of the abdominal wall; and most cases of enlarged mesentene glands are accompanied by this phenomenon. Cramps in the legs are said to be sometimes caused by pressure upon the nerves of the abdomen; and ascites may be the consequence of pressure upon the portal vein by the glands occupying the

hepatic notch.

The usual termination of scrofulous glands in the abdomen is that by shrinking and petrifaction. They rarely soften, although cases are re-

conted in which suppurating glands have become adherent to a coil of

intestine and have discharged their contents into the bowel.

From the preceding description it will be seen that the phenomena produced by the development of the scrofulous cachexia are very numerous. The mainfestations of the diathesis must therefore vary greatly in different cases, the constitutional tendency expressing itself now in one way now in another; for in addition to the general prehisposition, the child seems also to inherit a special weakness of particular tissues. Thus, in one family we see child after child suffer from scrofulous inflammation of the eye, in another there is equal susceptibility of the pharyngeal or the nasal mucous membranes; in a third we detect a special proneness to disease of the tonics or of the joints. All these disorders are apt to run a tedious course and to resist treatment with singular obstinacy. They can only be attacked successfully by using means which improve nutrition, and weaken the morbid tendency on which the lesion depends. Until this be done morbid tendency on which the lesion depends. Until this be done

characters which indicate their constitutional origin. Their real nature must therefore be inferred from their lingering course, their tendency to recur, the frequent absence of any discoverable local cause to account for them, and the coexistence of other disorders of a like nature, espe-

cally of glandular enlargements.

The subcutaneous abscesses may be, and often are, mistaken for syphilitic gummata. They must be distinguished by the history of the case,

noting the complete absence from it of any syphilitic symptoms.

The diagnosis of the early stage of spinal caries has been already indicated in the description of that disease. Remembering how the pain radices in this affection to distant parts, we should always look with suspicion apain in the chest or stomach in a child of scrofulous tendencies until the spine has been tested for the effect of sudden jars or shocks, and the child's attitudes as he walks or plays have been inquired into. Persistent pain in the occipital region, if combined with any stiffness in the neck or any altered manner of holding the head, is always suspicious of caries of the cervical vertebra. Pain in the chest or stomach, unaffected by food but increased by movement and relieved by lying down, is highly suggestive of doreal caries. In all cases where spinal disease is suspected the child should be made to ruse himself from a recumbent position, to pick up a small object from the floor, or to climb on to a chair or table, and the manner of performing these sets should be carefully observed, noting the degree of movability of the spine, and whether any part of it is held and

In the case of enlarged glands we may consider that a gland has become cheen if it have enlarged without evident cause, and if it persist for a long time as a painless indolent tumour showing no tendency to subside.

Casestion of the bronchad glands may be detected in their early stage by the experiment of listening over the upper bone of the sternum while the child's head is retracted, as already described. Dulness at the upper part of the sternum, if combined with any sign of pressure, is very suspensive especially if there be fulness of the superficial veins of the neck, alle of the head, and temples. Spasmodic breathing and paroxysmal cough are also characteristic symptoms—the more so if they are combined with any altered quality of voice. In all cases where children have attacks of so-called "asthma," attention should be always directed to the bronchial glands (see page 182).

In the case of the mesenteric glands the only satisfactory proof of the enlargement is holding them between the fingers. Even in these cases however, we have to satisfy ourselves that the substance is really a giral, and not a cheesy mass attached to the omentum, or a lump of harmed ficees. Cheesy omental masses are much more superficial, and consequently more easily felt than enlarged glands. They are also more freely more ble. In feeling for mesenteric glands the fingers have to be proved down firmly towards the spine, and the glands, if enlarged, can be detected

as slightly movable lumps with ill-defined margin.

The sensation conveyed to the fingers by facal masses is very different to that furnished by enlarged glands. Fiscal accumulations can be ready studied in cases of typhoid fever where there is no diarrhea, and the distaking milk. Here we find elongated masses of moderate size only with their long axes in the direction of the bowel, and situated at size point in the course of the colon. They are never very deeply placed call can be always readily reached by slight depression of the abdominal will. By firm pressure they can be indented by the finger. If any doubt is the in such a case, the effect of a copious chema should be tried. Facal masses are readily removed by this means; while lumps due to any other curse are only made more evident by the injection; for this by removing gases distantion and fæcal matters, renders a full exploration of the abdominal cavity more easy than before.

Progness.—It is the exception for scrofulous children to die from the direct effects of the disease. In fatal cases death usually results for acute tuberculosis; the outbreak of the tubercular malady being determined by some mysterious process of infection through softening these matter or allowly ulcerating bone. Again, children the subjects of the diathesis are more sensitive to the ordinary causes of disease. They each cold very readily, and therefore are apt to suffer from various chest affections. These, besides their own special dangers, may lead to evil consquences by causing enlargement and cascation of the bronched glants. Pheumonia, again, has a risk of its own in its propensity to undergo one partial absorption, and so to induce chronic changes in the lung.

Scrofulous children are singularly susceptible to the influence of contagion. Few such children exposed to the infective principle of zymotic becase will be found to escape, unless protected by a previous attack. Such diseases, too, have a special power of intensifying the disthetic tunt. They leave the child not only depressed by his late illness, but also more exposed than before to suffer from the consequences of his constitutional weakness.

Enlarged bronchal glands, if sufficiently advanced to cause serious presure upon parts around, must always occasion anxiety. If there be invited of face or attacks of dysphosa, a very guarded prognosis should be given Still, when placed under favourable conditions such children often do well.

Enlarged mesenteric glands if unaccompanied by ulceration of bowest or signs of tubercular personntis, are in themselves of httle importance. If signs of intestinal ulceration be present, the case is more serious, and the prognosis depends upon the amount of diarrhea, the presence of disease in other organs, and the effect of the lesion upon the matrition of the patient. This subject is considered in another place (see page 665).

Amyloid disease of organs set up by chronic suppuration is of moment, as tending to induce amemia and lower the strength. Still, in childhood, if the primary suppuration be arrested and the scrofulous disease removed, the amyloid degeneration often undergoes a surprising improvement (see

"Amyloid Liver").

Treatment.—The constitutional tendency to scrofulous lesions is best attacked by measures which encourage and maintain healthy nutrition. The causes which excite the dormant eachexia have been stated to be expense to cold and damp, insufficient and unsuitable food, impure air, and want of exercise. It is therefore exclent that a careful regulation of the diet, combined with warm clothing and daily exercise in the open air, must

be the first measures to be adopted.

With regard to food, the child should be fed liberally; meat, fresh eggs, and milk should enter largely into his diet, and his stomach should not be overloaded with puddings and starchy matters to the exclusion of more structly nourishing articles of food. Fresh vegetables are a valuable addition to his dietary, but potatos must be given with caution, although they are not to be entirely excluded. If the appetite be poor, a small amount of stimulant is often of service, and the child should be allowed a good wineglassful of sound claret diluted with an equal quantity of water to his dinner. It is needless to say that cakes and sweetments between meals must be strictly forbudden. In the case of infants born of scrofulous parents, a healthy wet-nurse should be provided if the mother be unable to suckle her child. If this be impossible, the utmost vigilance must be exercised in the feeding and general management of the baby. Directions are given elsewhere for the healthy rearing of infants, and the re aler is referred to the chapter on "Infantile Atrophy" for fuller information upon this important subject

Climate is a matter of great moment for children who are, or are likely to be, the subjects of scrofula. A bracing air is indispensable to the successful treatment of these cases. Residence in low-lying clay soils does much to encourage the predisposition, while sandy or gravelly places, with a dry air, are of the greatest benefit in increasing the vigour of the constitution. On account of the tendency to catarrhs in this disthesis, a dry air is of especial importance; and a place which is sufficiently warm during the winter months to allow of the patient passing a large part of his time out of doors is of the utmost service. Large towns, with their smoke and vituated air, are bad residences for scrofulous children. When compelled to live in cities, care should be taken that the child is warmly clothed and sont out as much as possible for exercise in the large open spaces with which most towns are now provided. For children of both sexes healthy out-of-door games should be encouraged; and they should be early trained in suitable gymnastic exercises, such as develop the muscles and expand

the chest.

The skin should be kept perfectly clean by a daily bath, but cold douches are often too depressing for such subjects, unless employed according to the plan recommended for delicate children (see Introduction). The bowels must be attended to, and habits should be inculcated of regularity in the use of the close-stool. When aperients are required drastic purgatives should be avoided. It is better to employ mildly acting drugs, in has the compound liquorice powder, or to combine an aperient with a tonic, as in giving the infusion of senia with the infusion of gentian or orange-peel.

In treating children in whom the cachevia has become developed, the above matters must be carefully attended to. Great stress should be laid up in the value of a suitable climate in aiding the child's recovery of health. If possible, the patient should be sent to winter in a dry air sheltered from cold winds. There, dressed from head to foot in warm, wooden clothing, he should spend the greater part of his time out of doors. Cod-liver oil is

usually prescribed indiscriminately in these cases, and while some children appear to be greatly benefited by the prescription, others seem almost insensible to its effects. It may be laid down as a rule that the stout scrofulous children are not the best subjects for cod-liver oil. It is the spare framed child with an active, nervous system who derives most benefit from the use of the drug. The oil should be given in doses of one tenspoonful two or three times a day, and its use must be continued for months together. If the child appear to be nauseated by this constant dosing, the oil may be remitted for a few days at a time, but must be shortly resumed. On the Continent much value is attached to acorn coffee, made by roasting together a mixture of acorns and coffee beans and grinding them in the usual manner. This coffee is generally given as an adjunct to the oil. It is especially recommended in cases where there exists a chronic catarrh of the howels. Cold bathing, when employed with proper precautious to induce a healthy reaction, is of vast importance in the treatment of many cases of scrofuls. These precautions are described elsewhere (see lutroduction). Cold douching is most useful in the case of stout children-those who derive little benefit from cod-liver oil.

For enlarged scrofulous glands, besides the above general treatment, iodine combined with iron is very useful. I am in the habit of prescribing iodide of potassium with the tartrate of iron and glycerme, as in the fol-

lowing mixture:

B	Potas. iodidi	Đij.
	Ferri tartamti	5 j .
	(Alycerini.,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,,	
	Aquam ad	ž iv.
	By Musture An eighth part to be taken three times i	in the d

The iodide should be given in fair doses. The above is suitable to a child of five years of age, and is better than the ordinary syrup of the iodide of iron, the sugar of which is so frequently found to disagree. Some practitioners prefer the common tineture of iodide, given in doses of three or four drops freely diluted with water.

Violent attacks of dyspanea from pressure of enlarged glands upon the nerves of the chest are best treated at the time by strong counter-irritants. After the attack has subsided gentler counter irritation may be continued. I have thought benefit has been derived from the careful and continued

use of the iodine liniment to the front of the chest.

Enlarged cervical glands are sometimes reduced by rubbing into them twice a day the cadmium ointment of the British Pharmacopeia diluted with an equal quantity of lard. The oleute of mercury salve is also of service. This application should be used of the strength of five per cent. It must be smeared on the part, not rubbed in. It can be used twice a day for the first five days; then at night only, and afterwards every other day. When the gland suppurates it should be opened with as little delay as possible, in order to avoid unnecessary scarring of the skin. It is important, however, to anticipate the suppurative process, if possible, and avoid the dangers of a chronic discharging sore. Therefore if the measures adopted to cause absorption are seen to exert little influence upon the size of the swelling, it is advisable to call in the aid of the surgeon. Dr. Clifford Allbutt strongly advocates free incision and enucleation of the caseous matter; and Mr. Teale states that he has successfully treated many such cases by scooping out the cheesy contents of the gland, merely leaving the sound portions with the enclosing capsule.

If softening has taken place and the abscess formed continues to discharge and often reinflames, the nightly administration of a powder containing one grain of hydrargyrum cum creta to eight grains of peroxide of iron is often attended with surprising benefit. This powder should not be given longer than for a week at a time. The sulphide of calcium in doses of one-lifth of a grain, given every two or three hours, is also recommended. Thus, however, is a very uncertain remedy. Sometimes it succeeds, but more often it fails completely. The chloride of calcium in doses of five grains every four hours is sometimes successful. An important point in the treatment of enlarged cervical glands is warmth. During the whole time that local applications are being used the swellings should be carefully protected from the cold. A good plan is to cover them with a thick pad of cotton-wool.

Lugol' his spoken highly of iodine in all forms of scrofulous lesions. He used the drug as a salve to the swellings, as a lotion to the ulcers, as an injection to the sinuses and fistulous sores, and as a bath for the cure of the affections of the skin and subcutaneous tissues. Iodine tinctures an lointments are still favourite applications to all glandular enlargements. They should be used, however, with caution. I have seen serious sloughing set up in a child's neck by the too energetic inunction of an iodine

ointment into the skin over a caseous gland.

in a war den vessel

long legions and sores,

Chronic discharges from the various nucous surfaces are best treated with a tringent injections. Otorrhoa from catarrh of the auditory meatus, if hunted to the part outside the tympanum, is readily cured by the following lotion:

B.	Borneis	 	 	 	 		 		gr. x.
	Zmer sulphatis	 	 	 	 		 A 9		gr. viij.
	Glycermi	 	 	 	 				3 2.
	Aquam ad	 	 	 	 	4 1	 , ,		5 j.

In using this application the passage must be first thoroughly cleansed by injection with warm water, and then half a drachm of the lotion must be poured into the car and allowed to remain. This can be done two or three times a day. It is important to cure a discharge from the ear as quickly as possible. The old notion that otorrhora in children should not be checked too quickly is one which if acted upon may have serious consequences.

1 The strength recommended by Lugol for his salve was:
B lodian
Pot a fodidi ,
Adipis
Misce
For his lotton or injection:
8. fodisti gr j -ij.
Potas, fodelt gr. ij -iv.
A4 destadata § viij.
Misce
For his bath, for the use of a child:
Il Iodinii 9tj.
Potas todidi 91v.
Aq destillate, q.s
Dissolve completely and add to three callons of water of the temperature of 98"

Thus same solution he recommends as a fomentation to scrofu-

CHAPTER II.

ACUTE TUBERCULOSIS.

Acute tuberculosis is an acute febrile general disease which arises, in most cases, as a consequence of special hereditary predisposition. The disease expresses itself anatomically by the formation of the miliary nodule known as the gray granulation in the various organs of the body. This nodule is in great part an out-growth from the lymphatic system, and may be found wherever lymphatic or adenoid tissue normally exists. Acute tuberculosis is not to be confounded with pulmonary phthisis. Indeed, the two affections are essentially distinct, for ulceration of the lung, although occasionally present, is by no means a necessary part of the tubercular process.

In the young subject acute tuberculosis frequently assumes a form which is rare in the adult. In childhood the disease not uncommonly presents itself as a primary febrile affection, giving rise to but few symptoms, and those the manifestation merely of the general distress without any sign pointing to local muschief. It is often not until a few days before the close of the illness that any symptoms are discovered to draw attention to any particular organ. This is the primary form of the disease,

which has much the character of an acute specific fever.

In other cases, almost at the same time with the beginning of the genoral symptoms, others, more or less severe, are noticed, showing that some particular organ is especially fastened upon by the tubercular process. This form is not uncommon in cases of tubercular meningitis.

A third form resembles that which is often met with in the adult where the disease arises as a secondary affection in the course of some other illness, and in such a case brings the life of the child quickly to an end. This form is seen when tuberculosis supervenes upon empyems, pneumonic phtlusis, etc.

Acute tuberculosis attacks children of all ages, and may be seen in very young infants. When it occurs at this early age the anatomical feature of the disease is always very widely distributed. On the other hand, the older the child the more likely is it that the formation of the gray granu-

lation will be limited to special cavities of the body.

The word "tubercle" has been and is still employed in so vague a sense by various authors that it has almost ceased to convey any definite meaning. It may be well, therefore, to state that in the following pages the word is in every case used to signify the miliary nodule called "gray granulation" in the adult, but which in the child very quickly becomes yellow and opaque.

Causation.-Heroditary predisposition plays a very important part in the etiology of tuberculosis. In a large proportion of cases a distinct family tendency to the formation of tubercle can be discovered. The tendency is not, however, always exhibited in the parents. These are often, to all appearances, of sound constitution. It may be necessary to push our inquires farther back and ask as to the health of the grandparents and of collateral branches of the family. In a child with this unfortunate predistron, any cause which impairs the nutrition of the body may excite the maintestations of the tubercular tendency. Therefore lowering complaints and insanitary conditions generally are justly regarded as important agents

in the production of tuberculosis.

There are certain acute specific maladies with which the tubercular formation is very apt to be associated. Whooping-cough and measles may be said to number tuberculosis amongst their sequelae, so common is it to find children convalescent from these complaints, who are placed under inflavourable conditions for complete recovery, fall victims to the disease. Typhoid fever is sometimes followed by it. Children who suffer from malformation of the heart with narrowing of the pulmonary artery are also very hable to become tubercular. They do not, however, often suffer from acute tuberculosis. In them the disease is more apt to assume primarily the form of chronic tubercular phthisis, even if the distribution of tubercie become afterwards generalised. When the predisposition is strong, any cause which gives a shock to the system, such as a fall, a blow, or other similar accident, may be sufficient to excite the outbreak of the disease.

In addition to the cases where tuberculosis is excited in the bodies of persons predisposed to the affection by febrile disturbances or unwholesome conditions of life, there are other instances where the disease appears to be set up by a local infective process. It has been well established by numerous experimenters that the inoculation of tuberculous matter nto the bodies of healthy animals will produce general tuberculosis; and it is held by Koch and his followers that the infecting agent in such cases is the minute organism known as the "tuberele bacillus." Until lately it was believed that the inoculation into a healthy animal of non-tuberculous or putrid matters would give rise to the formation in the system of a body indistinguishable by the microscope from the gray granulation. But recent investigations have made it evident that some fallacy must have been present in the experiments which appeared to establish this result; for a repetition of the experiments by competent observers have shown that no ill consequences of any kind may follow the introduction of such matters under the skin. Still, arguments drawn from experiments upon animals, especially upon the rodentia, which are usually selected for these investigations, are not perhaps strictly applicable to the human subject. In man the presence of softening cheesy matter in any part of the body may set up an infective process which is indicated by fever, wasting, and symptoms of general distress, and eventually by signs to be atting implication of special organs. After death a general distribution of small no lules which have all the characters of the gray granulation is found in various organs. In children a chronic empyema often induces such a condition, and the child usually dies with the symptoms of tubercular meningitis. Acute tuberculosis may be also set up by other forms of cheesy degeneration. Softening caseous glands and cheesy pneumonia we common exciting causes of the disease; indeed, the scrofulous habit of boly appears in itself to be a favouring influence, and the tissues of such subjects furnish a congenial soil in which the growth of the tubercular bodies can be readily excited. The share taken by the tubercle bacillus in the production of tuberculosis - whether it is the sole medium by which the infection is conveyed, as is maintained by some, or is merely a casual addition to the septic agent, as is believed by others—is still at the preent moment a matter of warm debate.

Mortad Anatomy.—The distribution of the gray granulation is very frequently general in the child. In the infant it is almost always to a older children it may be limited to one or more cavities of the look. MM. Rulhet and Barthez have commented upon the carrious fact that the in the adult, according to Louis' canon, if tubercle exist anywhere is the body it will be found also in the lungs, in the child the lungs sometimes escape altogether although every other part of the body is attacked. When found in one cavity of the body alone, the part affected is usually

the skull or the abdomen.

The gray granulation is a firm, gray, translucent, projecting nodule which varies in size from a fine pin's head, or even a smaller object, to a millet seed. In children the colour very quickly changes to yellow and the translucence disappears, so that whatever organ is examined grav and yellow nodules (the latter usually predominating) are found mixed together. The growth occurs, according to Rindfleisch, as the result of a specific irritation of the endothelia of the lymphatics, the serous nembranes, and the blood-vessels, especially the former; and the nodules are found to follow the ramifications of the finer arteries because the lympisties run chiefly in the adventitia of the blood-vessels. On careful examnation the miliary bodies can be seen growing upon the fine vessels involving the whole calibre of the channel in the smallest arteries, and a those a degree larger forming protuberances on one side. Rindfleischdescribes the granule as a product of inflammation, and states that it comes in an increasing accumulation of leucocytes in the connective tissue of the part irritated. Of these white cells a portion take on an epithehead claracter. These grow to three or five times the size of a white blood corpocle and are called tubercle cells. Others develop into the arregular branching bodies called "giant-cells." The giant-cells are not, however. as was at one time supposed, peculiar to tubercle. Schappel believes that they arise within a blood-vessel from the accumulation and adhesion of tenacious masses of molecular matter. When they have reached a sor which causes distention of the vessel, nuclei begin to appear. According to this observer, the epithelioid cells are derived from processes of the giant-cells. They lie around the latter and constitute the greater part of the nodule. According to most observers, a section of the tubercles, after they have been some time in existence, shows a delicate reticulum, the meshes of which contain the cells. This, bowever, is denied by others.

In proportion as the tubercular body enlarges by accumulation of cells the central part is found to degenerate, and when examined at this stage (i.e., after degeneration has begun) it will be seen to consist in great most

ure of small, shrivelled, and granular cells.

The presence of the gray granulation in any tissue is usually quickly followed by inflammation in the neighbourhood of the growths. In use case of a scrous membrane, such as the meninges of the brain or the pertoneum, lymph is quickly thrown out, and, if time be allowed, become caseous. In the lungs an early consequence is bronchitis and catarba pneumonia. In these organs the granules very quickly become yellow and cascous, and every stage of degeneration of the nodules is usually to be discovered. Dr. Wilson Fox has described in the lungs of children desifted tuberculosis: gray translucent granulations; opaque white granules—soft, but of varying firmness and resistance; the same, but cascous in the centre; yellow granulations, very soft and easily crushed; chees,

granules—dry, opaque, and friable, with or without a surrounding zone of gray transparent matter; groups of the latter forming little masses the size of a pea, bean, or even wainut; indurated pigmented granules, single or in groups, and, lastly, tracts of variable size and irregular outline, granular on the surface, passing insensibly into the so-called "gray infitration." Sometimes, also, he noticed little cavities from softening of the tubercular masses. There were, in addition, signs of secondary catarrhal

pneumonia and its consequences.

Ulceration of lung and the formation of cavities is not a common consequence in early life of acute pulmonary tuberculosis. In infants in whom the discuse runs a rapid course this lesion is very exceptional. It is, however, sometimes met with. Thus, in an infant, aged eight months, with four teeth, who died in the East London Children's Hospital of acute general tuberculoses with secondary bronche-pneumonia and meningitis, tuberculoses with secondary bronche-pneumonia and meningitis, tuberculoses gray and yellow, were found after death occupying all the cavities in the body. They were discovered at the base of the brain, on the pertoneum, in the substance of the liver, spleen, and kidneys. The lungs were completely stuffed with them, and in the lower lobe of the left lung a small cavity had formed of the size of a hazel-nut. Such a condition is, however, not common. Even in older children, although the duration of the illness is longer, breaking up of the lungs, as a consequence of acute tuberculosis, is comparatively rurely seen.

In the orderines the gray and yellow granulations are scated especially in the smaller bowel, and involve principally the ilium and the part of the accum in the neighbourhood of the valve. The nodules lie in the submicous tissue, and in the acute form of the disease do not, as a rule, give rise to disease. In the laser the tubercles are developed on the smallest manifestions of the hepatic artery. They may be seen under the scrous coat, and are also found in the interlobular spaces and in the interior of the lobules. They are usually few in number. In addition to being the coat of tubercle, the organ is often found to present other pathological characters not especially distinctive of the tubercular disease. Thus, it may be enlarged from a simple hypertrophy or from fatty intiltration, and assometimes the seat of a currhous change. In the latter case it may give

rise to ascriter.

The sphere is one of the organs most commonly attacked by tubercle. Gray and vellow granulations and large cheesy masses may be found, so that the size of the organ is considerably increased. In the kidneys miliary no lules may be thinly scattered through the parenchyma. The little masses are developed, as elsewhere, in the sheath of the smallest arteries. Sometimes more extensive disease is met with, and large masses of cheesy matter are formed which soften and give rise to tuberculous ulcers. These may penetrate deeply into the rend tissue. According to Rindfleisch the disease begins in the papillary portion of the gland, spreading from the nurous lining of the calices. In extreme cases the kidney is converted into a thick-walled sac, with hemispherical protrusions, each of which corresponds to a Malp, ghian pyramid. The bladder is sometimes involved, although comparatively rarely in early life. Miliary nodules appear in the submucous tissue and soften, giving rise to circular ulcers the edges of which are found on examination to be infiltrated with closely packed gray and vellow granulations.

In addition to the lesions which have been mentioned, the bronchial and mesenteric glands are always enlarged and cheesy. Sometimes they are softened.

How far the cheesy matter, which is often found in large quantities in the more prolonged cases of pulmonary tuberculosis, is to be regarded a tubercular is a question upon which opposite opinions are held and his followers look upon all such caseous matter as the consequence of catarrhal pneumonia; and there is no doubt that the miliary hoddle is primarily an extra-alveolar growth, while the caseous masses, such as are found in cheesy pneumonia, take their origin from a proliferation of the epithelial elements in the air-cells. Before the giant-cell was known to he a constituent of other than strictly tubercular structures, the pastice of this cell was held to be confirmatory of the tubercular nature of the pathological product. Now the presence of the bacillus is considered by many to point to the same conclusion. But is the question one which can be determined solely upon anatomical grounds? The chinical history of the disease is surely a not unimportant element in the solution. It is generally admitted that the closest examination discovers in the gray grandle tion no peculiarity of structure which can be relied upon to separate the nodule from other bodies having a like appearance, and under the name scope all cheesy matter has very similar characters. The case is one a which the clinical features of the malady should have an exceptional who in determining the nature of the pathological product; for if two dis set are found to differ widely in the mode of origin of the attack, in the nature of the symptoms, and in the course of the illness, we may hesitate to almit identity of nature, however close may be the resemblance in the aratomical conditions.

Symptoms.—Primary tuberculosis in the child commonly assumes the form of an acute general disease. It excites moderate pyrexia and markel interference with nutrition, and from the indefinite character of the caracteristic symptoms and the absence of any manifestation of local distress of presents great difficulty in the diagnosis. Sooner or later signs are decovered pointing to disease of special organs: cerebral symptoms are or there are indications of pulmonary mischief. Tubercular meaning and cerebral tubercle are described at length in special chapters. The present description is confined to cases where the disease is general, and where the local symptoms are limited to the lungs and other organs are elsewhere referred to.

Children who fall victims to acute tuberculosis, although often of decate appearance, are not necessarily thin and feeble-booking. In many cases the nutrition of the patient is very good, and the child is considered to be in every way a healthy subject until the disease appears. It is not at all uncommon, especially in cases where the chief violence of the mainly is expended upon the cerebral meninges, to find that up to the time of his illness the child had never suffered from a day's indisposition. In other cases the patient has been noticed to be sensitive to chills and prone to stacks of indigestion. These latter children are often of fruit appearance and have the "tubercular aspect." Their skin is thin and transpirate their hair fine and silky, their features regular and delicate, their bear

anuall, and their shoulders narrow and sloping.

Acute tuberculosis may begin gradually or suddenly. In exceptions cases the disease has an abrupt beginning. There is high fever, headant epistaxis, relaxed or confined bowels, and the child is very restless and stupid. But this mode of beginning is very rare. In the large majory of instances the onset is so insidious that there is a difficulty in fixing used a date for the beginning of the attack. The earlier symptoms, as has been said, are so slight and vague, and the child passes so gradually from bealing.

to sickness, that the mother is usually quite unable to determine when she first noticed any signs of indisposition. She will say that for some weeks the child had seemed to be less brisk and lively than was his wont; that he would often lie about instead of playing; and that his appetite tral seemed to fail; but that no special importance was attached to these amptoms until something more definite was noticed which excited alarm. To first influence of the disease is upon general nutrition. The child begars to look pale, with a curious transparent pallor. His conjunctive have a blush tint, and the lower eyelid is discoloured. He loses his sprighthgess and gets dull and moping; his appetite is poor, and he fulls off in his Ilesh A certain amount of fever usually accompanies this condition. the evening the cheeks may be brightly flushed, and the hands and feet feel hot to the touch. At this time a thermometer in the axilla marks between 100 and 101° The patient is thursty, and often asks for water in the night. In the morning the temperature is normal; but the child when he leaves his bed generally looks pale and distressed. The anxious expression of the face in these cases is indeed commonly a noteworthy phenomenon; and if combined with mildness of the general symptoms, and complete absence of all signs of local discomfort, is an indication of illness of very serious moment. In some cases there are repeated attacks of chillipess followed by heat; and these may have a periodicity which suggests suspicions that the child is suffering from ague. The chilliness, however, ediom amounts to shivering, and sweating is seanty or absent. Loss of Besh is never very long in showing itself. The wasting is often very gradual, unless some relaxation of the bowels is present, and in the majorby of cases is intermittent. In hospital patients, under the unaccustomed adhence of good food and nursing, it is not uncommon for a child to regain some of the flesh he had lost, although all the time the fever conto acs and the general disease is pursuing its regular track. Even in children who are living in better circumstances the progress of the illness s often very unequal the child seeming to be alternately better and worse, and the temperature fluctuating currously from day to day. Sometimes, in leed, the pyrexia is found entirely to subside, and for a few days the improvement may be such that recovery is confidently anticipated. The intermission is usually, however, of short duration, and the patient relapses into his former state. At this time a common symptom is redema of the legs and sometimes of the face, and the urine may contain a trace of albumen. In young babies the only symptoms of the disease for a cone lerable time may be slight fever, pullor, some loss of flesh, an inelastic state of the skin, and a little cedema of the extremities.

For the first few weeks the above general symptoms are all that can be discovered; and the most careful examination detects no cause to which the evidently serious condition of the child can be referred. He is thin, pale, weakly, and listless; but his tongue is clean, and although feverish in i restless at night, he sleeps fairly well, is not light-headed, and in the distance makes no complaint. His abdomen is normal, rather flattened taxa distended; there is no enlargement of the liver or spleen—at least forming the first few weeks of the illness, and pressure of the belly cheets to sign of tenderness. In some cases a few rosy spots, rather more red than the typhoid spot, and of a larger size, are noticed on the abdomen

in I chest. The skin generally is dry and harsh,

After a time local symptoms arise. These often point to cerebral irritation. An attack of convulsions occurs, followed by squinting; the pupils are dilited, there is drowsiness and rigidity of joints; and the child dies

with all the symptoms of tubercular meningitis. It other instances we cranial cavity escapes, and symptoms are noticed showing implication of

the lungs.

The first local sign of scute pulmonary tuberculosis is cough. This is short and hacking, and in the earlier period not very frequent. It was be accompanied by some hurry of breathing; but the respirations are not always increased in rapidity, and even at an advanced stage of the disage. if there be only a moderate amount of catarrh, may be little, if at all more rapid than in health. The cough at this time is not accompanied by any abnormality of physical signs. Repeated examination of the chest discovers no dulness on percussion; and an occasional click of rhoulsor a sibilant wheeze may be the only phenomenon present. In some cases the child dies without any fresh symptoms; but usually a secondary broadstis develops after a time. The breathing then becomes rapid, the face is haggard and livid, and the nares dilate in inspiration. The pulse is shall and rapid, and there may be some slight perversion of the pulse-requise tion ratio; but this never occurs to the degree noticed in eases of broads pneumonia. The temperature rises, and may reach 103' in the evening sinking to 100 in the morning. With the stethoscope we now find the breath-sounds covered by a crisp, bubbling rhonehus, which occupies he whole extent of both inspiration and expiration. If the breathing can be heard through the rhonehus, it is not bronchial although the expunsion is perhaps prolonged. There is no dulness if collapse be absent, but sometimes local collapse of small extent occurs at the apex; and we may find a little local dulness at the supra-spinous fossa, or above the clause, with faint bronchial breathing. There is nowhere any increased resonant of voice or cough.

The above signs may persist without alteration to the close. Often, however, the inflammation passes into catarrhal pneumonia. Patches of dulness are then discovered at the apex or elsewhere. At these spots the breathing is blowing or tubular; the rhonchus becomes consper, fiver, and more crepitating in character; and the vocal resonance may be intensity brenchophonic. The patches of consolidation, as in cases of the anti-tubercular inflammation, may coalesce until large areas of tissue are soul-

ified.

The occurrence of broncho-pneumonia is also indicated by increase severity of the previous symptoms. The lividity deepens; the breating becomes laboured; the soft parts of the chest and epigastrium sink is at each inspiration; the nails become purple, and the superficial veins of its extremities are fuller than in health. The temperature also rises to higher level, and may reach 104° or 105° in the evening. When the symptoms are noticed the illness is very near its close; indeed, the child seldom survives longer than a day or two. Death may be preceded by a

fit of convulsions, due either to meningitis or asphyxia.

A little girl, aged ten, with a consumptive family history, was a petient in the East London Children's Hospital. The child was said to have suffered when quite young from measles, whooping-cough, and scarlatus but had recovered perfectly from each, although the latter had been followed by dropsy. She had also had an attack of ague when between two and three years of age. Still, the child had been in fair health until an west-before admission. Her illness had begun suddenly, but the symptoms if first were not marked. She had seemed generally poorly, but did not be flesh to any considerable extent; nor was she troubled with cough for the first three weeks. When the cough began it was short and dry, but and

distressing. Three days before admission it had become loose, and the child land expectorated some yellow phicgm. After the cough began she was noticed to waste and to be feversh, sweating much at hight. For a week her feet had been a little swollen.

On admission the child's expression was anxious. There was some lividity of the face, and in the evening her cheeks flushed brightly. Her tongue was clean and her bowels regular. Temperature at 7 r. m., 100.4°. On examination of the chest the percussion-note was slightly high pitched above the clavicles, but elsewhers was normal. Everywhere about the chest the breath-sounds were concealed by a metallic bubbling rhonchus. This was coarser behind than in front, and occupied the whole extent of both inspiration and expiration. The vocal resonance was normal. A rhonchul fremitus could be felt everywhere about the chest.

After admission the physical signs persisted with little alteration. The duliess disappeared from the apices and none could be detected elsewhere. The pulse was very rapid, 150-168; respirations, 60-68; temperature each evening, 101-102.4. After a few days the lividity deepened, the child became very restless, and she died on the ninth day—the fifty-first day of

ber tilness.

On examination of the body gray or yellow miliary nodules were found in the hver, spleen, and kidneys. Gray granulations were also seen under the serous coat of the small intestine, and were numerous on the pia mater. The lungs were stuffed with tubercle throughout, and the nodules formed projections on the surface underneath the pleura. The nodules tarted in size, the largest not exceeding a hemp-seed in diameter. The lung tissue between them was of a deep red colour and tore readily. It, however, floated in water. The mechastinal glands were enlarged and cheesy, and one or two were softened.

Besides the parts which have been mentioned, tuberculosis sometimes involves the urinary apparatus. The kidneys indeed are often affected, and the consequent congestion is no doubt a cause of the slight albuminuria which is a common symptom of the affection. But besides the kidneys, tuberculosis may occur in the bladder. This lesion is more common in the will than in younger subjects, but is met with from time to time in the older children. As it gives rise to many of the symptoms of vesical calculus this form of tuberculosis must not be passed over without a word

of mention.

The presence of miliary tubercles in the bladder sets up a cystitis, and gives rise to symptoms which are attributed almost invariably to stone. There is great unitability of the bladder and increased frequency of micturition; and according to Guébeard, these symptoms are more marked at might than during the day. At the end of the flow of urine some pus may be passed, or a drop of blood may appear at the extremity of the urethral canal. There may be pain, which is referred to the region of the bladder, and the passage of urine is often accompanied by uneasness. Sometimes metarition is only effected by straining, during which the rectum may protapse. The urine may be normal, but often is cloudy and thick. It may contain a trace of albumen. The temperature and general symptoms of tuberculosis are present in these cases. Exploration of the bladder with a bound discovers no calculus; but digital examination by Volkmann's method (e.c., passing a finger into the rectum and palpating with the other land above the pubest sometimes detects a tubercular nodule at the fundum of the bladder.

In the stomach, intestine, liver, and spleen the development of tubercle

rarely gives rise to sufficient local symptoms to furnish grounds for diagnosis. In the atomach the lesion may excite digestive trouble; but even this is an uncommon consequence of the disease, and when present is significant merely of catarrh of the mucous membrane. Bignon, indeed, has reported a case in which a child died after vomiting a large quantity of blood, and on examination of the body an ulcer was found at the larger curvature surrounded by tuberculous nodules. This case is, however, a very exceptional one. In the intestine the lesion seems to excite no symptoms whatever. The spleen, if thronged with masses of tubercle, may be enlarged; but the liver is rarely increased in size from this cause. It is, however, sometimes the seat of fatty infiltration.

The duration of acute tuberculosis in the child is seldem prolonged. In infants it may last six weeks or two menths; in older children somewhat longer. The length of the illness principally depends upon the duration of the early stage, for when local symptoms occur showing unpheation of special organs, the disease usually runs rapidly to its

close.

Inagnosis.—The disease with which acute tuberculosis is most apt to be confounded is typhoid fever. This is especially the case when the tubercular affection begins abruptly with high fever, headache, and bleeding from the nose. A diagnosis is then impossible at the first; indeed it is often only by the after-course of the illness, and the prolongation of the pyrexia beyond the time when in typhoid fever a fall of temperature may be looked for, that suspicious are excited of the real nature of the disease. The diagnosis between an ordinary case of acute tuberculosis and typhoid

fever is given elsewhere (see page 83).

Sometimes cases of acute gastric catarrh may present considerable resemblance to acute tuberculosis in its early stage. Not long ago I was consulted about a boy, seven or eight years of age, who had at one time suffered to my own knowledge from slight consolidation of the right apex, the consequence of an attack of catarrhal pneumonia. The boy was of scrofulous type, thin and pale. He was said to have been losing flesh for some time and to have had a poor appetite. For more than a week his appetite had been exceptionally bad; his temperature had been rused, and he had had a hacking cough. I saw the boy at 5 p.m., with Dr. J. N. Miller, whose patient he was. The boy's temperature was then 100.2". He was pale with no flush on his cheeks; and his face was bright and lively without any sign of distress. His chest was everywhere perfectly normal, except for a little dry rhonchus about the back. His belly was not distended. There was no enlargement of the liver or spleen, and no swollen mesenteric glands could be felt. He had no sore throat. The tongue was furred, and the breath had a faint unpleasant smell. There was no allowmen in the water, nor any trace of cedema of the legs. The spirits of the child were said to be remarkably good; and I was told that that morning he had been seen attempting the aerobatic feat of standing on his head. This latter fact, joined with the bright expression of the boy's face, the mgns of gastric derangement, and the absence of all evidence of pulmonary mischief, appeared to me to afford sufficient ground for excluding tuberculosis. I accordingly expressed an opinion that the boy was suffering merely from a subacute attack of gastric cuturrh. Shortly afterwards I heard that the febrile symptoms quickly disappeared.

According to my experience, children suffering from the development of tubercle are invariably dull and spiritless, and usually show signs of distress in the face. If a boy jumps about and plays boisterously, as if he

were well, acute tuberculosis may be excluded with a high degree of prob-

shibty.

The detection of acute tuberculosis depends in a great measure upon the absence of symptoms capable of explaining differently the serious condition of the patient. If a child is brought with a history of fever and wasting of some weeks duration, if he looks ill, with a distressed haggard ace, and if a careful examination of the whole body discovers no discover of organs, the state of the child is evidently not to be attributed to any local cause. In such a case the diagnosis will lie between typhoid fever arel tubs reulesis, and if from the duration of the illness, or for reasons given elsewhere (see page 83), typhoid fever can be excluded, we shall be reduced to tuberculous as the only other probable explanation of the child's state. In a bully fed infant who has been irregularly feverish from teething, and whose nutration has been some time defective, the history of wasting and pyrexia may raise suspicions of tuberculosis. But in such a the child will not look haggard and pinched like one suffering from that disease; the irregular and often greatly elevated temperature of denlition is unlike the moderate pyrexia of the tubercular affection, and will be sufficiently explained by inspection of the gums. Moreover, the history of the illness, which will almost certainly include several attacks of diarthere or sickness, and the account of the child's diet will furnish an amply sufficient explanation of his continued indisposition. In an infant acute tuberculoses is almost always accompanied by orderna of the legs. At this period of life the combination of wasting, moderate pyrexia, and cedema of the lower limbs is a very suspicious one.

Even when the case is first seen in its later stage, after signs of local disease have become evident, the diagnosis is not always easy. The physiad signs of tuberculous bronchitis have no special character distinctive of their specific origin, and they must be read in the light afforded by the astory and course of the illness in order that they may be rightly interpreted. In tuberculous bronchitis the temperature is higher than is found in an uncomplicated case of the catarrhal disease. In simple capillary broughitis the pulmonary affection is seldom accompanied by marked pyrexia, and the mercury rarely rises higher than 101" in the evening. In tuberculous bronchitis, on the other hand, a temperature of 104° is not succommon. The chief point, however, is the occurrence of the bronchial bsorder in a child worn and weakened by illness of undefined character and accompanied by fever and wasting. If this illness have succeeded after a variable interval to an attack of whooping-cough or measles, the fact alone should raise a suspicion of the tuberculous nature of the pulmonary complaint. So, also, if broncho-pneumonia supervene, with spots of local consolidation, the history of previous ill health is essential to a right understanding of the nature of the child's complaint. In either case the anset of symptoms pointing to intracranial mischief is of the utmost value in confirming our suspicions; and if convulsions occur, followed by squinting, ptosis, unequal pupils, and rigidity of the joints, the tuberculous nature of the disease may be considered to be established (see also

page 110)

In tuberculosis of the bladder the child's distress is usually attributed to the presence of a vesical calculus. There is, however, one diagnostic point of con-iderable importance. The irritation excited in children by a stone in the bladder is rarely a cause of noticeable pyrexia, while, when the symptoms are due to vesical tuberculosis, the evening temperature may reach 102 or higher. Moreover, digital examination after the manner re-

commended by Volkmann, already referred to, will sometimes detect a

tuberculous nodule in the fundus of the bladder.

Prognosis.—The prospects of a child in whom acute tuberculosis has revealed itself unmistakably are very desperate. In the earlier stage of the disease, while any uncertainty exists as to the nature of the illness, we can still hope; but when a secondary broughitis or catarrhal pneumonia arises, or signs of intracranial muschief are noticed, death may be considered certain. Attacks of gastric catarrh in children with tuberculous and scrofulous tendencies are almost invariably accompanied by fever. If the attack is protracted or rapidly recurs, an intermittent pyrexis may continue for some weeks, and on recovery the child may be thought to have passed through an attack of tuberculosis. Probably most instances of alleged

recovery from scute tuberculosis are cases of this kind.

Treatment. —When a case of acute tuberculosis has occurred amongst the younger members of a family very special measures should be taken to preserve the health of those who remain. They should sleep in well ventilated rooms, be warmly clothed, and be taken out of doors regularly for exercise. Such children should, if possible, live much in the country on a sandy or gravelly soil, and should avoid the vituted air of towns. Their diet should be plain, and excess of aweets and fermentable matter should be forbidden. Children with tubercular tendencies should not be taught too early. It is wise to postpone regular education until they reach their sixth or seventh year; and every care should be taken that their sensitive brains are not overtasked. The mother, if herself of frail constitution, should be forbidden to suckle her infant, and a healthy wet nurse should be promptly treated, and the utmost vigilance should be exercised to maintain the nutritive processes of the body at a healthy standard.

All catarries, however mild they may be, should at once receive attention, and the parents should be warned of the danger of treating the child as if he were well before all signs of his temporary ailment have disappeared. Acute diseases, especially the exanthemata, have peculiar dangers for these children; and during the period of convalescence the patients should be put into the most favourable conditions for insuring complete recovery. A good sea air should be always advised in these cases as soon

as the child is well enough to be moved from his home.

When the disease declares itself no drugs appear to have any value in arresting its course, and very little in retarding the fatal issue. Something may be done by treating symptoms and putting a stop to enfeebling complications. Thus the looseness of the bowels, which is often an early symptom of the disease, may be usually controlled by a powder containing three or four grains of rhubarb with double the quantity of aromatic chalk powder every night; and twice a day a draught containing dilute sulphuric acid (M ij.-v.), with tinct. opii (M j.-ij.), and a few drops of glycerine in aced (m, ij.-v.) may be substituted with advantage for the rhubarb in the powder. If in spite of these remedies the looseness still continues, gallic acid (gr. ij.-v.) can be given with laudanum.

It is very difficult to reduce the pyrexia in acute tuberculosis. Large doses of quinne have no more than a temporary effect, and often appear to be quite useless; saheylic acid and its compounds have little beneficial influence; and the hypophosphites have not in my hands been followed by satisfactory results. The hypophosphite of lime, however, although it

to treduce the heat, is useful in alleviating the various forms of a so common in tuberculous children, and often has a sensible tes in improving the appetite, and sometimes, temporarily, the th.

fammatory chest affections must be treated upon ordinary principles. strength of the child declines, stimulants will be required, and the y-and-egg mixture must be resorted to. The diet should be such recommended for other febrile diseases.

CHAPTER III.

INFANTILE SYPHILIS.

Syrams in the infant is generally the consequence of an inherited taint. It then presents a combination of the so-called secondary and tertiary stages of the disease. Sometimes, however, it is acquired, and there is then a primary lesion as in the adult. In this latter case the symptoms resemble more those of constitutional syphilis acquired after puberty. Still, the progress of the disease is not entirely uninfluenced by the tender age of the patient, for in after-childhood we can often discover many symptoms which are common to the inherited form of the malady.

Consulton.—The congenital taint may be derived from either the father or the mother; and the severity of the transmitted disease is in direct proportion to the shortness of the time which has clapsed since the

appearance of constitutional symptoms in the parent.

The disease may originate with the father. In this case much discussion has arisen as to the mode in which the mother becomes affected, or as to whether she becomes affected at all. In cases where there is no evidence of direct contagion, it has been held by some observers that the mother may be infected by tainted spermatic fluid, although no primary lesion is produced. Others believe that the infection only takes place at the time when conception occurs; others, again, deny that even in this case can infection be conveyed; while a fourth class insists that when the mother becomes herself syphilitic the virus is introduced only indirectly, being absorbed into her system from the tainted embryo. This discussion has, no doubt, great scientific interest, but is of little practical value. Of far greater importance is it to remember that a man may beget a syphilitic child long after constitutional symptoms have ceased to appear in his own person. From the researches of Dr. Kassowitz it appears that when left untreated, a series of years—six, eight, ten, or even more—may clapse before a man is relieved from the obligation of transmitting the taint to his offspring. When mercurial treatment is adopted, the remedy destroys for a time the power of the virus, and the parent is then capalle of begetting a healthy child. But this immunity from transmitting the disease is not permanent. In some cases the influence of treatment becomes exhausted after a longer or shorter time, and the poison recovers something of its former virulence.

With regard to the escape of a mother who has borne a syphilitic child, it seems certain that the escape must be incomplete, for she acquires a strange immunity from further infection. Long ago Colles laid it down as a canon that "a new-born child affected with inherited syphilis, even although it may have symptoms in the mouth, never causes ulceration of the breast which it sucks, if it be the mother who suckles it, although continuing capable of infecting a strange nurse." This law holds good as completely now as when Colles wrote in 1837; and it is difficult to understand

box the mother can be proof against the poison unless she he herself the subject of the disease.

Still, there is no question of the apparent immunity of many women mothers of syphilitic children. Dr. Kassowitz has brought forward instances to prove that the most careful examination, combined with watchagesten ling over many years, may fail to detect signs of syphilis in women of have borne diseased children. It certainly does appear possible that, M: Hutchinson believes, a woman may have a form of disease too feebetigive rise to external manifestations, but strong enough to protect ber from further contamination. Mr. Berkeley Hill insists that in all these ces the escape of the mother is not real. He believes, too, that in most case she has contracted syphilis in the usual manner by direct contagion, Little the primary sore has escaped notice through examination having bea delived too long after the date of infection.

The mother alone may be diseased, the father being healthy. In this awd the mother have contracted the disease shortly before conception, saleshibit the secondary rish during her period of gestation, the child all, r never escapes If four or more years have clapsed since her inthe time when she becomes pregnant, she may have lost her

power of transmitting the disease and the child may be spared.

If the mother be actually pregnant when the virus first enters her systen she may or may not communicate it to her offspring. Much depends up the period of gestation at which infection took place. The more adthe disease in the mother before her continement, the more likely is I fast to inherit the taint; and if a secondary rash have appeared upon suffer's body before the end of her pregnancy, the child usually suffers were is from the transmitted disease. In the initial stage of the malady power of the mother to impart the taint is less certain; and it is improble that the feetus can be infected if the parent have not herself the from constitutional symptoms. Therefore, if she only contract the less towards the close of her pregnancy, the infant has a fair chance of There is no evidence to show that the disease contracted by the and or after the eighth month of her pregnancy can be communicated to the fety, in her womb.

The induence of mercurial treatment in destroying the transmissive Parts very decided. If a woman who has borne a dead or diseased on I be properly treated before or during her next pregnancy, the infant he after treatment will be either perfectly healthy or will suffer very' to from the inherited taint. Still, as in the case of syphilis in the father, the counterscting power of the remedy is apt to be diminished by

When a healthy infant acquires the disease after birth, it is usually durwhiten, the supple of the mother or nurse having become infected the mouth of another child who suffers from the disease. Another and by which the sypmittic poison may be conveyed to a healthy child a rac mation The possibility of such communication was long denied; well-authenticated cases in which this deplorable accident has were I have now been published, and the evidence in its favour is com-

Horist Anatomy.—Infantile syphilis, like the other distinctic diseases

of childhood, may affect the tissues very widely. The pathological characters may be divided into three classes, according as to whether the part affected is a mucous membrane, a solid organ, or a part of the bony frame-work.

The macous membrane may be the seat of catarri, of mucous patches, or of ulcers. All these may be seen on the inside of the cheeks and lips, the fauces, and sometimes the small intestine; also upon the laryux, the

traches, and even the bronch

The inside of the mouth is a common seat for crosions and mucous patches. They do not spread down the gullet, according to Dr. John Mackenzie; nor are they to be seen on the posterior wall of the pharynx. In rare instances syphilitic ulceration is found in the small intestine. I once saw a little boy-four years of age-the subject of obstinate diarrhea, in whom the evacuations had all the characters usually found in cases of ulceration of the bowels. His father had had syphilis, and his mother in her next confinement gave birth to a distinctly syphilitic child, and had afterwards several miscarriages. The case resisted all ordinary remedies, but was eventually cured by the continued application of a mercural oint-

ment to the abdomen.

Mucous patches and ulcers may be seen on the glottis and epiglottis. The vocal cords may be destroyed by ulceration or may be the seat of warty growths. A case is elsewhere related (see page 417) in which obstruction of the larynx by warty growths occurred in a child who had a past syphilitic history, but in whom no other constitutional lesion could be discovered. Sometimes great thickening is noticed in the mucous membrane of the glottis. Thus, in a case reported by Eross—a syphilitie child aged three and a half years—a laryngoscopic examination showed that the epiglottis was thickened to three or four times its natural size; the ary-epiglottidean cords were thickened and pale red; the left rocal cord was more than twice as thick as the right, and bulged out at its edge towards its fellow. The symptoms were aphonis, and frequent convulsive fits of coughing with suffocative attacks. The child was treated with mercurial munctions, and was well in two months and a half. According to Dr. T. Barlow, the larynx, even after recovery, is left very sensitive and susceptible to fresh catarrh. The mucous membrane of the trachea and bronchi may be affected in a similar way. There may be catarrh, or mucous patches, or shallow ulcers; but these lesions are less common here than at the upper part of the respiratory passage. In rare cases the uiceration may be extensive. Thus, Woronichin found in a child of fourteen months old ulceration of the lower part of the traches, and a similar lesion of the right bronchus which extended as far downwards as the next division of the air-tube.

In solid organs syphilitic lesions assume the form of fibroid growths. which may be either diffused or circumscribed. Whatever organ be affected, the nature of the lesion is the same. There is hyperplasis of the connective tissue of the part. This grows, thickens, and finally contracts. so that the proper parenchyma of the organ is obliterated and replaced by a solid fibroid material. When the lesion is circumscribed it is called "gumma." This has essentially the same structure as the diffused form, but tends to soften in the centre by a process of fatty degeneration.

Diffused fibroid change is seen in the lungs, liver, spicen, and pancreas. Gummata have been found in the same organs; also in the heart and subcutaneous tissue. Occasionally they are found also in the tongue and soft palate, but not in infants. This is a later symptom and seldom occurs be-

fore the end of the sixth year.

In a lung the seat of diffused fibroid change, the part is solid and gray colour, with a smooth shining section traversed by fine fibrous lines. It very dense and tough. Under the microscope the alveolar walls are seen be untiltrated with round cells, spindle cells, and fibrous tissue. The and spindle cells develop into fibrous tissue, which thickens the pt and compresses the alveoli. There is also free production of new seek so that the new growth is very vascular. The area of lung thus forted varies. Usually the disease extends over a part of a lobe, or even by bolie. Besides the diffused form, gummata are seen sometimes in blace These are rounded well-defined masses, few in number, usually the size of a put, and yellowish-white or gray in colour. They are firm with circumference, but get softer in the centre, and the interior may be followed by fatty degeneration to a puriform matter. Microscopic exa sahon shows the alveolar walls to be infiltrated at the circumference of the turnour with nucleated cells, while nearer the centre round or oval was are seen in a finely reticulated tissue. These two forms of the same bet are seldom seen, except in dead-born or very young infants.

The liver may be affected, and, according to Dr. Parrot, is most freyears found deseased in infants who die six weeks after birth. The orsee a calarged and hardened, and may be the seat of a sclerosis, diffused, the lungs, or, more rarely, of the circumscribed form. According to Goder, who first drew attention to this condition, the organ in the diffirst shoul change is hypertrophied, globular, hard, and clastic, and its tiles are counder than in health. It creaks on section, and the cut surhe spinkish-white or rellow, and shows layers of small, white, opaque man a yellowish uniform ground. The capillary vessels are obliceand the calibre of the larger vessels is mereased. These changes are do to the development of new fibro-plastic tissue which compresses the lepate cells, obliterates the vessels, and checks or prevents secretion of but Gummata may be combined with the preceding, and are seen as accumer: bed nodules embedded in healthy tissue. The masses are bright mow, and present under the microscope the usual round or oval cells. Isers is commonly more or less softening in the centre, while at the cir-

The spleen is often enlarged, and, according to Dr. Gee, if the enlargement is great the child will probably die. Dr. Gee considers the degree of elargement to be an index of the severity of the eachexia. If the child improves the size of the spleen does not diminish as the other symptoms display, but continues unaltered—often for years. In the spleen, as in other solid organs, the disease consists principally of a diffused inter-

direction the normal hepatic cells, between which the infiltration is ad-

Kitai hyperplasia.

mang, become hypertrophied.

In neart and lungs may be also affected. Gummata have been found the former organ, and Dr Coupland has described a specimen in which much walls were thickened and hardened, and showed under the miscope an almost universal infiltration of small round cells amongst the miscolar theres. In the same case the kidneys, although normal to the cir. were seen to be undergoing similar changes, and their substance are unturally firm.

The thyritis gland is seldom diseased. Sometimes collections of material formal scattered through its interior, but it is not clear that these

the consequence of the syphilitic taint.

The suprarenal bodies are said by Virchow to be frequently the seat a latty degeneration. Huber has described a condition in which these

bodies are large, gravish on the outside, translucent, and thick, with numerous white, irregular spots dispersed through their substance.

The bones are often the seat of profound structural disease. Our knowledge of the bone disease which occurs as a consequence of inherited syphilis is only of recent origin. Dr. G. Wegner was the first to describe these lesions, and attribute them to their true cause, in 1870. More recently Drs. Parrot and Cornil have laboured at the same subject. Dr. Taylor, of New York, who has collected many cases of his own and analysed those of others, gives a graphic account of these affections in his well-known volume.

Disease of the osseous system is a far from uncommon lesion. According to Dr. Abelin, of Stockholm, it is found in ten per cent. of the cases. The bones especially affected are the long bones of the limbs; next come the bones of the skull, the ribs, the scapulæ, and the iliac bones. In the long bones there are two chief varieties. One begins with the periosteum—periosteogenesis: the other is not connected with the periosteum, but is confined to the ossifying line of the displays osteochondritis.

Pernostcogenesis begins as a periostitis. Parrot divides it into two forms: the osteoid and the spongioid or rachitic. The former may occur from the earliest period of life; the latter is rarely seen in infants of less

than six months old.

In the osteoid form we find one or more layers of a new growth which is composed of interlacing trabecular lying perpendicularly to the axis of the shaft. The periosterm is thickened and adherent to the growth, and the latter has a chalky appearance from copious infiltration with calcareous salts. Consequently it is whiter and more friable than the bene beneath, and the line of junction is well defined. The osteoid material is found on the shafts of the long bones and on the cranial bones. In the latter situation it may reach an inch or more in thickness. By the microscope we find differences in structure from true bone. There are no bone corpuscles regularly disposed round the Haversian canals: instead, corpuscles—three-sided or polygonal, resembling the stellate corpuscles of connective tissue—anastomose by their processes with the cells of the periosteum, with corpuscles in the medullary spaces, and with one another.

In the spongioid form, which is not seen in children under six months

In the spongioid form, which is not seen in children under six months of age, a new fibroid tissue, pearly gray or yellowish in colour, is formed between the periosteum and the bone. It is more vascular than normal

osseous tissue.

The osteoid and spongy growths are often combined. If the new material consist of several layers, some may be more trabecular, others more spongy in structure—the chalky layer being nearer the bone, the fibroid immediately beneath the periosteum. While this process is going on around it, the shaft of the bone may be unaltered. This is usually the case in very young babies. In older children the calcareous matter of the shaft may become absorbed, and the tissue be separated into layers by the formation of furrows filled with medulla. The bone as a consequence becomes light, porous, and brittle. The ends of the bones are thickened, partly by the periosteogenetic growth, partly by granulations thrown out from the spongicial tissue of the shaft.

Osteochondrius appears to consist in a suppurative ostitis affecting the epiphyseal end of the bone. The layer of cartilage preparing for ossification becomes thickened to three or four times its natural width, and gets transparent and soft. This increase in width is due to excessive proliferation of the cartilage cells, which assume much the shape and size of the

sund granulation cells of syphilitic gummata. At the same time the interellular substance is diminished. The cartilage which is actually indergoing assistation is thickened, and shows on section a broad wavy like. By the interescope the osteoblasts are found to be replaced more or less ampletely by small granulation cells or spindle-shaped elements. There time destructive changes set in in the bony tissue. Dr. Parrot describes a "gelatimiform softening," in which the bone is replaced by a soft, after transparent material of a vellowish or brownish colour. After deat, when the bone is dry, a cavity is left. The cancellous structure is also infiltrated with purulent watery fluid, so that the lamelle disappear at leave a fibro-vascular network filled with the same fluid. According to Wegner, a characteristic feature of this osseous disease is the protruct of bundles of fibrous tissue along the course of the blood-vessels. The bundles pass through the cartilage, the calcifying layer, and the protect of spongy bone, and penetrate deeply into the cancellous tissue this shaft.

As a consequence of this lesion the epiphyses with the ossifying layer to separate from the shaft of the boffe. Suppuration is then set up, an above forms, and the pus escapes into the surrounding tissue by penetratic the periosteum. The joint itself is not involved as a rule; but Dr. bes has reported a case in which the left elbow-joint and both knee-joints because filled with pus.

benested genesis is more common than osteochondritis. It attacks par-

Lea luring life, which will be afterwards described.

An osseous lesion, due probably to changes similar in character to the les ribe I above, and called dactylitis, may attack the bones of the has and feet. Dr. Taylor, of New York, has contributed much to our Laweige of this affection. According to this author, the disease begins else in the fibrous tissue surrounding a joint or in the periosteum. In the test form slight enlargement is seen of one or more toes or fingersthe of the whole length, as occurs in the toes, or of one or more phalarger, as is seen in the case of the fingers. The process is slow and is by Lpanied by little or no pain, although the swelling interferes with the placed the joint. The second form is most frequently seen in the fingers. Out or more of the phalanges becomes evenly rounded or fusiform. Wen the first phylanx is attacked, it usually assumes the shape of an The metacarpal and metatorsal bones may be also affected in the line way In all cases, as a rule, the tendency is to resolution. Still, basetimes, if the enlargement is great, the part is exposed to accidental pary The skin then becomes swollen, red, and tense; ulcerates or is cased, and discharges a soft, cheesy detritus mixed with pus. Limited cross may follow and lead to shortening of the finger. Dactylitis is The seen in very young children, but it may be a later symptom. The unber of fingers affected varies. Dr. Taylor mentions a case in which A the phalanges of both hands were involved.

The bones of the skull may be affected by the two forms of disease who attack the long bones. Gelatiniform softening is comparatively, i.e. but is sometimes found in very young infants. It begins beneath the remaining but does not penetrate deeply into the bone, so that it rarely when the dura mater. After death the bone has a worm-caten appearance. This form cannot be diagnosed during life. The osteoid growths only found in older children. At first they always occupy the same mation, viz., the frontal and parietal bones surrounding the anterior for-

tanelle. Sometimes they are also seen in the temporal bones, but are never found, unless the disease be exceptionally severe, in the orbid plates or the occipital bone. As they grow they produce a very characteristic deformity of the skull. The fontanelle comes to be surrounded by four elevations, which are separated by two furrows intersecting one another in the form of a cross—the one transverse, the other antero-posture These osteophytes are usually spongy and porous, but they may become hard and smooth like normal bone tissue. They sometimes reach as not and a quarter in thickness.

In addition to the above purely syphilitic changes, local thinning of the bone, called *crauto-tabes*, is often found. This condition, which is a thinning or even perforation in certain spots of the cranial bones, was unlately considered to be exclusively a symptom of rickets. It is due to derect pressure upon the bones of the skull by the brain within and the pillow without, and is found especially in the occipital bone. It may be present in rickets where no trace of syphilis can be discovered, but is most

common in cases where there is a distinct syphilitic taint.'

It is difficult to say with certainly at what age a child becomes hable to syphilitic disease of bone. Gelatiniform softening and osteochodium generally occur early, beginning before the sixth month, and it is probable that they may even be present in intra-uterine life. Dr. Taylor has roof frequently seen osteochondritis about six weeks after birth. The charges in the cranial bones seem to be later symptoms, and to occur most examinate the second year. In some cases reported by Drs Barlow and Lees the ages of the children were between two and three years. Pear changes usually occur in the most severe cases, although it is said that they are sometimes the only symptom of the disease. If the patient recovers, all traces of the morbid growth may disappear, but it is not set to find curvatures or twists left as evidence of the cachexia which is passed away.

Symptoms.—The first manifestation of the constitutional taint may occur early or late, according to the degree to which the system is affected by the virus. When the syphilitic poison is very active, the disease may first show itself during intra-uterine life. The foctus then dies and is born dead before the proper time. Syphilis is thus a common cause of miscarriage, and in all cases where premature labour is found to have occurred reputedly, we should not fail to make inquiry as to the previous health of the parents. If examination of the aborted feetus be made, the lames and uternal organs exhibit signs of being profoundly affected by the syphilis

poison.

In a less active state of the virus the child, although diseased, may be born alive. He is then much emaciated and looks shrivelled. His body is covered with an eruption of pemphigus which extends even to the palas of the hands and soles of the feet. He snuffles and has a hourse cry. If is generally happens, the internal organs are extensively diseased, the cross dies. If no disease of the internal organs be present, the child may large for a longer time, but he generally dies in the end. It is only in very rate cases that he struggles on and eventually recovers.

Usually when a syphilitic child is born alive, he has at first a healthy

Out of one hundred cases of cranio-tabes collected by Drs. Barlow and Low 5 forty-seven there was satisfactory proof of syphilis, in forty there was more or evidence of the disease, only in twelve was there no indication of syphilis to be detected.

appearance. After a time—often between two and six weeks, rarely after three months—the first signs of the disease appear. Before this, however, the child in many cases has an unhealthy look, although it is difficult to say in what this unhealthiness consists. There is often great restlessness; and the infant may sleep badly at night, sometimes breaking out into paroxysms of violent crying, which are a source of great perplexity and distress to his attendants. It seems probable that this symptom is due to nocturnal pains in the bones, such as often affect adults before the outbreak of constitutional symptoms. The sleeplessness soon ceases under the influence of specific treatment. Sometimes the outbreak of the general symptoms is determined by a febrile disease, such as vaccination or one of the exanthemata. Thus, it is not very rare to see the rash of measles subside

leaving the syphilitic eruption in its place.

Smuffling is one of the earliest symptoms. It should always be inquired for, as write the child is breathing through the mouth it is not noticed, and the mother attributing the symptom to a cold may not think it deserving of mention. The smuffling is most evident when the child takes the breast, and his manner of doing so is very characteristic. Each breath is drawn with difficulty through the nostrils, and if the obstruction is great respiraton has to be suspended while the babe sucks. Consequently, he can only draw the milk by short snatches. After every two or three mouthfuls he is forced to desist, and can be seen lying with the nipple in his half open would so as to renew his supply of air before he begins again. A discharge from the nostrils soon appears. This is at first watery, but soon becomes tacker and forms crusts which block up the masal openings. Little ulcerato as and cracks are generally seen about the nostrils and upper hp, due other to mucous patches or to scalding by the writating secretion from the In land cases ulceration of the Schneiderian membrane may take per, and the septum is sometimes perforated. Occasionally, necrosis of be assal bones follows, and fragments of the bones may be found in the theil discharge. The bones may be also loosened so that the bridge of the bose is flattened and sinks down.

Another early symptom is the rash. This appears, as a rule, shortly For the beginning of the coryza. It is seen as flattened, slightly elevated nots, of a rusty red or coppery colour, scattered over the permanim, upon the generals, and around the anus. Sometimes it begins as a uniform, dingy at blush covering the belly, the perimenm, and the buttocks. It soon sumes the tint of the lean of ham; its edge is distinctly circumscribed, and at the circumference isolated spots are seen of the same colour. The emption is not confined to the lower part of the body. It is often seen in the folds of the joints, particularly of the armpits, along the sides of the seck, and over the chin. Other varieties of eruption are also seen. Eethynatous and tubercular spots are not uncommon, and mucous patches and Merrations are constantly present on the skin. The ecthymatous pustules are met with in the more weakly children. They are generally covered with a thick scale, under which the skin may ulcerate into deep, sharply cut sores. Mucros patches he at the outlets of the various passages opening on to the surface of the body, and in other places where the skin is especially delicate and moust. Thus they are seen around the anus, and in a girl round the sulva, also about the commissures of the hps, and between the fingers and They are round or oval patches, slightly elevated. The surface is of a gravish colour and is moistened by constant secretion. On a mucous membrane they quickly become converted into shallow ulcers. Ulcerations and cracks invade the angles of the mouth and alse of the nose. They are

linear and leave behind them linear cicatrices when they heal. The saitself of a syphilitic child presents a very characteristic appearance in severe cases it is dry, inelastic, and wrinkled in loose folds. The emphrion is yellowish, and has been compared to weak café-au-lait. This mis unequally distributed, being most marked on the prominent parts, as is nose, checks, forchead and chin. The general colour of the skin may be middly; but in children who survive it generally becomes angularly tholless, and remains pale long after other symptoms have disappeared.

The hair and eychrows sometimes fall out. The nails may also be affected. Inflammation and suppuration occur in the matrix, so that the nutrition of the nail becomes impaired and the hail gets dry and is care

off.

The cry of the infant is a noticeable symptom. It is house and highpitched from laryngeal catarrh or extension of the mucous patches to the farynx. Occasionally the houseness is accompanied by attacks of larygismus stridulus. In almost every case the ossification of the craisal bones is delayed and the fontanelle is widely open; but the growth and development of the teeth are not interfered with, for the teeth are cut carly, as a rule, and with little inconvenience to the child. Cramo-tains is present in the large majority of cases, and the posterior cervical glards

are often enlarged.

The bone disease presents many very characteristic symptoms. The long bones should be examined for signs of enlargement, especially the humerus, the femur and tibia. If we place the finger and thumb on the anterior and posterior aspect of the humerus at the upper part, and carry the hand downwards along the shaft, we shall often notice that the both becomes thickened at the lower end, and that the thickening is greatest at the point of junction of the shaft with the epiphysis. In the tibia the thickening can be often detected on the inner surface, in the femur to the outer and inner aspects of the shaft. Besides these, there may be beading of the ribs and thickening of the radius and ulma above the wint. The osteophytes on the cranial bones have already been described.

When suppuration takes place outside the joint, especially if there is fracture of the neck of the bone, we find peculiar symptoms. The chili appears as if paralyzed. His arms he pronated by the sides of his lody, his legs are stretched out straight in the cot; and when the patient is lifted up, they hang loose, like the legs of a doll, swaying from soil to side. Crepitation can sometimes be detected between the shaft and the separated epiphysis; and if an abscess forms, the joint, which had been tender before, becomes bent and stiff and exquisitely painful. Parad has

called this condition "syphilitic pseudo-paralysis."

A form of real paralysis has been occasionally seen affecting the branches of the brachial plexus, and causing more or less complete loss of power at the arms. In two cases, described by Dr. Henoch, voluntary movement was almost completely lost in the upper extremities, the flexor muscles of the fingers alone retaining a slight trace of contractility. There were offer signs of syphilis, and the paralysis disappeared under the influence of mercury. In some cases a peculiar twisting of the head backwards believe noticed when the child is placed in a sitting position.

The degree to which the child is affected in cases of inherited syphilic varies—partly according to the virulence of the poison, and partly assume ording to the general strength of the infant. In rare cases, where two are born of parents suffering from this disease, the two children may be affected very unequally. An instance of this came under my own poison.

The children were three months old. One was much emaciated, with a strive limb, parelment-like skin, covered with pemphigus. She smulled and eried housely. The other was a healthy-looking child, fat and strong, with a good complexion. She snuffled and showed on her buttocks signs of recent eruption; but was never thought sufficiently ill to require medical advice.

In practice we see every degree of intensity of the syphilitic cachexia In one case, like the healthier twin just mentioned, the infant may be plump and strong-looking, with few symptoms and those trifing in character. In another the child is wizehed and wasted, with a wrinkled, mensile, blotchy skin. He is prevish and restless, crying hoursely and winnpering almost constantly. He is always hongry, for the state of his mouth and result passages offers a continual impediment to his drawing sufficient nourishment from the breast. He gets weaker and weaker—partly from disease, partly from want of food. Vomiting and diarrheea perhaps come on, and his miserable little life soon draws to a close.

When the infant survives, he may seem quite to throw off all traces of his illness, and grows up a strong healthy child. But usually, when the symptoms have been severe, more or less permanent impression is produced up at the system. The body may be stunted in growth; the complexion earthy or unhealthy looking; the hair thin and brittle. The brain may be also more or less affected, and epilepsy, deficient memory, loss of perceptive power, and even gradually advancing imbecility are enumerated

as consequences of the disease.

It troves. In rare cases the symptoms of inherited syphilis are said to be delayed until the seventh, ninth, tenth years, or even later. Most of these cases are no doubt instances of relapse of the disease, the symptoms which occurred during infancy having been slight and transient. The relapse shows itself in coppery eruptions on the skin with discharges from the nose, cars, etc. The skin often ulcerates, and the nose is depressed. The spongy bones and hard palate may ulcerate away, and the velum and pillars of the fauces may be destroyed so us to throw the nose and month into one cavity. The eyes may be affected with interstitial keratitis; the p-rm ment increase testh may be notched and dwarfed; and deafness may occur. Definess is the consequence, as a rule, of some morbid condition of the nultury nerve. It is seldom accompanied by any disease of the outer or middle ear, for there is tunntus, and the patient cannot hear a tanang-fork place I on the head. It is most common between the fifth and fitteenth years, and can seldom be improved by treatment.

Epilepsy has been mentioned as sometimes occurring in syphilitic children. It is usually one of the later symptoms, and may exist, as was seen in one of Dr. Hughlings Jackson's cases, without any sign of organic disease being detected in the brain after death. Syphilitic children sometimes the from a basic meningitis with symptoms similar to those produced by the tubercular form of the disease. They may also succumb to a cerebral humovrhage. Dr. Barlow has described a diffused thickening with openity of the arterial coats in the brain as sometimes occurring in cases of a herited syphilis. This may lead to thrombosis of vessels or rupture of

the artery with fatal hamorrhage.

Lastly, in many children who have suffered from the hereditary form of the disease we may find amyloid degeneration of internal organs, especially of the hyer, the spleen, and the kidneys.

Inagrams. - When the symptoms are well marked the nature of the

disease can scarcely be mistaken. The little, old-looking face, with its dusky complexion, its fissured hips and crusted nostrils; the snuffling and hourse cry; the wasted body; the wrinkled and inelastic skin; the hamlike redness of the buttocks and perinaum—all these symptoms are sufficiently characteristic. Doubt is only permissible when the symptoms are few and indistinct, when nutrition is unaffected and the child has the appearance of fair health. Insuch cases there is general pollor of the skin and careful examination may detect a few coppery spots upon the body; the splicin may be big, and we may, perhaps, discover some enlargement of the lower end of the humerus or shaft of the tibia. Chronic corver is commonly of syphilitic origin. If it be combined with pailor of the skin, speculic treatment should always be adopted, especually if a history of previous miscarriages can be obtained from the mother.

In older children the signs of past disease are: Flattened bridge of the nose from long-continued swelling of the nasal mucous membrane when the bones are soft; marking of the skin by little pits or cicatrices from former ulceration, especially when these are scated about the angles of the mouth; protuberance in the middle line of the forchead between the frontal eminences from specific disease of the frontal bone; enlarged spleen and marked pallor of the skin. If the permanent teeth have appeared the incisors should always be examined for signs of the charac-

teristic malformations.

In cases where there is enlargement of the ends of the long bones, the dugnosis from rickets has to be made. As compared with inherited srphilis rickets is a late disease. It rarely begins before the ninth month. The lesions of symbilis are seen early, almost always before the sixth month. Again, the bone disease in syphilis is usually evidence of a profound cachectic state. It is, therefore, in most cases accompanied by other and unmistal able symptoms of the disease. Moreover, it is very partial, seldom affects the ribs, and is not symmetrical. In rickets it is always symmetrical and general and the ribs are the earliest of the bones to be affected. In syphilis separation of the end of the bone and suppuration around the joint are not uncommon. In rickets these lesions are never seen. Again, the preliminary symptoms of rickets are very characteristic, and are quite wanting in an uncomplicated case of inherited syphilis. If, many case, we find that the bone lesions are symmetrical and involve the ends of all the long bones, if there is an absence of the signs of inherited syphilis but a history of the symptoms characteristic of the early stage of rickets, and if we find that the child's dentition is backward, and that at ten months old he is showing no disposition to "feel his feet "-we shall have little difficulty in reaching the conclusion that the case is one of rickets. Still, a mild form of rickets is sometimes engrafted upon a syphilitic constitution. Here we shall find symmetrical and general enlargement of the joints and beading of the ribs combined with some of the symptoms of present or past syphilitic disease.

Dactylitis occurring in syphilitic children must be distinguished from the necrosis which sometimes attacks strumous subjects. In syphilis the diseased bone is evenly enlarged, and no inflammation in the integuments occurs unless the size of the lump exposes it to accidental injury. In the fibrous form, also, the swelling is inducent and painless, and although not quite symmetrical, as in the osseous variety, is distinguished by its little tendency to end in suppuration and abscess. In strumous necrosis the bone is enlarged unevenly and generally forms a lump on one side. This tump gets bigger, then softens and suppurates, adhesions take place with the integument, and finally the abscess opens and discharges cheesy pus. On exploring the abscess bare bone is found at the bottom of the cavity. In all these cases careful inquiry should be made for history or sign of

syphilis in the patient or other children of the family.

Preparate.—The prognosis is serious in proportion to the intensity of the cachexia. The general condition is, therefore, of greater importance in counting the chances of a child's recovery than the severity of any particular symptom. The degree of intensity of the cachexia may be estimated by the date of appearance of the first symptoms of the disease, and by the extent to which nutrition is interfered with. If the symptoms appear during the first fortnight and the child progressively wastes, death may be anticipated with certainty. All intercurrent derangements which interfere with digestion and assimilation of food sensibly increase the gravity of the case. Thus, vomiting and diarrhess, which rapidly reduce the strength of even a healthy child, must be looked upon as very serious complications.

D. sease of the internal organs or of the bones, as they indicate profound contamination of the system, make the case a very anxious one. Moreover, the interference with function which results from the visceral disease is another reason for forming a very unfavourable opinion as to the

result of the illness.

There is one special symptom which must not be overlooked in forming a prognosis. This is the condition of the nasal passages. When these passages are occluded from swelling and incrustation the child is forced to breathe through the mouth. Consequently, he can take but little nourishment, for while he sucks he cannot breathe, and while he breathes he cannot suck. The amount of food he takes is, therefore, very inadequate to the wants of his system, and he is in danger of actual starvation.

If the disease first appears several months after birth, and if the child continues plump, and does not sensibly emaciate, the prognosis is favour-

able even although particular symptoms may be severe.

In cases of relapse, or of so called delayed syphilis, when symptoms appear after the seventh year, much depends upon the early recognition of the nature of the malady. Syphilitic lesions urgently require specific treatment, and the so-called tertiary forms of the disease cannot be neglected without serious consequences. Therefore, to look upon such lesions as scrotulous in their nature, to be treated with cod-liver oil and tonics, is to commit an error which may be a very fatal one to the patient.

Treatment.—In every case where a woman gives birth to a syphilitic child the nature of the illness should be explained to the father, so that by suitable treatment of one or both parents their future children may be enabled to escape the disease. Treatment begun during pregnancy is often successful in preventing the taint from being transmitted to the factus; but at should be begun early and, if it can be borne for so long a time, should

be continued for fully three months.

In the child it is important to attack the cachexia at the carliest possible moment. Therefore, if previous children have been syphilitie, and the parent in the interval have undergone no treatment, it is well to place the new-born child at once under the influence of remedies, even although he may have a healthy appearance and present no symptoms of the discusse. Moreory is indispensable to the successful treatment of infantile syphilis. It may be either given internally or applied externally. In laid cases it is well to combine internal administration with external application, so as

to bring the system as quickly as possible under the influence of the

drug.

Externally, mercury can be employed in the form of the ordinary mercurial continent. The most convenient method of using this salve is to smear it inside the flannel band which covers the infant's belly. When this is done great cleanliness must be observed. The whole body must be washed well with soap and water every night so that all old outment is removed before a fresh application is made. Another way of using mercury externally is in the form of mercurial baths. Thirty to ninety grains of the perchloride may be dissolved in two gallons of warm water. It is better to begin with the smaller quantity and gradually to increase the strength of the solution. The baths, besides their effect upon the general system, have a very beneficial local influence upon the cutaneous lesions. When the cachexia is very severe, it is well to combine external with internal treatment; and in cases where there is great irritability of the stomach or bowels, we may be forced to depend exclusively upon the cutaneous ab-

If a mother who is giving suck to her diseased infant be herself undergoing treatment, it may be unnecessary in addition to give mercury to the child. Doubts have been entertained as to whether mercury is really secreted by the breast. Cullerier has tested the milk of mercuralised mothers without finding evidence of the drug in the secretion. Still, it seems certain that an appreciable amount of the remedy must reach the child by this means, for in mild cases very rapid improvement is noticed in his symptoms while he remains at the breast. In cases of severity I am disinched to trust to the child's getting a sufficiency of the drug by this channel, and prefer to supplement the treatment by the direct application of

mercurial ointment to the abdomen.

While specific treatment is being adopted, we must do our best to improve the general nutrition of the infant. The milk in syphilitic mothers is too often poor and watery, and ill-adapted for the supply of sufficient nourishment to their offspring. Therefore if the child wastes, especially if, by frequently requiring the breast and crying previshly after his meal, he seem to be ill-satisfied by the milk he has swallowed, it is well to give alternate meals of cow's milk diluted with an equal quantity of barley-water, and containing a small quantity of some malted food, such as Mellin's Food for Infants. If the child have a difficulty in sucking, on account of the condition of his nasal passages, this food must be given with a syringe. If a feeding-bottle be used, care must be taken that no other child be allowed to suck at the mouth-piece used for the diseased infant,

at the nurse should be cautioned not to put the teat into her own bouth. In connection with this subject it may be well to remark that it is a laty in all these cases to warn the nurses and servants in immediate tentance upon the child of the danger of infection from nucous patches adother discharging sores upon the patient's body. They should be discipled to observe great cleanliness; to avoid wiping their hands upon any maker towel used for the infant; and if they have a finger wounded by as weadcutal cut or abrasion, on no account to handle the child unless the part is properly protected.

the infinit must be kept perfectly clean. His whole body should be lated with warm water twice a day; and if mercurial inunctions are being appoyed, soap should be used for the evening bath. Care must be taken buy the child thoroughly after each washing. Fresh air is of the utmost importance, and if the patient be strong enough and the weather dry, he

or is taken out every day warmly dressed into the air.

Vennting is best treated by suspending the mercurial for a few days. If the symptom continue and there be a sour smell from the breath, the bit must be altered, as recommended in such cases (see Infantile Atrophy). It has nesses of the bowels occur and be not arrested by stopping the medicar an alkali with fincture of catechu will usually check the derangement at one. In arrhive as seldom obstinate in these cases if the diet be regulated and the child's body be sufficiently protected from the cold.

It is important to attend to the condition of the nostrils. All hard costs must be removed by bathing with warm water after softening with the read of the read oxide of mercury may then be emposed to the inside of the nostrils. Mucous patches must be well touched with the solid nitrate of silver, and if large ecthymatous crusts have trued on the body, they must be removed by poultieing. The uncovered

weren then be treated with the red mercurial cintment.

laternal treatment must not be continued long after the symptoms of the decree cease to be noticed. On account of the profound anomia often mixed by the long-continued administration of mercurials it is wise to issay the treatment as soon as the skin has recovered its healthy appearance and the other specific symptoms have subsided. Cod-liver oil and into on then be given. In addition, every care must be taken to promote health nutration by judicious regulation of the diet, and vigulant attention to also the minor agencies which exert so material an influence upon the web-being of the infant.

Part 4.

DISEASE OF THE DUCTLESS GLANDS AND BLOOD.

CHAPTER L

LEUCOCYTHEMIA.

LECCOCTHEMIA (leukhæmia), although a rare disease in childhood, is occasionally seen in the young subject, and therefore may be shortly described. The disease is characterised by great excess of the leucocytes of the blood, enlargement of the spleen, sometimes of the lymphatic glands, and a morbid state of the bone medulla. Two cases have come under my notice, both in children under three years old. In each of these the malady assumed a febrile form, and was accompanied by enlargement of the spleen without any apparent affection of the lymphatic glands. In lymphadenoma, which is described elsewhere, an increase in the number of the white corpuscles is exceptional. Sometimes, however, in that disease excessive overgrowth of lymphatic elements is combined with multiplication of the colour-less blood-cells. These cases present a great resemblance to the lymphatic form of leucocythemia, and, indeed, anatomically appear to be almost indistinguishable from it. In the present chapter the spleme form of leucocythemia will alone be described.

Causation.—The etiology of leucocythemia is not clear. Out of 150 cases analysed by Dr. Gowers in one-fourth there was a history either of ague or of habitation in an ague district. Of my own two cases, one had hved at Malta; the other was a resident of London, but had lived in a street in which the roadway had been broken up for repairing and relaying drains; and for two or three months the upturned soil, saturated with coal-gas and other unhealthy offluvia had remained heaped up by the side of the foot-pavement. The disease appeared shortly before the close of these operations, and I cannot but think that the illness took its rise in the offensive emanations to which the child had been constantly exposed.

Morbid Anatomy.—The spleen is enlarged and may reach a great size. This increase is due to an overgrowth of the splenic pulp, the leucocytes and the fibrous stroma being equally increased. The organ, although enlarged, retains its normal proportions, so that its shape is not changed. Its density is increased and its colour is paler than natural. On the surface it is smooth unless local peritonitis have occurred, in which case particles of

in the may adhere to the capsule. From this cause it may contract adhere to parts in its neighbourhood. Its section is smooth and of a transh-yellow colour mottled with paler streaks from thickened transher, and but little blood escapes from it on pressure. The Malpighian colors are not very prominent, and may be seen under the microscope to be the sent of fatty or landaceous degeneration.

The liver is often enlarged from congestion, and may be fatty. The siters, too, are often the seat of fatty degeneration. Hamorrhagic extractions are common, and may be seen in the skin, the heart, the lates, the brain, and the retina, and fluid effusions may be found in the

PONE CANTLINE

le some cases the lymphatic glands undergo slight enlargement, but the mercase in size is rarely universal as it is in lymphodenoms. On minutation they appear to be normal in structure without any hyperplais of the reticulum, and suppuration or cascation rarely occurs. As in burtadenous, adenoid growths may be also found in the tousils, the blaces of the tongue, the glands of the stomach and intestines, and in that situations. The capillaries in various parts are distended with colletimof isucceptes. The marrow of the hones is more fluid than natural, in growth in colour, and shows an accumulation of white and red corpus-The blood itself is much altered. It is pale in colour, congulates bedy, and shows an enormous excess of white corpuscles, together with immention in the number of the coloured cells. Consequently the relthe proportions, instead of being one white to four hundred and lifty red, m m health, may fall to one to twenty, one to ten, one to five, or even to an can equality of number. The white cells may also present peculiar char-They are sometimes seen of two quite different forms; the one watle the size of the other and full of small fat granules. According to Moder this larger form is evidence of morbid change in the bone medulla. Wer death thick creamy-looking clots may be found in the cavities of the but the terminal branches of the pulmonary artery, and the systemic Penela

comptons. The illness begins insidiously. Sometimes at first the real health alone seems to be impaired; sometimes even from the beparage the belly is noticed to be large. The child loses his sprightliness at begins to look pale and to droop. His appetite fails and be slowly there is almost always more or less fever, but this is at first that and occurs irregularly. Afterwards it becomes more continuous and

the temperature ruses to a higher level.

Intergement of the spleen, although not always noticed at an early rol of the disease, is usually to be detected on careful examination. Includes of the organ should be always estimated by percussion as well imputed. The degree of enlargement varies. In neither of my cases hit is lower edge reach more than three fingers breadths below the rabs, at there did not seem to be any great upward extension. In many cases, haven, the increase in size is much greater. Some enlargement of the large may also be noticed.

When the disease is fully developed, the child is pale and weakly looking. His complexion is very white round the mouth and eyes, and at the lies of the nose, but often there is a flush on the cheeks, which at times have a literal su blenly to disappear, leaving the face ghastly pale from the limitest. Often especially when the disease is advanced, there is a peculic allow half jaundiced tint of the skin. This has been attributed to have manning the altered blood being unable to destroy the bile pigment

absorbed into it from the intestine. The belly is usually swollen from flatulent accumulation, as well as from enlargement of the liver and spleen. No tenderness is noticed on pressure of the abdomen, but if the bone medulla is diseased, pains in the limbs may be complained of in walking. There is no loss of elasticity of the skin. The tongue is furred and the bowels are often capricious. Sometimes the stools are loose and slimy; at other times there is constipation. The child may cough, and his breathing may be short; but unless a complication be present, examination of the chest discovers merely a little large-bubbling rhonchus at the bases of the lungs. The pulse is quickened, especially at night. It is usually over 100, sometimes considerably so. In one of my cases—a little bey aged two years and a quarter—the urine was high-coloured and offensive, and contained bile, but no albumen. There was some difficulty in holding it at night,

The temperature rises in the evening to between 102° and 103°, sinking to 99° in the morning. The fever, however, is very irregular, and on some days is much higher than it is on others. The skin may be most at night, and sometimes there is copious perspiration. An examination of the blood discovers a great excess in the number of the white corpuscles.

As the disease goes on the child remains very fretful and pining. He sleeps bully at night and continues to lose flesh. His expression is very distressed, and his face is white and haggard. He is thirsty, but cares little for food. Often ha-morrhages come on, and these effusions form a very characteristic symptom. The nose may bleed, or blood may be discharged by the mouth or by stool. Although usually a late symptom, ha-morrhage is not always delayed until near the close of the illness. Epistaxis is sometimes noticed quite early in the disease.

Enlargement of lymphatic glands may occur, but this is rarely considerable in a case of pure splenic leucocythemia, and pressure signs from this cause are rarely noticed. Towards the end of the disease ordems and dropsical effusions are common. There may be ascites or hydrothorax or tedema of the lung, and the lower limbs may swell and pit on pressure.

The fever usually perseveres to the end, and the child grows thinner and weaker. Various complications occur before the close, especially croupous pneumonia and pleumsy. Death is often proceded by an attack of convulsions, due, probably, to obstruction of the cerebral capillaries by masses of leucocytes, as described by Bastian,

Diagnosis.—The symptoms of leucocythemia are sufficiently characteristic of the disease. Irregular pyrexia and general impairment of nutrition, combined with a distressed, pallid face, a sallow complexion, a swollen abdomen, an enlarged spleen and liver, and the occurrence of epistaxis or mekena, point very distinctly to leucocythemia; and the diagnosis is at once confirmed by a microscopical examination of the blood.

When seen for the first time, the case often presents some resemblance to enteric fever; and a harmorrhage occurring from the bowels might appear to confirm this view of the illness. But the history, which usually indicates disease of considerable standing, the complete absence of rosy spots, the enlargement of the liver as well as of the spleen, the peculiar sallow tint of the skin these symptoms are very unlike typhoid fever; and if at a late stage ædema of the lower limbs occurs, the presence of a symptom so uncommon in enteric fever should make us at least doubt the correctness of this diagnosis. An examination of the blood showing a large excess of leucocytes is of course conclusive.

Leacocythemia may be diagnosed with certainty if, with an enlarged plan, the proportion of colourless corpuscles is greater than one to twenty. In a doubtful case, therefore, it is well to count the corpuscles with the brancytometer. If the proportion of leucocytes is less than one to twenty, the use may still be one of leucocythemia in process of development; and as Dr Gowers has pointed out, to exclude this disease it will be necessary what repeated examination of the blood, and satisfy ourselves that the proportion is not increasing.

la cases where the lymphatic glands undergo hyperplasia, the disease a bringuished from lymphatic ombiguation of the lymphatic embracement is only moderate, and occurs as a late complication. Also that the cross of white corpuscles in the blood is very pronounced. In lymphatic on this increase is either absent or is comparatively insignificant translate cases are, however, occasionally met with, and may be a source

of perrilexity.

Proposis.—The disease invariably terminates fatally; and the more assist the number of the white corpuscles in the blood approaches to an equity with that of the red, the greater the prospect of an early terminates to the illness. Humorrhage, unless it be from the nose, is a very

on e wimptom.

"restained. - No treatment has yet been discovered which is capable of arresting the progress of the disease. Arsenic, which is of great value in are of happhalenous, has no influence in leucocythemia, and quinine, and and tomes generally have proved to be quite useless. Cod-liver oil however, be given, and is said to be sometimes of temporary benefit. la a curv stage of the illness faradisation of the splenic region for fifteen we twice a day is said to diminish the proportion of white corpusin the blood In a case reported by Moster this application, comhave with the internal administration of piperine, oil of encalyptus, and in law a orate of quinine, reduced the size of the liver and spleen and with improved the condition of the blood. Dr. G. V. Poore finds the as of the sphen to be dimmished temporarily after fundisation, but "its that the therapeutic benefit derived from the application is very transmit. Many times a spleen which was felt to be smaller and softer manalistely after gulvanism was found after only a few hours to have reserved its former size and again become tense and hard. Dr. Poore state that the lemonytes in the blood are increased in number directly after the application. Injection of various substances into the spleen has boon attempted, but the results have not been encouraging. A case is repoted in which a grain and a half of salicylic acid was injected into the organ and the patient died six hours afterwards.

Excusor of the spleen has been tried, but has invariably led to such clause of blood that the death of the patient has very quickly followed. We can do is to treat distressing symptoms as they arise, and to supply the patient with such nutritious food as his stomach can digest. Quiet try important when the anomin is great. Looseness of the bowels must be treated with small doses of rhubarb and the around clark powder or with dilute authoric acid; addena with digitalis and diurcties; he manage with the ordinary styptics. If the pain is complained of over the splear, it is best relieved by counter-irritation and anodyne applications, when a supplication is a smearing the surface with equal parts of the extract of belladouna.

and glycerine, covering the side afterwards with cotton-wool.

CHAPTER II.

LYMPHADENOMA.

Lymphadexoma (adacaia, lymphatic anaemia, Hodgkin's disease) is one of the less common diseases of early life, but it occurs sufficiently often to render the affection a not unfamiliar one in Children's Hospitals. Lymphadenoma consists in a hyperplasia of lymphatic tissue in various parts of the body, even in situations where such structures do not normally exist in any great quantity. The lymphatic glands are chiefly involved, but the spleen, liver, and kilneys may be greatly enlarged and altered in structure. If the enlargement be limited to a few glands or organs, the disorder may have the characters of a local complaint. Usually, however, the affection spreads very extensively and exhibits all the phenomena of a general disease, being attended with fever, wasting, great and increasing pallor, and marked weakness. In the end it is almost invariably fatal.

Causation.—The causes of lymphadenoma are obscure. Disthetic tendences have been supposed to give rise to the disease, and there is no doubt that in some cases pulmonary consumption or syphilis has been noted in the parents. In other cases, however, the family history has been good. Acute disease in the child himself has sometimes appeared to be the starting-point for a slow deterioration of health which has eventually developed into undoubted lymphadenoma. So also the occurrence of the illness has been attributed to bad or insufficient food or insaniusly conditions generally. In some cases, however, no sufficient cause has been discovered to account for the failure of health. The disease, like tuberculosis, with which it presents certain affinities, may develop without apparent reason in a child whose health had previously given no cause for anxiety.

In not a few cases some local derangement or injury has appeared to be the exciting cause of the enlargement of the lymphatic glaids. Thus a decayed tooth, a patch of eczenia, an otorrhoea—all these have been known to be quickly followed by a swelling of the glands in the neighbourhood of the irritant. In scrofulous subjects a persistent caseous enlargement of glands from this cause is not uncommon. In lymphadenoma, however, the morbid changes do not remain limited to the neighbourhood of the irritant. Others more distant from the seat of irritation take on the same unhealthy action, and thus the disease spreads widely so as to

involve adenoid tassue in all parts of the body.

The age of the children affected is usually four or five years and upwards. I have, however, seen a well-marked case in an infant eight mouths old, who had begun to suffer at the age of three and a half months.

Morbid Anatomy.—After death in a case of lymphadenoma we usually find great enlargement of the lymphatic glands, and often of the spleen, the liver, and the kidneys. In addition there is commonly overgrowth of

the more minute collections of adenoid tissue in various parts of the body, as in the tonsils, the pharynx, the gullet, the stomach and intestines, etc. Of these the more considerable enlargements are often limited to a compartisely few organs and structures, but microscopical examination discuss very wide-spread changes in parts which present little or no apparent adention to the unassisted sight.

The lymphatic glands are greatly enlarged, and the enlargement may be in two forms—a hard and a soft swelling. This difference appears to depend less upon the nature of the growth than upon the rapidity of its progress, for the two varieties may be found combined in the same

sit tota

The size of the swollen glands commonly varies from a hazel-nut to a ber's e.g., but in exceptional cases the growth may reach still more considerable dimensions. The first glands to be affected are usually those in the neck. Then follow in order of frequency the axiliary, inguinal, retropert neal, bronchial, mediastinal, and mesenteric. But besides enlargement of glands, circumscribed growths may be developed in spots where, the migh adenoid tissue exists normally in small quantity, it is not collected into glandular masses. By this means the various groups of enlarged gazis may be found connected together by chains of newly developed

hapiutie nodules.

When a group of glands takes on the morbid process, the individual boles at first remain distinct and are movable. As the disease progresses the cease to be movable, and eventually become welded together into a stil mass. The process of union consists in a disappearance of the capwhich becomes pierced and ultimately almost destroyed as the new traplatic tissue accumulates. On examining such a mass the outline of desired glands can be recognized here and there by a thin fibrous capsule, but the confluence is for the most part complete, and no intervening infltrum can be discovered. On the surface the mass is often very irregular as a no-lulated, and may be mottled with white or yellow patches, but result in is seldom seen. If the mass be superficial it may be adherent to the skin. In rare cases it suppurates. The greater or less hardness of the salarged gland is determined, as has been already said, by its rapidity of development. If it grows very quickly the gland is soft. On section of so ha gland the substance appears often to be almost diffluent. If firmer, " yelds a creamy juice when scraped. If very firm the hardness is found to be due to hyperplasia of the fibrous stroma, dense bands of fibrous tisse running in various directions through the mass.

Under the microscope the morbid change in the glands is seen to consist in an enormous increase in the lymph corpuscles. These accumulate, and by their pressure may perforate the capsule and even split up the septra and cause them to disappear. In the softer growths the diseased process is chiefly of this kind. In the firmer glands there is an increase in the fibrons strong, which becomes greatly thickened. The hypertrophy may even obliterate the meshes of the reticulum and convert the organ

into a mass of fibrous tissue.

The spices commonly suffers, especially if the disease begins in the himpirate glands of the neck. The organ becomes greatly enlarged. Its armed lymphatic tissue takes on a rapid growth, and shows the same tendency to tibrosis that is noticed in the glands. Externally the organ is of a dull redbish colour with paler patches, and yellow spots from the size of a mustard-seed upwards are often seen scattered over the surface. To the touch it is usually dense and firm. On section whitish or yellow nod-

ules are discovered on a dark-red ground. The nodules are more or less closely aggregated so as to form masses of varying size and shape. The new material appears to originate in the Malpighian follicles and the perarterial sheaths of lymphoid tissue. It is composed of lymphoid cells and large quantities of imperfect fibrous tissue. The fibrous stroms is often thickened, and may show bands of fibrous tissue without definite arrangement, or running loosely parallel so as to form oval loculi by their divergencies. In a late stage the bands are sometimes pagmented at their edges. Under the microscope these bands appear to be formed by rapid induration of a lymphatic tissue growing around the vessels.

In the liver the new growth usually appears in the form of small, irregular, infiltrating masses which may project as irregular prominent patches on the surface. The structure of these growths is similar to that of the new material in other parts, but in this organ there appears to be a greater tendency to caseation. The lymphatic new growth occupies the interlobular spaces. In a case reported by Dr. Greenfield it seemed to start in the portal canals as small masses which extended around and into the lobules.

the liver-cells becoming degenerated and shrivelled.

When the kulneys are affected the organs are enlarged and often irregular in shape. Their colour is light yellow or even dull white, and ecchymoses may be scattered over the surface. Sometimes signs of more profuse hemorrhage are found, and large purple blotches are seen through the capsule on the pale surface of the gland. On section the cortical substance is more or less swelled, and is of a yellowish-white colour mottled with points and patches of red. By the microscope an excess of adenoid tissue is seen between the tubules, sometimes separating them widely. The growth is collected in large quantities around the glomeruli, and in some cases the new tissue appears to pass along the vessels into the interior of the Malpighian capsule. In both liver and kidneys it is common to find blood-vessels blocked by masses of colourless corpuseles.

The new growths developed in places where adenoid tissue exists normally in minute quantity are usually rather soft and elastic. They are of a pinkish colour and very vascular. Such local developments of lymphatic tissue may be seen in the tonsuls, at the back of the pharynx, and in the gullet, stomach, and intestines, originating in the follicular glands. All these often undergo ulceration. Growths have also been found in the testicles, peritoneum, omentum, pleura, and in the lungs. In the latter situation

they often break down and form cavities.

When the blood is examined microscopically the red corpuscles are seen to be very pale in colour, but they usually form rouleaux in the ordinary manner. Amongst them are corpuscles of much smaller diameter. The red corpuscles are considerably reduced in quantity, but there is seldom any material addition to the number of white corpuscles: indeed, in many cases, like the red cells they are diminished in number. Sometimes, however, the leucocytes may appear to be slightly more numerous than in the healthy subject; but even if the spleen be greatly enlarged, no increase sufficient to constitute leucemia is observed in cases of true lymphadenoma, and the white cells never present the altered characters which are noticed in the former disease. As a rule, a greater excess of white corpuscles is seen in cases where the lymphatic growth is of the soft variety than where it is hard and chiefly fibrous. Forms of mixed disease are also sometimes met with in which there is increase in quantity of the splenio pulp. The affection has then some of the characters of leucocythemia.

Symptoms.—The symptoms of lymphadenoma may be divided into

or proper to the illness, which may be called the regular symptoms, if these which are irregular and accidental, being the consequence of the many set up by the growths upon the parts around.

The regular symptoms consist of the general constitutional disturbance and by the disease, the changes in the state of the blood, and the pres-

per of enlarged lymphatic glands.

The general constitutional symptoms may precede or follow signs of augment of glands. They consist of a febrile movement more or less light with gradually increasing wasting, pallor, and loss of strength.

A little boy, aged three years, was under the care of my former colbow, Dr Mitchell Bruce, in the East London Children's Hospital. The this bad been ill and languid for three months before admission, gradualls wasting and suffering from occasional attacks of diarrhosa. When longist to the hospital he was weakly, with a pale complexion and haggod, anyons look. His face often flushed up suddenly; his skin generas was harsh and dry. At first no special disease of organs could be discovered. The spleen could be felt projecting about half an inch below the nin the liver was normal in size, and no enlargement of the lympinte glands was noticed. The boy coughed occasionally, but the physcu sens about his chest were normal. His temperature on the first cruzz was 1014, and continued to stand at much the same level for were time. It sometimes sank to 99° and at other times rose suddenly for a few hours to 104, but it usually varied between 100 and 101. The be continued in much the same state, being usually apathetic and dull, and aga he brightened up a little at times and would play listlessly with Interior The course of the illness was very variable, and the child seemed worse at some times than at others. Once or twice he seemed denadly better and regained a few ounces of his weight, then he relapsed and waste I, rapidly losing a pound and a half in a week. Often he was drows, and his appetite was always poor.

Astune went on the liver and spleen became moderately swollen, signs of energement of the bronchial glands were noticed, and deep pressure in the abdomen discovered some enlargement of the mesenteric

Elateda.

The bowels remained more or less loose. The boy grew slowly weaker, the heal after a resulence of four months and a half in the hospital.

The was never any ordenia of the limbs, and the glands in the neck were not affected.

On examination of the body after death, large yellow, cheesy-looking were found adherent to the under surface of the breast-bone, and the atterior mediastinum was filled with a large mass of agglutinated plants. A similar mass was found in the abdomen in front of the spine of the disphragm and surrounding the head of the pancreas. The large was large, soft, and flabby to the touch. Its section showed a half beginner appearance, and on close inspection this was found to be due to a multitude of closely set little masses, the size of a pin's head or less, and its section showed the appearance usually noticed in this disease of a line has been already described. Both lungs were found on section be pervaled with small masses of new adenoid growth.

In this case the general symptoms preceded the signs of local mischief.

Sen, conveyer especially if the illness begins, as it commonly does, with
furgement of the corrieal glands the affection has at first the characters
a local disease. But sooner or later, as the lymphatic tissue becomes

more and more involved, the patient begins to suffer from irregular few

and grows very decidedly ansemic.

The glandular swellings in the neck usually form an irregular nodust mass which may extend from one side to the other, passing underment the chin, or may be limited principally to one side. At first the listicial glands can be made out, and the masses are movable. Afterwards the glands become more welded together and the masses are fixed. The swellings are painless, and unless of very rapid growth are dense and firm to the takk. In some cases a mass of enlarged glands will become very soft and suggestate, forming an abscess which discharges and heals up in the ordinar manner. Besides the neck, enlarged glands may be felt in the axilla ad groins. In the armpite the size of the growths may interfere with the movements of the arms. Examination of the chest and belly often iscovers a similar change in the glands lying in the anterior mediastican and abdomen. The enlargement of the liver and spleen is usually noterate, although sometimes—especially in the case of the latter organ is

may be very considerable.

While the disease is limited to swelling of a few glands in the next the child, although pale, may be active and cheerful, apparently suffering in no way except from the local inconvenience. When, however, the glands grow rapidly, or the disease spreads from the neck to other pars of the body, constitutional symptoms begin to be noticed. Fever is almost invariably present, although in the earlier stage it is slight and internative. In the cachectic stage the temperature often rises to a high level and for a few days together may range between 103° and 105°, sometimes ena passing the higher limit. Sweating is not common; indeed, in most cross the skin is excessively harsh and dry. The digestive organs almost have rubby suffer. The tongue is covered with a white fur, and the papille are prominent and red. Ulcerative stomatitis may be present on the inter side of the cheek. The appetite is poor and indigestion and vomiting tast be complained of. The bowels are sometimes costive, but often the are loose, and the dejections may be preceded by griping pains in the belly. The looseness is due in many cases to small ulcerations of the deam There is then usually abdominal swelling, increased tension of the pine ties, and tenderness on pressure. More or less cough is a common system tom, and an examination of the chest often discovers signs of cousehlstion and softening. These lesions commonly result from growths in the lung which soften and break down into cavities.

Great spathy and dulness of mind are in many cases associated with the cachectic stage of the disease. The child may be found to sleep alm of constantly, his senses seem dulted, and his wants are so little pressay that he asks for nothing and makes no complaint. Indeed, sometimes its most difficult to get him to speak at all. The urinary function is now interfered with, but sometimes blood is passed with the urine. In a case reported by Dr. Goodhart—a little girl aged ten months—the child a water

towards the end of the disease became red with blood.

The amemia is usually extreme. The whole surface of the body is accessively pale, and the nucous membranes are singularly bloodless. Purpure spots may be found on the body, face, and limbs, and semetires larger dark purplish blotches are seen from more extended extravastical Flushing of the face is a common symptom, and a redness of the checks at this time forms a curious contrast with the dead whiteness persisting round the mouth and eyes. A nucroscopic examination of the blood shows the diminution in the number of the red corpuscles which has been alresty

referred to. The white corpuscles are rarely in notable excess. As a consequence of the anomia cedema may occur in the limbs, and there may be sented. Pressure of the enlarged glands upon the venous trunks may also

ad in the production of serous effusion.

A good example of the more common form of the disease, where the general constitutional disturbance occurs subsequently to the primary quotalar enlargement, was seen in the case of a little boy, aged thirteen rus who was under the care of my colleague, Dr. Donkin, in the Eost Labor Children's Hospital. The boy came of a healthy family and had be self been strong and healthy untal the age of eight years, when he was lade professional for three months in consequence of a fall on his head and spine, in this illuess the lad could not rest on his back or side, but was obliged to be as his face. Although he began to walk again in two months' time, and was convalescent at the end of the third month, he never recovered his storyth completely. Twelve months after his illness he was again laid up with pairs in the chest and swelling of the face and arms. The swelling on subsided, but the boy remained weak and complaining and was often under me lical treatment.

On a limison the patient complained of lumps in his neck which he stated were of three years' duration. For three months he had been losing field and his belty had been growing larger. His skin, he said, had been lay for some time. His legs had never swelled, but he had noticed a swelling of his screetum for three or four days. He was subject to cramp-like puns about the umbilious which were often severe, and the belty at these takes was tender. He had had a cough for a month without expectoration,

and his howels had been relaxed for a week.

On examination the boy was found to be very thin, and his skin was dry, rough, and furfuraceous, especially about the belly. The cervical and submazillary glands were enlarged on both sides so as to form a collar round the neck. The avillary and inguinal glands were normal. No enlargement of the liver or spleen was noticed. The abdomen was distended, with fulness of the superficial veins. There was some tenderness on pressure below the umbilities, and the tension of the parieties was increased. No growth could be felt in the belly, and there was at first no series. There was some adema of the scrotum, but none of the arms or legs. The tongue was red and rather raw-looking, and some superficial alceration was noticed at the angles of the mouth and inside the left chick. The basels were relaxed, the stools being loose and lightish veltow in colour. There were signs of consolidation of the right lung. The urine was pide, slightly alkaline, but contained no albumen. An examination of the blood showed the absence of any excess of white corpuscles.

After admission the boy remained in a very apathetic state, and whether up or in bed seemed to be always drowsy. He would be found asleep with his head on his arms or curled up on a sofa. His face was habitually serv pale, but at times it would flush up irregularly. He coughed occasionally, and expectorated tenacious mucus. His temperature was always high, rising at hight to 103° or 104°. He continued to waste and grow weaker. Death was hastened by a severe attack of vomiting which pro-

duced great prostration, and he died soon afterwards.

After death the cervical, broachial, retro-peritoneal, and mesenteric glands were found to be enormously cularged, forming agglemerated masses in which, however, individual glands could still be made out. The colorged glands were very tough. On section, the larger number were of yellowish that and seemed fibrous, but a few were grayish and translucent.

de course is usually very slow at the first,

with may be years before the general glandular system becomes affected, when, however, the cachectic stage begins, the course is more acute. Sai, the progress of the malady is always variable, and growth is more rapid at some times than at others. In the child the general disease rapy lasts longer than any or eight months. Death may result from asthematic from some complication, as pneumonia, pleurisy, vomiting, or districts. It may be preceded by convulsions. Sometimes the end is haster, by the injurious effects of mechanical pressure upon the air-passages.

the radet, or the large veins of the abdomen.

because.—In the diagnosis of a case of lymphadenoma we have to card for evidence of general affection of the glandular system. So the disease remains limited to a few glands of the neck the nature of the swelling is not always easy to ascertain; but even at this time it may be sometimes distinguished by the elasticity of the growth, for, accessed to Birch-Hirschfeld, even in the harder variety of lymphadenoma were a certain elasticity as compared with the dense, boardlike harders of the cheesy gland. Moreover, there is no inflammation set up the mass, and caseous degeneration and softening are very rare. It agroup of scrofulous glands some usually soften early and form an absence in such a case, too, the general signs of scrofula may be noticed.

Second to us glands present a greater likeness to lymphadenoma; but set extension takes place in the former disease the tissues involved are the lymphatic tissues; indeed, the disease tends to spread

ration to organis than to glands.

be the eachectic stage lymphadenoma is usually easy of recognition. The regular fever, the extreme pallor, the great drownness and unwill-specific to speak, the general implication of lymphatic glands in all parts of the body, the character of the blood, which shows dimmution in the Latitus of red corpuscles with no or only slight increase in the proportion

of secretor. These symptoms are sufficiently characteristic.

Propose. -Although some cases of recovery from this disease have recorded, the illness is so generally fatal that little hope of a favourable can be entertained. In the cachectic stage speedy death may be attriputed. In the earlier period a prolonged course may be hoped at especially if the enlargement is slow; but it is unwise to speak too in tably even of this prospect, for the disease may at any time suddenly and uncommon. Examination of the blood may be of some service in the probabilities of a lengthened course. If the number of red to be a greatly reduced, the child's prospects are very unfavourable.

To some it. In every case the child should be put into as good sanitary takens as possible, and every effort should be made to improve the testal health. Cod-liver oil, iron, quinine, and tonics generally are useful a this respect, but none of these remedies have the power of delaying materially the progress of the disease after the affection of the lymphatic blude has become general. Arsenic, however, is highly spoken of for its discrete in this stage of the disease. The dose should be a large one; the trust be remembered that most children have a special tolerance for the irug, bring often able to take it in larger quantities than can be with borne by the adult. For a child of eight years old ten drops of forms solution may be given three times a day, freely diluted, directly that, and every few days the dose can be increased by two drops. The effect of the medicine is to increase the softness and mobility of the stable. Soon pain begins to be complained of in the swellings, and this

is quickly followed by an arrest in their growth, or even an appreciable diminution in their size. Iron may be given with the arsenic if thought desirable, and the combination is preferred by some. Phosphorus has been also recommended as useful in promoting reduction in size of the glands; but this drug appears to be decidedly inferior to arsenic. Indide of potassium has been found quite useless as an absorbent in this disease.

If the patient come under observation when the glandular swelling is limited to the neck, and the general system appears to be unaffected, we may begin the treatment with greater hopes of success. Early extirpation of the growths is often advocated, and the operation is said to have been followed in some cases by complete recovery. Even if this happy result he not attained, we may expect that in a suitable case the progress of the disease will be sensibly checked by the operation. We can, however, only anticipate good results when the glandular enlargement is limited strictly to one group of glands, the spleen is unaffected, and the proportion of red corpuscles in the blood is not greatly reduced. Dr. Gowers recommends that in every case the actual proportion of red corpuscles be estimated by the hamacytometer, and states that if the proportion of coloured cells be less than sixty per cent of the normal average, the idea of operating should be abandoned. On the other hand, a slight increase in the quantity of white corpuscles is not to be considered prejudicial to the success of the operation. After removal of the swollen glands the child should be sent to a bracing seaside air, and arsenic with quinine or iron should be given in full doses.

According to some writers, friction of the growing glands with the hand alone or with some simple salve has been found useful, and compression and blastering have been also recommended. Injections into the glands of various substances, such as iodine, carbolic acid, etc., is not a safe method of treatment. In one case in which I injected truct, iodi into a large lymphomatous swelling the operation was followed in a few days

by a rapid and permanent increase in the size of the tumour.

CHAPTER III.

ANJEMIA.

Decreasors in the quality of the blood, combined often with deficiency in its quantity, is a common result in infancy and childhood of any condition which causes a temporary failure in the nutritive processes. In the child america is commonly symptomatic of some discoverable ill; for the obscurer form, called ichopathic or pernicious aniemia in the adult, is but

rapdy met with in early life.

The reason of the exceptional frequency of impoverishment of the blood in childhood is not difficult of explanation. From the researches of Dems, Poggale, Wiskemann, and others, it appears that in infancy although the quantity of blood is greater than it is in maturer life, in proportion to the entire weight of the body, this blood is of lower specific gravity, and contains more white corpuscles, but less fibring and soluble albumen, smaller proportion of salts, and a considerably smaller quantity of hamoglobin,' With this comparatively dilute blood the growing child has to undertake a larger work than is required from the adult. He has to supply material for growth and development instead of merely maintaining the necessary nutrition of tissues and organs already matured. The heart and lungs are forced to greater efforts to answer the demands made upon them: the first to drive a sufficient quantity of blood along the relatively wher arterial channels; the second to aerate the larger proportion of blood carned to them by the more capacious pulmonary artery. The lungs elimiaute carbonic acid in far higher proportion than is the case in older per-The amount of area, too, excreted by the kidneys is relatively much greater than it is in the adult. The work required from the different seottory and excretory organs whose united labours go to build up the growing frame may be judged from the fact that within twelve months of is both the body has mercased to three times its original weight. As Dr. landy has observed, the "organs are in constant exertion, or rather overelection, and all this at the expense of a blood which contains less solid constituents than the blood of the old. Thus the natural oligamia of the that is in constant danger of increasing from normal physiological pro-The slightest mishap reduces the equilibrium between the capital at the labour to be performed, and the chances for the diminution in the amount of blood in possession of the child are very frequent indeed.

Although the blood of the child is thus relatively poor as compared with that of the adult, a constant inflow of nutrient material enables if to preserve a healthy standard and carry on its functions with success. The

^{&#}x27;Homoglobin is the chief constituent of the red corpusales. In the newly born infact to an most is relatively larger than it is in the adult, reaching the high ration of the whole solid constituents (at adult are it is only 1190 per cost). The lash percentage rap, thy diminishes until it reaches the lowest point at the ago of at months. It then slowly rises again.

amount of food consumed by the growing child is far greater proportionately than that required by the fully developed man. According to be Edward Smith, the infant as compared with the adult consumes the times as much carbon and six times as much nitrogen for every possible his weight. If now, from any cause, either from deficiency in the say of food, or demagement of the machinery by which food is elaborated as prepared for its purpose of nourishing and renewing the tissues the results, the standard of the blood at once sinks below the average of health and a state of amenia or oligemia (poorness of blood) is induced

The constituents of the blood which are of the greatest importance nutrition are the albuminoid compounds of the plasma and the red biod corpuscles. The albuminoid compounds constitute the material continued which the tissues are nourished; the homoglobin of the red copied carries the oxygen, without which the chemical changes necessary factorition are impossible. In animia the blood is impoverished in its alternation are impossible. In animia the blood is impoverished in its alternation are impossible. In animia the blood is impoverished in its alternation are impossible in the homoglobin. Therefore, as the amount of iron is in direct proportion to the amount of harmeglobic a diminution in the latter means a deficiency in the former; and as the challenge of the homoglobin is that of conveying oxygen to the tissue, to blood in animalia is no longer able efficiently to perform its respirators almutritive functions.

Consistion.—In early life any cause which interferes with the orbit renewal of the normal constituents of the blood leads to an emma. In the infant—a being who is dependent for health upon a full daily supple of food—not only serious disease but even the most simple neute decarement will leave the blood in a state of temporary oligamm. This is usually rapidly recovered from, for in the healthy child convolvence is about, and the mutritive functions quickly resume their course when the obstacle to their proper exercise has disappeared. By animal, however is usually meant a more prolonged poorness of the blood—a condition which the symptoms of general debility are allied with others indicated an imperfect performance of the bodily functions.

The causes of such a condition may be divided into two classes according as to whether they interfere with the continued renovation of the blod or abnormally increase its consumption.

In the first class are included all the various conditions which hades the introduction and claboration of nutritive material. Thus, actual disciency of food, such as arises from extreme poverty or wilful neglect of unscotable diet, the stomach being loaded with food which, from its nature or form, is beyond the child's power of digestion; functional decomposate of the gastro-intestinal canal, owing to which an otherwise suitable feet is rendered temporarily inappropriate—these causes may prevail at apperiods of childhood, but are especially frequent during the pariet infinity; and the aniemia and wasting which are so common in handful babies can usually be referred to the action of these agencies. To they must be added the influence of imperfect ventilation. Oxygen is as essential to healthy tissue change as are the elements of food themselves, and its absence the chemical changes necessary for the renewal and development of the tissues are impossible. Consequently infants confined to

The above causes are also powerful to impede nutrition and promote the impoverishment of the blood after the period of infancy has gone to The influence of digestive derangements, combined or not with want of

close, ill-ventilated rooms are pale and flabby, however carefully ther

dietary may be adjusted.

fresh air and exercise, is one of the commonest causes of anamia in later childhood. The causes which induce impoverishment of the blood are no doubt often complex; but of such as act alone imperfect digestion from extarrh of the stomach is perhaps to be blamed more often than any other injurious condition. These attacks tend to be repeated, and, as is elsewhere explained, recurring gastric catarrh may induce a degree of pallor and wisting which excites the greatest alarm in the minds of the parents, and often requires very careful treatment for its prevention and cure (see Gastric Catarch).

Again, the diathetic diseases—tuberculosis, scrofula, and syphilis—often induce a degree of anemia, even before any local manifestations of the constitutional disposition are discoverable. In syphilis, also, the disease after apparent recovery, is apt to leave behind it a state of profound animum, which in many cases is to be attributed, not to the malady, but to the medication to which the patient has been subjected: for a prolonged course of increary is an unfuling cause of impoverishment of the blood. In rickets, the beginning of the disease is announced, and its progress accompanied, by a marked degree of anamia, which indicates the unfitness of the blood in such a case to fulfil all the requirements of healthy nutrition. Of other special general diseases which may lead to diminution in the amount of hemoglobin and so set up animic may be mentioned rheumatism, scurvy, and the cachectic condition induced by malaria.

Disease of special organs concerned in sanginfication - the spleen, the lymphatic system, etc.—is, of course, followed by great alteration in the quality of the blood. In extensive amyloid degeneration of these organs, the marked pallor of the patient is one of the most striking symptoms of the disease, and in lymphadenoma the patient is peculiarly pale and

blocalless.

The causes which increase the consumption of the blood are: Profuse homorrhages as in melena neonatorum, homophilia and homorrhagic purpora, severe duarthea; chronic purulent discharges, as in cases of chronic empyema with a tistulous opening in the chest-wall; cirrhosis of lung with distation of bronchi; albuminuria; onanism; etc. In this class, two, must be included rapid growth, which is a very frequent source of languor and amenia. It must be remembered, however, that at the age when growth is apt to be most rapid the child is often exposed to other ratherness which may also tend to set up impovershment of the blood, such as confinement to close rooms and want of exercise.

bliopathic amenia (which is sometimes seen in young people) may result from bad and insufficient food or other depressing cause acting upon the general system, sometimes it is the consequence of mental shock, as in the case of a boy who was under the care of Sir William Gull, in Guy's Hospital. The lad began to suffer shortly after being attacked by a num-

ber of sheep in a field,

Morbil Instancy.—In amenia the blood may be merely deficient in amount (oligenta), but it is usually found that there is also a deficiency in the brenegic bin caglobulosis). It is not often that actual diminution in the number of the rel corpuscles occurs in ordinary symptomatic anemia unless, indeed, the impoverishment result from severe harmorrhage; but these bodies are said to be considerably reduced in size, and in certain forms of anemia it is common to find many corpuscles with a diameter greatly below the average. The blood is paler than natural, for in consequence of the decrease in the harmoglobin it is deficient in iron. Its specific gravity is also lower, and it congulates slowly into a loose clot.

As a result of the imperfect nutrition of the tissues which is the essequence of the deteriorated quality of the circulating fluid, a degree of fatty degeneration may be found in the heart, the liver, the kelmon and even in the walls of the blood-vessels; also in the voluntary muscles, and

the glands of the stomach and intestines.

In idiopathic amenia fatty degeneration of organs is also common observed. There are, moreover, eachymoses of scrous membranes, there time, etc. The blood is not only diminished in quantity, but the reblood corpuseles are also greatly reduced in number, being, according a M. Lépine, one-fourth, one-sixth, or even one-tenth of their normal poportions. The white corpuseles are not more numerous than nature, at least they are not increased to anything like the degree observed in lasking in. In some cases of pernicious amenia minute red corpuseles has been noticed measuring only one-fourth of their natural size, and warring the characteristic bi-conate shape. These bodies, however, appear not to

be present in every case.

Synaptoms. Poorness of the blood implies an imperfect state of the general nutrition. This is especially the case in young a bjects when blood, as has been already explained, can only carry on its functions efficiently on the condition that it is continually reinforced by a regular miss of properly elaborated nutritive nuterial. Consequently, in midition to general pallor, the muscles of such subjects are small and flatby, then strength is reduced, and their spirits may perhaps be depressed. Learn and indisposition to exercise are not, however, constant symptoms of america in childhood. Boys suffer in this respect much less than grant and when free from actual pain or discomfort such patients are the lively, and join with as much alacrity in boisterous games as if they were perfectly well. Indeed, this cheerfulness and activity may in some cases be an important and to diagnosis (see Tuberculosis).

The tint of the skin may be a clear, transparent whiteness. Often however, it is dull and pasty; or may have a faint greenish cast smaler to the hue of chlorosis, and the lower eyelid may be had and purplish. To mucous membranes are also pallid. Coldness of the extremities is a familiar feature of this condition. In anomic little girls we are extented that the feet and legs are never warm, and the hands feel cold and along to the touch. Slight cedema is often met with. It may affect the lower cyclid, but less commonly than in the adult. Usually it is noticed in the feet and ankles, and if the anomia be great, may involve also the hads

and arms. In rare cases there may be moderate ascites.

Breathlessness and palpitation on slight exertion sufficiently pronounced to cause distress are not common symptoms of anæmia in the child, but they are sometimes present. The appetite is often poor, discomfort and be complained of after food, and the bowels are usually contined. As the conclution of the blood is in many cases a consequence of gastric derangement, all the symptoms which are elsewhere enumerated under the bearing of gastric cutarrh are often to be noticed. Flatulence, especially, is a common phenomenon, and faintness or actual syncope may occur from pressure upwards against the heart of a suddenly distended colon. The pressure upwards against the heart of a suddenly distended colon. The Pyrexia may, however, be present as a consequence of the cause to what the impoverishment of the blood is owing, or to some accidental complication, such as teething, catarrh, etc.

Children, the subjects of anamia, are usually very nervous and excitable, and on examination of the chest we often find the heart acting violently,

can notice a strong pulsation in the neck, and with the hand placed upon the pracerdial region can feel a well-marked systolic thrill. As the violence of the carchae action subsides the thrill ceases, and the carchae pulsations diminish or disappear. The sounds may then be heard to be ill-accentuated, or perhaps murmursh. Although anomic cardiac murmurs are said to be uncommon in young subjects, it is not rare in cases of pronounced anomic to detect a murmur which ceases to be heard as the patient improves. The murmur may be at the apex of the heart and issometimes at least—accompanied by displacement of the apex-beat upwards and to the left, as if from dilatation of the left ventricle. Basic murmurs are, however, the more common phenomens. At the base of the heart the least pressure upon the pulmonary artery from enlarged bronchial glands will give rise to a loud systolic murmur in that vessel. In many cases we can hear a venous hum in the jugular vein in the neck, sometimes, also, in the left innominate vein, behind the upper part of the sternum.

Electing from the nose and gums is not rare in ansemic children; and in hospital patients petechise are common in the skin as the result of fleabates. From this cause the bodies of poor children are often speckled all

over with little extravasations of blood.

Pain across the forchead, or sometimes at the back of the head, is often complained of. In infants more serious symptoms may be met with as a consequence of anemia of the brain. The child lies with a pale shrunken face, cyclois only partially closed, and fontanelle depressed. His extremities feel cold, and a thermometer in the rectum registers a temperature below the normal level. Soon the infant sinks into a state of semi-stupor, and unless aroused by energetic stimulation will probably die. Impover-islament of blood and prostration so profound are apt to be complicated by thrombosis of the cerebral sinuses or collapse of the lung.

The duration of a case of ordinary simple anzemia varies according to the measures which may be taken to remove the cause or causes which are imposing the supply of nutritive material to the blood. If the cause can be removed, and the child be afterwards fed with judgment and placed under good sanitary conditions, recovery usually follows very quickly.

In adoptine rangua all the preceding symptoms may be noted. In this form of the disease the anemia is more profound. The skin is of the colour of wory and the mucous membranes seem perfectly bloodless. Optic neuritis may occur with hemorrhage into the retina. Epistaxis is common, and vointing may be frequent and distressing. The child becomes excessively feeble, and has irregular attacks of pyrexia in which the temperature rises to 103° or 104. Towards the end of the disease, however, elevation of temperature ceases to be noticed; indeed, the hodily heat usually falls to a subnormal level. The blood has the characters already described.

Proposes. In every case of anemia it is important with regard to prognosis and treatment that we should exclude serious organic and distribute disease. The diagnosis of the many conditions which induce impoverishment of the blood is treated of under their several headings. It may be only stated generally that if the cause lie elsewhere than in some obvious derangement of the digestion, we should institute very searching inquiry into the family and special instory of the patient, particularly with regard to distribute tendencies, and should make careful examination of the various organs.

I hopathic incemia may be distinguished by the profound deterioration of the blood without increase in the white corpuscles; the absence of discoverable cause for the pallor and weakness; and the attacks of irregular

pyrexia. Leucocythemia is characterised by increase in the proportion of white corpuscles, and by enlargement of the spleen or lymphatic glands.

Prognosic.—In anamia the prognosis depends very much upon the primary disease, if any such can be discovered. If the poorness of blood be the sequel of some previous acute illness, or other cause which has ceased to prevail, the patient usually responds well to treatment and quickly recovers under ordinary restorative measures. In cases of idiopathic anamia, when the prostration is great, the patier extreme, and the

temperature high, the child's prospects are very unfavourable.

Treatment.-Ansemia must be treated according to the cause which has produced it. Impaired nutrition and a palled face form in themselves no necessary indication for the employment of chalvbeate remedies. The commonest cause of anomia in the child, as has already been stated, is gastro-intestinal derangement. In such a case iron has no power to improve the condition of the blood until the hindrance to digestion has been removed. In anamic infants the dictary must be reconstructed upon the principles recommended elsewhere (see Infantile Atrophy). In older children if, as often happens, the patient be suffering from repeated attacks of gastric catarrh more or less severe, the digestive disturbance must receive careful treatment, and measures must be adopted to lessen the child's susceptibility to changes of temperature and to protect his sensytive body from the cold (see Gastrie Catarrh). In all cases plenty of fresh air should be prescribed. The parents should be warned of the necessity of thorough ventilation of nurseries and sleeping-rooms, and the child must be sent out as much as possible into the open air. It is important, however, not to force the patient to take exercise when his feeble powers will not admit of his deriving benefit from muscular activity. If his weakness be great, the child should go out only in a carriage; and when in-doors care should be taken that his wenried muscles are allowed a sufficiency of needful rest. As he mends, however, he should be urged more and more to exert bimself, and in severe cases a desire for exercise is a valuable sign of improvement.

The child must take plenty of nitrogenous food, and if, as sometimes happens, the appetite is poor, with a special dislike to meat, his fancies must be consulted in every way possible. Often a child will eat a small bird, as a lark or a single, when he turns with disgust from beef and mutton. Pounded underdone meat spread upon bread and butter will often be taken, or the meat may be diffused through a meat jelly. Eggs, milk, and tish are all of service, and a moderate quantity of furnaceous food may be allowed; but the child must be prevented from taking starchy matters to the exclusion of more nutritious articles of diet. When the appetite is poor, it may be often improved by taking three times a day a drop or two drops of the dilute hydrocyanic acid (P. B.) with five grains of bicarbonate of soda in infusion of orange peel. The draught can be sweetened with spirits of chloroform, and should be taken an hour before

meals.

Iron is only to be resorted to as an addition to the more general measures for restoring nutrition and improving digestive power, and it must not be given until the disorder of the gastric functions has been attended to Iron acts far more energetically when it is combined with aperients. Often, indeed, until the bowels have been well relieved by appropriate purgation the remedy seems to be perfectly inert. Not seldom, after giving an iron mixture perseveringly for a length of time without any sign of improvement, I have noticed an immediate alteration for the better when

be chalvibrate has been exchanged for a morning and evening dose of the property sonna mixture of the British Pharmacopagia. The form in which beion is given is of little importance. The dose should always be as are some as the child can bear without discomfort; and if the digestion h is good or ler, the acid preparations are to be preferred as a rule to the dians with Still, if there be any remains of catarrh of the stomach, the wamo-citrate should be given with an alkali. Most children bear the a tide of mon well. For a child of six years old, five gruns of the dried all now be given in a teaspoonful of giveorine three times a day directly the last. This dose may seem rather a large one, but it is rare to find are sees of irritation produced by the medicine, and the tonic effect upon to sistem is usually rapid and decided. The perchloride is also a good for slor administration of the remedy. Twenty to thirty drops, well dibe, with water and sweetened with glycerine, may be taken after each These preparations are far more useful than the various iron syrups were recommonly preferred. I have seen many a case of amenia arisby han gustro catarrh prolonged by the use of these syrups, which report neglity and flatulence and encourage the excessive secretion of

In some children almost all forms of iron seem to act as direct irritants to be somach, inducing indigestion and previshness of temper and causage idefulness at night. In these cases the dialysed iron is the best term which the remedy can be administered. Pure chalybeate waters at the of service if the child can be induced to take them. Their value is to both, enhanced by the fresh country air and exercise by which the three to a chalybeate spring is usually accompanied.

Unler the use of from the red corpuscles increase in size and the properson of homoglobin is therefore largely augmented. The improvement is a counced by a healthier tent in the complexion, an improvement in the section, and, if the child had been previously listless and dull, by greater

bedon and sprightliness in his movements.

As an arrests vomiting. As a tonic the remedy should be given to a ill day years old in the dose of three or four minums of Fowler's soluble inserts after food. When the digestive organs at the arrests vomiting. As a tonic the remedy should be given to a ill day years old in the dose of three or four minums of Fowler's soluble breaty after food. When the digestion is greatly impaired by repeat attacks of pastric cutarrh the effect of this medication is often very taked. The arcenic may be usefully combined with a drop or two of the proof of max tomics. Another remedy from which good results have been been as phosphorus. This powerful drug may be safely given to a cliff of any years old in doses of also to a factor of a grain. I have, however, the research experience of its value.

proportion of water, is usually taken readily by the child, and is a

bely to other treatment.

Clienter packing is said to be useful in improving the condition of the item. Drs. M. P. Jacoby and V. White have reported a series of

cases in which anæmia was treated by the regular application of the cold pack followed by massage. The patient was enveloped in a cold wet sheet, this was covered by a drier sheet, and over all six blankets were laid and carefully tucked in. After the lapse of an hour the coverings were removed and the skin and muscles were vigorously shampooed. This plan of treatment was combined with rest and careful feeding, and was attended by very good results. It might be employed with advantage in the case of weakly, pallid children in whom anorexia is a marked feature, for one of its most pronounced effects was found to be an immediate improvement is the appetite. The induction of sleepiness by the pack and massage is usually an indication that the patient is benefiting by the treatment.

CHAPTER IV.

ENLARGEMENT OF THE SPLEEN.

Excasorment of the spleen is common in early life, and is found in the course of a variety of diseases. The symptom is alluded to incidentally in the descriptions of the various forms of illness in which the phenomenon occurs; but the subject is of sufficient importance in a chinical point of

view to deserve a special chapter for its consideration.

A splenic tumour may be of acute or chronic growth. Acute enlargement is seen in typhoid fever and ague, sometimes in acute tuberculosis, and, it is said, in cerebro-spinal fever; also the enlarged spleen found in cases of lencocythemia may be included in this class, for in early life leukhamia often runs an acute course. Rapid increase in size of the organ is also occasionally met with as a result of splenic embolism in the course of ulcera-

tive endocarditis.

Chronic enlargement of the spleen may be the consequence, and sometimes the only manifestation, of the cachectic condition induced by malarious poison. It occurs in some cases of amyloid degeneration, although a spleen so affected is not always increased in size. It is a common symptom of lymphadenoma, is not unfrequently a consequence of atrophic circlesis of the liver, and may be met with in cases of old-standing disease of the heart. Lestly, it may be due to a simple hyperplasia. Hypertrophy of the spleen may occur in rickets and syphilis, especially the latter; but is also found in cases where syphilis may be positively excluded, and in cases, too, where there is no reason to suspect any malarious origin of the swelling.

In the child a spleen is not necessarily diseased because its lower edge is within reach of the finger. The healthy organ is sometimes pushed down, so as to be felt. This displacement may occur in cases of copious effusion into the left pleura, and is common in rickets where there is much retrac-

tion of the riba

In determining the existence of enlargement of the spleen it is not sufficient merely to ascertain the position of the lower edge; for considerable swelling of the organ may be present although its inferior border does not project below the margin of the ribs. In the child the spleen often extends back wards and upwards as well as downwards, and may reach posteriorly to the spinal column. By percussion in such cases we can often detect duliness in the axilla reaching upwards as far as the fourth or fifth rib, and in the back extending as far upwards as the inferior angle of the scapala. In all cases where a splenic tumour is suspected the size of the organ should be estimated by percussion as well as palpation. When the lower part of the organ projects below the ribs into the abdomen it is easily felt by laying the hand that upon the belly and pressing gently with the finger tips. That the swelling thus discovered is due to increase in size of the spleen is indicated by the superficial position of the tumour, by the comparative thinness

of its inner border, and by the notch which can often be distinctly perceived

by the finger.

An enlarged spleen is usually firm and resisting to the touch, especially if the enlargement is a chronic process. In typhoid fever, however, the substance of the swollen organ is unusually soft, and on this account can sometimes be only felt by a practised linger. In acute forms of swelling the increase in size is accompanied by some tenderness on pressure. In chronic enlargements there may be also tenderness, but this is commonly due in such cases to the presence of local peritonitis.

In the present chapter it will be unnecessary to refer again to all the forms of splene tumour met with in the child. It will be sufficient to consider the chronic culargement which occurs as a consequence of a simple

hyperplasia of the organ.

Simple Hyperplasia of the spleen is a not uncommon condition in infancy and early childhood. Often the patient may bear traces of inherited syphilis or show some symptoms of rickets; but this is not always the case, and sometimes no sign of diathetic disease or constitutional weakness is anywhere to be detected. When the enlargement is thus present in a child of apparently healthy constitution its etiology is difficult to establish. In some of the cases which have come under my notice the enlargement has been preceded by gastro-intestinal derangement. In others the child has been subject to frequent attacks of pulmonary catarth. Sometimes the splenic tumour was first discovered shortly after an attack of measles; but it is difficult to admit a connection between these derangements and the splenic hyperplasis.

Morbid Anatomy.—When enlarged from simple hypertrophy the spleen retains its normal shape. It is firm and smooth; its capsule is thickened; and a section shows a pale red or reddish purple surface, with the Malpighian

bodies more or less distinctly visible.

Symptoms.—The existence of enlargement of the spleen is at once indicated by the complexion of the child. The whole body—both skin and mucous membranes—is pade and bloodless; but the tint of the face is characteristic. It has something of the colour of ivory or wax, with the addition of a faint olive cast which is not found in either of these substances. Often we notice a curious transparency, especially about the mouth and eyelids. The belly is large and the spleen can be readily felt as a smooth, firm mass. If the increase in size is great, the tumour projects diagonally across the abdomen, and presents on its inner surface the abrupt edge broken towards the middle by the notch. Usually the organ projects upwards and to the back as well as downwards, and its limits in these directions can be estimated by percussion. Sometimes it is freely movable by the hands, and it always descends when a deep breath is taken, rising again in expiration.

Although pale and bloodless the child has often a considerable amount of flesh, and is greatly wasted only in exceptional cases. He is, however, weak and languid. The bowels are often irritable, and in children of three or four years old the appetite is capricious and perhaps perverted, so that the patient shows a curious tendency to eat cinders, chalk, slate-pencil, and other grifty or even disgusting substances. (Edema of the lower limbs and eyelids is sometimes noticed, and petechia and bruise-like patches may be present in the skin. There is also a marked tendency to

epistaxis,

On examination of the blood the red corpuscles form rouleaux in the usual manner; but tested by the haemacytometer their number is found

be reduced considerably below the normal average, and the white cells to often appreciably increased, although acidom to the degree observed a case of leavecythemms. Sometimes both red and white corpuscles are

regular in shape.

A little boy, aged one year and seven months, was said to have been box strong and healthy. He was the youngest of four, his elders being a strong and well. He did not snuffle after birth, nor were any spots and at that time on the buttocks. Until the age of ten months the dilexcited no anxiety, but he then began to get pale and to lose flesh.

he and been litely very restless at night.

On examination the infant was seen to be very ansemic over the whole belt, and his complexion was of a dull yellowish-white, especially on the short. He was then although not emacuated, and his expression showed being of distress. The child was the subject of slight rickets, he had a two teeth, his chest was a little flattened laterally, and there was instant enlargement of the epiphyses of the long bones. His legs were than the had never been able to walk. The fontanelle was about half a solution of the diameter. The frontal bone was rather prominent on each side of the middle line, and there was some inconsiderable thickening of the

mucal bones. Cranio-tabes was well marked.

The belly was very full and prominent, especially on the left side. As the dald lay on his back, the lower border of the spicen was found to reach to be left crest of the ilium, and the inner margin passed obliquely downwith from beneath the ribs to within two fingers'-breadth of the right Men r superior spine of the ilium. The notch was felt just above the The organ was freely movable, descending appreciably in inand it could be pushed upwards until its lower border was on a but with the navel. Its substance was firm and hard, and its surface the upper border, estimated by percussion, rose to within two ware-breadth of the inferior angle of the left scapula. The edge of the aver was one such below the costal margin. A small nodule could be delt on each side behind the ramus of the lower jaw; otherwise there was Languagement of the lymphatic glands. A little blue mark, like a bruise, the torchead, and there was another on the back, but there We be petechne present on the skin. There was no ordenia of the legs. The child's appetite was good, and he was not suffering from digestive disbuleace. An examination of the blood showed no excess of white cor-

We teturn to its normal dimensions.

A title boy, aged twelve months, with no teeth, was brought to me, as a said to be weakly. The child had been reared by hand, and was abject to attacks of sickness. A short time previously, during a visit to be easily, he had been joundiced. There was some slight enlargement has en is of the bones and his fontanelle was large. The child could stand, but liked to be danced about and played with. His complexion to treesively pale, with a faint olive east. The abdomen was full, and pleen, which was large and har I, reached to the level of the navel. I could was put upon a nutritious thet, and was ordered cod-liver oil

and plenty of fresh air. In five months' time he had cut ten teeth and although still pale, had a better complexion. Seven months aftersare, (twelve from his first visit) he had sixteen teeth and could run about additional splicen was now greatly reduced in size, being just perceptible bear the ribs. His complexion was good and he seemed perfectly well

In this case no special medication was attempted with the object of reducing the size of the spleen. The general weakly state was impossibly fresh air and a suitable dietary, and cod-liver oil was given on account of the signs of incipient rickets. Moreover, further intestinal catantowers prevented by a carefully applied abdominal bandage. The hope that under these altered conditions the size of the spleen would diminish as the

general health improved was perfectly justified by the event.

Disquests. There is little difficulty about the diagnosis of these case. The complexion of the child is very characteristic. Indeed, in a semichild extreme anismia should always direct attention to the spleen. When a hard lump is discovered in the left side of the abdomen, it is easy to ascertain if the swelling is due to splenic enlargement. The superturn position of the tumour; its passing upwards beneath the ribs, its less rounded inner edge, with a perceptible notch; the free mobility of the mass, which can be pressed upwards by the fingers, and may be seen to move in correspondence with respiration, descending when a deep break is drawn, and rising again with the diaphragm as the lungs contract all these signs leave little doubt of the nature of the enlargement. That the tumefaction is a simple hypertrophy, and is not due to lymphadenoms or leacocythemia, is inferred from the absence of lymphatic enlargements in the former case, and in the latter from the small increase in number of us white corpuscles of the blood.

Prognosis.—The prospects of the child in simple hyperplasia of the spleen depend in a great measure upon the care bestowed upon him, and the watchfulness with which he is guarded from intercurrent admerts. The prognosis is therefore much more favourable in the case of children of well-to-do parents than in those belonging to the class by which our bepitals are supplied. If the patient show marked signs of rickets or syptilis, a cure can hardly be anticipated; but if the signs of rickets are only moderately developed, or the syphilitic origin of the enlargement is used a matter of suspicion, the child, under favourable conditions, has a far chance of recovery. Any considerable excess of white corpuscles in the blood must greatly diminish our hopes of a successful termination to the

CREA

Treatment.—In the treatment of cases of simple hypertrophy of the spleen we must not allow our attention to be directed too exclusively to the swollen organ, to the nuglect of the general health. Much injury to often done in these cases by long courses of mercury or nodice of putassium, and the energetic application of mercurial ointments to the left

hypochondrium.

Our first care should be to attend to any gastro-intestinal derangement which may be interfering with the patient's nutrition. Vomiting must be stopped, looseness of the bowels must be arrested, and the diet must is arranged so as to supply the most ample nourishment with the least us upon the digestive powers. Most of the patients are weakly children under two years of age. They must therefore be dieted upon the precuples recommended in the chapter on Infantile Atrophy. Milk, will be egg, Mellin's food, Chapman's baked flour, broths, thin bread and butter and, if the child is eighteen months old, raw or underdone mutton, pounded

na mortar and strained through a fine sieve, should be given. Watchthese must be exercised that the size and frequency of the meals are ale proportioned to the digestive capabilities of the patient; and in the we of milk in particular, it is important, by careful inspection of the are le to a wi-fy ourselves that curd is not passing away in large quantities If this be the case, milk should not be given pure as a dank, but be always mixed with barley-water or other thickening material, was to aid its digestion by insuring a fine division of the curd. Three or four grains of pepsine, given just before the three principal meals, will

boof great assistance in these cases

Hwing attended to the diet, attention should next be directed to the d dong of the chill. These patients, especially if they show any signs of neb to are very sensitive to changes of temperature, and it is of extreme importance that they should be thoroughly protected from chills. The carfully, so as to cover the whole of the abdomen, from the hips to the wast, and should fit closely to the skin. In cold or changeable weather the childs legs and thighs should be protected by long woollen stockings, and all his under lotting should be of flamel or wool. So protected, the putent must be taken out of doors as much as possible, and in suitable wather should pass the greater part of the day out of the house. Before be leaves home, his feet should be examined to see that they are perfectly warm, and in cold weather it is best to pack the child in a permitulator, so that his back and sides may be properly supported. His feet can then wet upon a hot-water bottle. If the patient be sent to a good seaside air, the effect of these measures is often very marked.

For mechane, unless there are positive signs of syphilis, mercurials and other lowering drugs should not be employed. The best treatment courts in the use of iron in full doses and cod-liver oil; but this treattorst must not be begun until the bowels have been put into a healthy state by appropriate remodies. For a child of eighteen months of age two or three grains of the exsiccated sulphate of iron may be given in glycente; or ten drops of the fineture of perchloride of iron may be administerel freely diluted with water and sweetened with glycerine, three times adm after meals. Quinine is also of service, and may be given in conpropon with the iron. The value of alcohol must not be forgotten. A tespeonful of the St. Raphael tannin wine, given two or three times a illated with an equal quantity of water, is an important addition to

the treatment.

I have employed frictions with mercurial salves to the splenic region, and seen them used by others, but have never noticed any special benefit from this proceeding. As a rule, it has seemed to me that the anæmia has been intensified by this means, and that the size of the spicen has inwased rather than diminished under the use of the drug. Unless the Exployment of the remedy is distinctly indicated by clear evidence of the presence of syphilis in the child, this method of treatment seems likely to be attended with a bad rather than a good result.

CHAPTER V.

HEMOPHILIA.

Hamorhita is a congenital tendency to bleeding which manifests itself shortly after birth and lasts the life of the patient. The hamorrlage occurs either spontaneously or upon slight provocation, and can only be arrested with great difficulty. The subjects of the disease also exhibit a curious tendency to obstinate swellings of the joints, which are often spoken of as "rheumatism." A temporary disposition to hamorrhages, such as is sometimes left after certain diseases, does not constitute hamophilia. The true disease dates from birth, or appears shortly after it, is always seen in childhood, and persists, as a rule, to the very end of life.

Causation.—Hemophilia, if not invariably hereditary, shows a singular tendency to hereditary transmission. The proclivity manifests itself more frequently in the male than in the female of of transmitting themselves exempt from this peculiarity, are still capable of transmitting the disease to their children. It is, indeed, a currous fact that the transmission of the tendency to the child is seen more commonly in cases where the patient, whether male or female, although spring from a family of bleeders, is individually free from the homorrhagic disposition. It is care to find a father transmit the disease to his child if he is himself a sufferer. In the majority of cases the unfortunate inheritance is derived from the mother, who has probably escaped.

In a family subject to this tendency all the male children may prove bleeders. Sometimes, however, one or more escape. Dr. Wickham Legg is of opinion that when transmission is only partial the first-born are more exempt than the others. The disease is found in all countries and all conditions of life. The Hebrew race is said to be pecuharly hable to it.

Morbal Anatomy.—In cases of death from hamophilia little is found to explain the nature of the disease. The body is usually blanched from loss of blood, but the organs, especially the heart and large vessels, present no appearance of disease. No change is discovered in the blood, and the vessels seldom present any alterations recognisable by the microscope. In some cases, unleed, a partial fatty degeneration of the lining membrane of the arteries has been observed; but this is probably the consequence of the amemia. Petechne in the skin, and bruise-like patches from subcutaneous extravasation, may be found; and sometimes large collections of blood have been met with. Sir W. Jenner has reported the case of a boy, aged thirteen years, in whom an enormous extravasation of blood was discovered beneath the fascia of the right thigh. The swelling of the joints appears to be due to extravasation of blood into the articulations. In a case reported by M. Poncet, on opening the knee-joint, which had been obstinately swellen and painful during life, all the tissues of the articulation were found to be stained with blood. At the circumference the lissues were chocolate-coloured; the articular surfaces were red and impreg-

nated with blood; and the cartilages were the seat of advanced lesions such as have been described by Charcot as characteristic of chronic rhen-matism. Microscopic examination reveded in the substance of the tissues yellow granules, irregular or rounded, and of variable size, pigment granules and fat granules. Other joints in the same subject showed similar lesions.

Symptons — There is nothing in the look of the child at birth to indicate any pseudiarity of constitution. Nor in after years, unless the individual be actually suffering from loss of blood or disease of the joints, is there anything in his appearance to distinguish him from another without the same tendency to bleed. The child may be fair or dark, tall or short, it what frame or of slender build. As a rule, he looks healthy, and his

intellectual capacity is above the average.

It is rarely before the end of the first twelve months of life that any the isnoticed of the hemorrhagin disposition. Bleeding seldom occurs at the time of separation of the umbilical cord, or during the operation of termstion; and it is not until the infant is able to crawl or walk, and the becomes exposed to injuries from falls or other violence, that his constitutional pseudamity can be recognised. Sometimes, however, evidence of the dispusse is postponed until later. Bleeding may not be noticed until the seemed crop of teeth begins to make its appearance at about the sixth jun. It has even been known to come on for the first time at a later per si; but is rarely delayed till after puberty.

The propensity to bleed viries greatly in its intensity in different subjects. In the lowest degree it may show itself merely in the shape of putaneous in the skin. In a higher grade the patient may complain of spataneous hemographic from the mucous membranes. In its most proposable form a tendency to every kind of bleeding is observed. The materials may give rise to copious extravasation into the tissues; petechne may give rise to copious extravasation into the tissues; petechne may give rise to copious extravasation into the tissues; petechne

at joints.

The harmorrhage usually occurs at a time when the patient appears to be it unusually good health, for it is at these times that there is a plethora the smaller vessels. The bleeding may be preceded by signs of excitement or irritability of temper, and it is said that there is sharpening of the senses of hearing and of sight. Epileptiform convulsions have been

total in one case by Boier.

It the bleeding be spontaneous, it occurs in the child usually from the box, but may be also noticed from the inside of the cheeks and hips, and from the gums, especially during dentition. In less common cases blood to so poored out from the mucous membrane of the stomach and bowels, the nay be somated up or discharged by stool. As a rule, the younger free child the more likely is the hemorrhage to come from the nose or courth. It is only towards puberty that hematemesis or melsena becomes manner. Renal hemorrhage is rare. Once started, the loss of blood may be extensions and copilus, so as to be arrested with the greatest difficulty; or may cease for a time and then return. Sometimes hemorrhage from one tree is quickly followed by a similar effusion from another, until the patent dies worn out by the constant discharge. When bleeding from one course alone ends in death, the hemorrhage occurs usually from the nose.

In addition to the spontaneous hamourhages, slight wounds or blows may produce a copious effusion. Lattle cuts or scratches bleed obstinately; the blows upon the body may be a cause of serious extravasation; and

in certain subjects even the rising of a blister may fill the blob with blood instead of serum. In such patients the extraction of a tooth, the application of a leech, or the prick of a pin may induce bleeding which for a long time resists the most powerful styptics, and may even destroy the life of the patient in spite of the most energetic measures for its suppression.

The tendency to bleed, even in the case of the same child, is subject to currous variation. A slight injury which at one time gives rise to excessive hierorrhage, at another is followed by no ill consequences; and a child in whom repeated hierorrhages from the nose or mouth are a source of anxiety may bear the removal of a tooth without unusual bleeding following the operation. Thus Dr. Wickham Logg has reported the case of a boy, aged eight years, who was subject to frequent hierorrhages from the nose and gums. This child could bear the extraction of a tooth or a cut on the finger without much loss of blood.

In all cases the source of the bleeding is capillary. The hamorrhage occurs as a constant oozing, which may last for hours, days, or weeks: and it is astonishing to note the enormous quantity of blood which may be thus poured out by the most trifling wound. In the case of traumatic bleeding the hamorrhage usually begins some hours after the infliction of the mjury. It often does not cease until the patient becomes faint, and even then is liable to renewal when consciousness returns. By this means the child may be reduced to a state of profound anomia, and only slowly

regains his colour and strength.

The petechia and subcutaneous harmorrhages which occur in ha mophiba are very similar to those noticed in cases of purpura. They are common on the buttocks and limbs of infant blenders, but the face usually escapes. Trifling blows may produce copious effusions. In some cases the blood infiltrates extensively through the areolar tissue of a limb, and death may even ensue from this inward bleeding. In other cases circumscribed collections of blood may be noticed, forming tumours of various sizes.

One of the most curious features of the disease in its higher grade is the joint affection to which these patients are so subject. The articulations attacked are usually the larger ones, and in the majority of cases it is the knee which suffers; but the ankles and hips, the shoulders and elbows are liable to be affected. The joint becomes swollen and tender, and the swelling usually increases until the ends of the bones can no longer be felt. It is accompanied by pain which is increased by movement, and there is a rise of temperature. Sometimes fluctuation may be detected. The swelling is said to be due, in some cases, to a simple effusion into the joint; but it is more commonly the consequence of articular humorrhage. It may occur either spontaneously or as the result of a triting injury. The symptom persists for a variable time, and it may be months before the joint returns to its ordinary dimensions. Several joints may be attacked in succession, or the joint affection may alternate with some form of visible hamorrhage. Blood tumours sometimes rise on the sides of a diseased joint. Thus M. Poncet has recorded the case of a boy, aged sixteen, whose right knee had been painful, stiff, and swollen for two years. Some time previously a small swelling had formed on the inner side of the knee. This had turned black, and then had burst, giving rise to obstinute harmorrhage. The boy was very subject to profuse bleedings from the nose, and eventually died in consequence of repeated hiemorrhage from wounds made by the application of the actual cautery to the diseased joint.

In addition to the articular affection, pains may be complained of in the limbs about the joints, although unaccompanied by swelling. These to be so severe as to interfere with exercise. The subjects of hamo-

sesposure to weather.

It might, perhaps, be expected that the existence of the constitutional testency would influence unfavourably the course of the exanthemata and contracted are influence unfavourably the course of the exanthemata and contracted are not be the case. Measles, searlet fever, and whooping-cough are sel to run their normal course in such subjects without manifesting except ally unfavourable symptoms; and although the patients are prone to cost affections, such as pleurisy and pneumonia, these diseases are not stead with special dangers. There is no peculiar liability to phthisis; let a unfavourable gargene are said to be not uncommon accidents in the

case of wounds and traumatic injuries generally.

1' proces - In pronounced cases the detection of the hemorrhagic to be even a matter of little difficulty. The history of repeated bleedings, the tal thrul appearance of bruises upon slight injury, and the affection of the parts, furnish sufficient evidence of the existence of this constitutional products. In cases where the tendency is present in a less degree the demosts is not so easy. Repeated epistaxis is often seen in children whose health in other respects is perfectly satisfactory; and the occurrence of spentaneous humorrhage from this source is therefore of no value in establishing the existence of hemophilia. Again, profuse and even fatal beeding from the stomach and bowels may be met with in new-born in-The cause of hemorrhage in the newly-born is often obscure; and it the absence of any evident reason for its occurrence some observers have stributed it to a special harmorrhagic tendency existing in the in-This may be so; but the cases differ from homophilia in the fact that where life is preserved no special proneness to bleeding is manifested wer years (see page 655). So, also, in hiemorrhagic purpura profuse he lag any occur from all the mucous surfaces and into the tissues; but to disposition to bleed is here, also, a temporary infirmity which passes of unlin completely recovered from,

is all cases of true homophilia careful inquiry will discover the existence of a hereditary tendency, especially on the side of the mother, and also most cases a disposition on the part of the child himself to bleed

provocation.

The nature of the joint affection can only be discovered by establishing the enstence of the hemorrhagic tendency; for there is nothing in the nameter of the joint symptoms to distinguish the swelling from that pro-

dated by other causes.

Prognous — Hamophilia is a disease which is accompanied by serious danger to life. The exhaustion produced by repeated hamorrhages is so to at that comparatively few of the patients reach adult years. Out of one hundred and lifty-two boys, the subjects of the humorrhagic disposition, (irandi her found that only nineteen attained the age of twenty-one, and that more than half of the number died before completing their accentation. Death usually occurs from humorrhage, but some kinds of bleeding appear to be more unfavourable than others. Thus hamorrhage after extraction of a tooth is found to be especially dangerous; obstinate epistasis is also to be viewed with grave apprehension; indeed, to these two caracters of bleeding a large proportion of the deaths may be attributed.

Children are said rarely to die from a first bleeding, and one profuse gush which causes fainting is thought to be more favourable than a slower and persistent cozing. Still, in any case we should speak very cautiously of the future, whether immediate or remote; for if the tendency be pronounced, the boy's chances of growing into manhoo lare not promising.

Treatment.—In cases of harmophilia great care should be taken to protect the child from all forms of injury. Vacculation has been seldom followed by dangerous bleeding; but the operation should be performed, as Dr. Wickham Legg suggests, rather by scarification than by puncture. Surgical operations, even of the sumplest kind, should be undertaken only as a last resource, and the extraction of a tooth should be expressly forbidden.

Constipation is likely to be particularly injurious to the subjects of homophilia. Therefore it is very important to see that the bowels are properly relieved. The child should take a dose of gray powder with jalapine every two or three weeks, followed by a saline; and the latter, in the shape of Dinneford's magnesia or the granular citrate of magnesia, may be given regularly every week. The dietary should include a good proportion of vegetables; and the white meats and fish are prefemble to too much beef and mutton. In case any of the premonitory symptoms of hemorrhage are observed, all meats should be at once forbidden, and a mercurial purge be administered, followed by a saline. Regular exercise should be enforced; but boisterous games, such as cricket, foot-ball, etc., can only

be includged in at a great risk.

When bleeding occurs, the treatment will depend upon the source of the hemorrhage. If this be at the surface, so that pressure can be brought to bear upon the part, as in the case of a cut or other injury, the application of a graduated compress, after careful cleaning of the wound, should be had recourse to. The local use of perchloride of iron, nitrate of silver, and other styptics, and of ice, is also recommended. In cases of spontaneous hemorrhage astringents applied locally are our chief resource. In epistaxis the nasal passages must be first cleared out by injections of icecold water. Afterwards the solution of perchloride of iron (of the strength of one drachm of the strong solution to an ounce of water) should be injected or sprayed into the nostrils. If this method fail, the anterior and posterior nares must be plugged. If the memorrhage occur from the socket of a tooth, crystals of the perchloride of iron applied locally will sometimes arrest it; or the alveolus may be packed with a graduated compress sonked in the iron solution. Bleeding from the bowels usually comes from the lower part of the rectum, and can often be staunched by injections of the iron solution (one or two directions to the ounce). Bleeding from the gums is usually stopped by washes of tannin, alum, or rhatany; and the child should be prevented if possible from encouraging the blueding by sucking his gums. Iron and other styptics given internally seem to be of small value; but ergot is stated to have proved of service.

The subjects of this tendency should be warmly dressed and carefully protected from the cold. If possible their residence should be elsewhere than in cold, damp situations. The joint affection must be treated by perfect rest, and cold or warm applications as are most agreeable to the patient. At a late stage blisters to the joint are said to be useful, but counter-irri-

tation with the actual cautery is to be avoided.

CHAPTER VI.

PURPURA.

Precase is a diseased condition in which extravasations of blood take place of the skin and the substance of the viscera, and blood may be poured to the skin and the substance of the viscera, and blood may be poured to the skin in the serous cavities. When the treasation takes place into the skin it is called purpura simplex; when be himseringe is more general the disease goes by the name of purpura with the peak, and sent forms of illness, febrile and other, are accompanied by the ready escape of blood from the vessels. In the malignant topological time, measles, small-pox, typhus fever, and diphtheria purpuric pessed himsering, and is occasionally met with in cases of Bright's disease, from of the liver, leucocythemia, and valvular lesions of the heart. It was peaking, however, the term purpura is applied to a temporary morthagic tendency unconnected with any of the acute specific diseases, in which no morbid condition of organs, other than that due to the

busisation and its consequences, can be discovered.

Common in children, and appears in many cases be a consequence of insanitary conditions and insufficient food. Still, in the disease may arose from other causes is shown by the well-nourded state and robust appearance of many of the subjects of this disorder. the Lenorrhagie tendency is sometimes seen to come on quite suddenly must apparent cause in one member of a healthy family, the others the appear to be living in precisely the same conditions escaping altohilten and born of healthy parents without any history of hæmorrhagic a store, had himself been strong and well all his life with the exception states of measles and whooping-cough during his second year. The saddenly began to bleed from the eyes, the nose, and the mouth, and at developed all the symptoms of severe hemorrhagic purpura. In such as this the occurrence of the disease can never be traced to are in diet or insufficiency of vegetable food or milk. Sometimes purmy come on as a sequel of an exhausting disease, such as scarlatina tuple ad fever, and I have known it to occur after a sovere attack of cupous pneumoma. It is said, too, to be occasionally induced by the dan stration of iodide of potassium in weakly subjects, especially in bouring under valvular disease of the heart. In many cases howour no antecedent condition of any kind can be discovered capable of II-a and the sudden propensity to bleed.

Mend Austony—In the skin the hemorrhage occurs in the rete mubeam and the pupillary layer of the cutis, and also into the subcutaneous face. The submucous fissue is also often the seat of extravasation, and Detuces much blood is poured out from the surface of the mucous Demorance. In this way, after death purple spots and extravasations of various sizes may be discovered beneath the mucous membrane of the mouth, guilet, stomach, and intestine both small and large. So also the serous surfaces and subserous tissues may suffer in the same way, and more or less copious extravasation may be found in the serous cavities—the pleura, the peritoneum, and the pericardium. The substance of organs is not unfrequently the seat of hiemorrhage, and clots may form in the lungs, the heart, the kidneys, etc. Fatal apoplexy may also result from this cause.

Pure purpura does not lead to disease of internal organs. If the anamus he extreme, fatty degeneration of the muscular fibres of the heart and a similar condition of other viscera may be found; but this is a consequence of the impoverished state of the blood induced by repeated ha morrhages, and is only a secondary consequence of the hemorrhagic tendency Amyloid and other degenerations found in the liver and elsewhere must be looked upon as a result with the purpura of a common cause. When bleeding is profuse and repeated the blood undergoes the changes incident to an advanced stage of anamia, the amount of hamoglobin is lessened, and the red corpuscles are diminished in number as well as reduced in size. Unless the blood be impoverished by hamorrhages, no morbid change in the fluid can be detected.

With regard to the pathology of the disease, the fault has been supposed to lie in some alteration of nutrition in the coats of the capillaries and smaller blood-vessels, so that they rupture readily under the pressure of the blood. This explanation may be a sufficient one when the purpura occurs in a cachectic subject, but it cannot apply to the sudden tendency to harmorrhages often manifested by a child whose health had been previously satisfactory. Henoch suggests that in these cases the cause of the effusion may be a vaso-motor neurosis which gives rise to stake in the blood, rupture of the wall of the capillaries, or migration of the blood

globules from paralytic dilatation of the smallest vessels.

Symptoms.—The spots may appear quite suddenly without previous signs of ill-health. Often, however, they are preceded by more or less aching of the limbs, slight feverishness, thirst, and symptoms of indigestion. The child has no appetite and is unwilling to exert himself, crying if obliged to walk, and complaining constantly of feeling tired. In some cases the appearance of the purpuric rash follows an attack of vomiting and diarrheea. The spots are circular and of a brick-red or deep purple colour. They are not elevated above the surface, and pressure does not cause them to disappear. In size they vary from a pin's head to the diameter of half an inch or more, and their outline is distinctly defined. They may be so closely set as to be confluent. This is especially common about the instep and ankles. Often they are accompanied by marks like bruises due to extravasation into the subcutaneous tissue. These are bluish discolourations without defined margin, and may be accompanied by some swelling. They appear to be sometimes the consequence of insignificant injuries, for a gentle pinch or feeble blow will produce them. The purpuric spots come out in successive crops, and each, after going through the ordinary changes of colour peculiar to such hæmorrhages, disappears in the course of a few days. At times the skin will be found to be nearly clear; then another crop is discovered and the surface is thickly studded with them as before. They are usually most numerous on the limbs, but are found besides on the trunk, and sometimes, although zarely, on the face. Mixed up with the true purpuric spots may be wheals of urticaria, little patches of crythema papulatum or crythema adoum, and occasionally blobs arise filled with bloody scrum. Inspecon of the mouth will also often discover minute hemorrhagic extravasaios into the nucous membrane of the hips and cheeks.

In the more acuts form of the disease, when the general health has been previously satisfactory, the purpure spots may be accompanied by adviatous swelling. The hinds then feel unusually firm and full and pit in pressure. Unless hemorrhage occurs from the urinary passages there are all unintered.

A healthy little girl, aged five years, began to lose her appetite and company of pains in the legs and knees. She was unwilling to take exfor and after walking for a short distance would say that her legs ded and ask to be carried up-stairs. These symptoms continued for from three weeks without improvement. The child then became slightly bansh, her knees swelled, and purpuric spots appeared on the lower part I me body and on the legs. When seen on the sixth day the child looked bel is the face and seemed cheerful. The spots were numerous on the beer limbs and varied from a pea to a fourpenny bit in size. They were circl m colour with a well-defined outline, and did not disappear on resure with the finger. In addition to these spots there were larger patches, like brunses, of a greenish or yellowish colour. Both legs were too maly swollen and felt very firm. They pitted distinctly on firm The knees were not swollen or tender at this time, but were and to have been very tender and painful. The skin covering the popand spaces was much ecclymosed. There had been no bleeding from the new or other mucous tract. The heart-sounds were healthy. There no albumen in the nrine.

The pains in the limbs usually continue after the spots have appeared, but subside in a few days. A return of the pain is sometimes found to precede the eruption of each successive crop of spots. The number of the crops varies. Sometimes there is only one. Usually, however, they have numerous. Exercise seems to encourage the homorrhages, and that therefore an important element in the treatment. In the simple form the disease is usually at an end in from one to three weeks.

In simple purpura the extravasations are limited to the skin, but in the more severe form, called hemorrhapic purpura, effusions of blood are overed from other parts. The nose bleeds, and the hiemorrhage may be reprose that it has to be arrested by mechanical means. Blood may be lischarged from the eyelids, the gums, the ears, the lungs, the much, the bowels, and the kidneys. Hiematurin is a common consequence of hemorrhagic purpura, and the amount of blood may be so the first blood from this source that the urine passed is of a deep red colour. The read hiemorrhage often occurs in one gush and then ceases entirely that time, so that two successive discharges from the bladder may be of michaeless that two successive discharges from the bladder may be of horizontal in appearance. Still, even if there be no naked-eye signs of horizontal in appearance. Still, even if there be no naked-eye signs of horizontal in appearance. Still, even if there be no naked-eye signs of horizontal hemorrhage from the bowels is seen as black clots at the other of the chamber-pan. It is rarely copious. Its appearance may be acceled by severe abdominal pain, which ceases when the blood is discoved by intestinal hemorrhage.

When poins in the joints are complained of, there may be some tenmens and considerable swelling. This symptom is often spoken of as beumatism," and the disease is then called purpura rheumatica. It seems probable, however, that sometimes, at any rate, the lesion is due not to rheumatic inflammation but to be morrhage into or around the joint. If it arise from this cause the articular affection is more chronic than a rheumatic joint lesion, and remains confined to the part first attacked.

There is no necessary discolouration of the skin.

During the progress of the complaint the general symptoms are often indefinite. The appetite may be good or more or less unpaired. A certain amount of thirst is usually to be noticed. The liver may become much swollen from congestion, and the bowels are often confined. Usually, until the loss of blood has produced amemia, the child complains only of aching and feeling tired. The temperature is often normal, but sometimes there is irregular pyrexia. The febrile heat does not, however, appear to bear any relation to the hemorrhage. I have not found it to precede or follow in any regular manner the flow of blood.

A robust little boy, six years of age, was in his usual health when he suddenly began to bleed from the eyes, nose, and mouth. During the next month he continued to bleed every morning from the gums, and on three separate occasions had copious attacks of harmorrhage from the eyes and nose. An accidental cut on the finger also bled profusely for two hours. During all this month the boy was very thirsty, drinking any fluid he

could get, even dirty water.

On admission into the East London Children's Hospital the child seemed to be well nourished and had a healthy appearance, with a fair amount of colour in his face. His gums were not spongy. His face, body, and limbs were thickly covered with purpuric spots of a brownish-red colour, which did not fade on pressure. There were in addition large bruness on the right arm, the trunk, and the left thigh. There was no enlargement of the liver or spleen. The urine had a density of 1.020. It was clear, without sediment, and contained no albumen. The heart beat in the fifth interspace in the nipple line. At the apex the sounds were healthy but muffled, and a loud anomic murmur was heard at the base.

While in the hospital the patient had frequent hamorrhages from the nose, the mouth, the bowels, the kidneys, and into the skin. On one occasion he repeatedly retched and vomited large black clots of blood. He also complained much of abdominal pain, and passed large quantities of black blood from the bowels. This may, of course, have been blood poured out by the nasal fosse and swallowed; but the hamorrhage was at any rate copious, and caused a marked blanching of the skin and much feebleness and languor. The boy's temperature varied considerably during his illness. He had irregular attacks of fever during which the temperature would rise to 101° or even higher, but the pyrexia did not always precede the gush of blood. If, however, there was fever when the hamorrhage occurred, the first effect of the flow was to reduce the bodily heat to a subnormal level.

The boy was treated first with iron, which seemed to have no effect upon the hamorrhages; then with aperients, which produced at first a marked improvement; later with iron and arsenic combined, under which

he became rapidly convalescent.

When anemia occurs, the ordinary signs of debility are noticed. The child is pallid and feelde. He is restless and complains of headache, and his pulse is frequent and irritable. A systolic murmur can usually be detected at the base of the heart, and a loud venous hum is not uncommonly heard at the upper part of the sternum.

There may be some cedema of the ankles, and even of the limbs and

five. In very severe forms of the disease the child may die from syncope or exhaustion, and sometimes death occurs in an attack of convulsions. Caruls: one are due in ture cases to hiemorrhage into the cranial cavity. If Hallowes has reported the case of a boy between three and four years old who had lived in a good air and been well fed. This lad, after being lazuid for one day, developed bruise-like patches on different parts of the body, and died on the third day after a convulsive attack followed by againty. At the autopsy extensive harmorrhage was found to have occurred into both ventricles with laceration of the brain substance. No ruptured ressel could be found.

Convulsions in purpura are not always the consequence of cerebral benerrhage. A little garl three months old was under my care in the last London Children's Hospital for vointing and diarrhoa. After these bragements had ceased a purpuric eroption developed on the body, and a few days the child had an attack of convulsions and died. Here the bragements to be unusually anemic, and there were no signs of intractanal extravasation. These are, however, exceptional cases. In the third a fital termination to the illness is mire. Usually after a longer or charter period the hismorrhages cease, and the patient regains his colour and strength.

The course of the disease is almost always irregular. The successive cops occur at uncertain intervals, and often the disease is thought to be and when a sudden return of the extravasations shows us that the hiem-

orrhagic tendency is not yet overcome.

Dirmosis.—Lisemorrhagic purpura cannot be confounded with a magrant form of exanthema, for the high fever and profound general sufbring manifested in such dangerous cases are not present in the milder

complaint.

In scurvy there is always a history of privation or injudicious feeding; the special symptoms follow upon a period of ill-health; general tender-tiess is a prominent feature; and there is marked feebleness from the very first. In all these points the affection differs from purpura. Moreover, the theatment of the two diseases is different, and measures which are found to have an immediate influence upon the scorbutic condition are powerless to wheek the hierorrhagic tendency in purpura.

In hemophila, which is characterised by similar symptoms to those of purpura, the disease is a constitutional one and is almost always hereducty; the family tendency is well recognised, and the hemorrhage is satisfilly first manifested as a consequence of a cut or injury. Moreover, the chaposition to bleed is a chronic and permanent state, and is not a make or less soute condition which can be made to cease by appropriate

retainedies.

Promotis.—In simple uncomplicated purpura the prognosis is always two urable. In haemorrhagic purpura the disease is more serious; but if the child be submitted early to treatment the illness rurely loss a fatal

Tratment.—In all cases of purpura the child should be confined to have been as rest is of extreme importance in preventing repeated relapses of the disease. The two forms of purpura, viz., that which comes on the suddenty in healthy children and that which attacks feeble or cachecome subjects, require a different method of treatment. In the first the plan of energetic purgation is peculiarly valuable. Often in such cases a securise of iron or other tonic is followed by no benefit whatever, while a few doses of some drustic aperient cause a prompt and final disappearance

of all hemorrhagic symptoms. This treatment is equally useful whether the complaint be of the simple or hiemorrhagic variety, and may be employed without fear even in cases where great amemia has been induced by the loss of blood. If the liver is found to be swollen from congestion, as sometimes happens, its size is quickly reduced by the purging. It is in these cases, perhaps, that the value of aperients is most strikingly illustrated; but all cases of the acute variety of the complaint seem to be benetited by this method of treatment. The best form in which the aperient can be prescribed is a combination of the oil of turpentine with castor-oil. For a child six years old, two drachms of each may be given made into un emulsion with mucilage of tragacanth and flavoured with syrup of lemons and peppermint water. This draught should be taken before breakfast every morning, or on alternate mornings, according to the effect produced. If the humorrhage is not arrested in the course of a few days, iron and arsenic should be given in addition after each meal. A child of this age will take without inconvenience fifteen drops of the tincture of perchloride of iron and three or four of Fowler's solution, freely diluted, three times a day. Other treatment is also recommended. Weilhof, who first described the disease, relied upon quinine and dilute sulphuric acid. Ergot is preferred by some, especially in cases where the hamorrhages are copious; but this drug should be always given by the mouth and never hypodermically by the injection of a solution of ergotin, as obstinate bleeding has been known to result from the puncture of the needle.

Special harmorrhages must be treated by special means: epistaxis by the injection of iced water, or by the use of a spray of perchloride of iron. In using the spray the nasal passages must be first cleared out completely of clot by the injection of water. Afterwards two drachms of the strong perchloride of iron solution diluted with water to two ounces must be sprayed into the nostrile. Harmorrhage from the gums may be usually arrested by an alum gargle or the infusion of rhatany; intestinal harmorrhage by iced-water injections and the application of an ice-bag to the ab-

domen. In hamaturia gallio acid should be given.

When the patient becomes anamic, stimulants (port wine or the St. Raphael tannin wine) must be given, and the child should take plenty of nutritious food.

In the cachectic form of purpura aperients are less suitable. In these cases stimulants are required from the first, and the child should take food in small quantities at a time so as not to overtask his feeble digestive powers. Iron wine may be given with arsenic, and cod-liver oil is useful. As a special styptic turpentine in ten-minim doses is of service, taken every three or four hours, or an equal quantity of the hquid extract of ergot may be administered several times in the day.

CHAPTER VII.

SCURVY.

Some is a disease which is now rarely seen in its most pronounced form seem the adult, unless under circumstances of exceptional hardship and proteon. As one of the diseases to which young children are hable it as been, until recent times, completely ignored. Lately, however, owing the observations of Des. Cheadle, Gee, T. Barlow, and others a form of the adult has been recognised as an occasional consequence in infants of half seeling and injudicious management. In such subjects the disease attending practed upon rickets; and there can be little doubt that it is a semigrated upon of the two maladies which constitutes the state described

" First and others under the name of acute rickets.

Creation - A scorbutic taint which reveals itself by the milder pheseems of scurvy appears to be less uncommon than was at one time supwel amongst the out-patients of large hospitals. Dr. Eule, of Norwich, by Relfe, of the London Hospital, have both met with such cases their patients; and Surgeon-General Moore has remarked upon to beparecy with which similar symptoms can be detected amongst the and tents of certain districts in India. In all such cases bad or insuffiand find is no doubt the cause of the impoverished state of the system, and vegetables the want of fresh meat, fresh milk, potatoes, and vegetables resulty. In young children the causes appear to be very similar to those * 12th have the power of setting up rickets although they are not identiod with them. If an infint be feel with excess of starchy food and supthat with sweetened preserved milk instead of the fresh milk of the cow; The bedirty and neglected as to his person, and breathe habitually a foul air, the conditions are just those which are capable of setting If the scorbutic state. An infant so brought up quickly begins to show and may perhaps be found all at once to develop the manifest similar the many articles of diet are orbatic, although not anti-rachitic; indeed some, while they prefrom scurvy, may actually aid in the production of rickets. Scurvy from rickets in not being a disease of general malnutrition. In the homer the affection is due merely to the absence from the blood of was westituent whose presence is essential to health. In the latter the while existent suffers, and the condition is one of general impairment of manufacture from deficiency of wholesome food. Consequently as long as the talespensable element is supplied to the blood the praient does not bewarbutic, however well the diet may be adapted to favour the ocsame of nekets. Thus a child fed largely upon potatoes may very I'm by grow rickety, but he will certainly escape scurvy. Again, in Eughallman fruit, being cheap, is largely consumed by the children of the For Even babies in arms are allowed to inbble at an apple or a plum

as soon as they are able to hold an object in their hands. During the summer months they get strawberries and gooseberries; in the autumn apples, pears, and plums; and in the winter and spring oranges. By such means a scorbutic tendency is no doubt counteracted, but general nutrition is little improved; indeed, it is not improbable that on account of the indugestion and acidity which such indulgences must necessarily excite at this early age the occurrence of rickets is actually promoted.

The outbreak of scurvy often appears to be determined by some influence which causes a temporary depression in the child's strength. Children who inherit a diathetic tendency are probably more prone than constitutionally healthy subjects to suffer readily from the want of milk and fresh and wholesome food. In many cases, however, it is noticed that the patient is enabled to resist for a long time the influence of a distinctly injurious dictary; and it is only when the nutritive processes are brought to a sudden standstill by an attack of gastro-intestinal catarrh that scorbutic symptoms begin to be observed.

Scurvy is not confined to the subjects of rickets, but most scorbutic children are found to be suffering from that disease. This is not to be wondered at, for the age at which rickets is most liable to occur is also that at which scurvy is chiefly found to prevail. The two affections are also, as has been said, induced by causes very similar in kind; and the general impairment of nutrition of which rickets is the consequence no doubt renders the patient especially sensitive to the effects of a scurvy diet. In most of the recorded cases of scurvy in the young subject the

patients have been under eighteen months old.

Morbid Austomy. - One of the most characteristic morbid changes induced by the disease is a copious extravasation of blood into the tissues of the limbs, especially of the thighs. The muscles themselves are usnally pale, but the tassues between them may be infiltrated with serum more or less blood-stained. Sometimes blood is extravasated into the substance of the muscles, but without any evident laceration of the fibres The chief seat of the extravasation is between the periosteum and the bone. In many cases the investing membrane is found to be separated widely from the shaft of the hone, retaining its attachment merely at the epiphyses. It is, moreover, greatly thickened and deeply injected. Between it and the bone lies a large, loosely adherent blood-clot in which the bone is embedded. When the clot is cleared away the bone is found to be perfectly smooth, although bare of periosteum. Another common feature is a separation of the epiphyseal ends of the long bones. This separation is not at the line of union of the epiphysis, but in the shaft of the bone just below the point of junction. The osseous structure at the seat of fracture can be noticed to be particularly loose and spongy. It is important to remark that in all these cases where separation of periosteum has occurred no sign of caries or exhibition of the bone is to be discovered. Nor does the extravasation of blood ever appear to end in suppuration. The shaft of the bone is curiously fragile and thinned. This atrophy is well seen in some cases in the ribs, which may appear to be reduced to the two bony plates by almost complete loss of their cancellous structure. Extravasation of blood never seems to take place into the articulations, as is seen in hemophilia; for all the joints and tissues immediately connected with them are found to be healthy.

The above changes in the bones and periosteum are common to all fatal cases of scurvy in the child. Mr. T. Smith's case exhibited at the Patho-

Expected Society of London in 1875-76, under the provisional name of Expertings percentiles," showed the above changes in both lower limbs. The parts principally involved were the thigh bones, but the bones of the loss acre affected, although to a less extent. In Dr. T. Barlow's beautiful propertions shown at the Royal Medical and Chirurgical Society in 1883, the same characters were observed. The effised blood has usually been food of a deep marone colour and coagulated. Of other organs the abite oil viscour are generally healthy in these cases. The same thing may be said of the chest; but once or twice Dr. Barlow has found some effusion in the cavity of the pleura, and in Mr. T. Smith's case there was a small accordage in the lung. Often no sponginess or inflammation of the gum in the satuation of the up-coming teeth. Other small extravastives may be present in the skin in various parts of the body. They may occur around the ribs, and may be discovered in the intestines and kidney.

The above morbid characters can leave little doubt that these cases are aghly closed under the head of scurvy. It has been objected to this new that although the symptoms observed during the life of the child do od as a rule, point to any very marked deterioration in the quality of the thel, the lesions noted after death are the later manifestations of the disthe such, indeed, as occur in the adult only as a consequence of profound a estational cachexia. Thus sub-periosteal hamorrhage, which is a late maplem in the sdult, is produced early in the child; and the affection of be sund which is usually regarded as one of the earliest and most characbrists symptoms of scurvy, may be absent in the young subject altogether. I has it may be replied that cachexia is produced very mondly in the must be scute disease, and that in some cases of scurve in the child an extratar degree of anarma and debility has been reached. But granting that in cast cases serious lesions have been discovered where the general symphave been comparatively mild, this is not to be wondered at, considerat the age and peculiarities of the patient. In a blood disease such as "By it might almost be anticipated that the tissues chiefly affected sould be those in which growth and development are making most active in new At the age at which young infants are usually found to suffer no bears or organs are undergoing more rapid changes than the long bones, specully those of the lower lumbs; and it is exactly in these attuations last the more pronounced lesions are observed. On the other hand, in the mu Lary bone; ossification and development are practically at a standstill; bette child being (as he almost always is) the subject of rickets, the jaws have reased for the time to increase in size, and the evolution of the teeth a ampletely arrested.

The cause of the deterioration of the blood in scurvy appears to be, but the more absence of potash salts, as Dr. Garrod believed, but rather, b. Dr. Buzzard supposes, the absence of these salts in combination with again acids. Dr. Rulfe has still further developed the latter hypothesis. This observer is of opinion that the primary change depends on a general control proportion between "the various acids, inorganic as well corganic, and bases found in the blood, by which the neutral salts, such as the chlorides, are either increased relatively at the expense of the alkables salts," or these latter are absolutely decreased. He concludes that there is a diminution in the alkalinity of the blood, and that this produces dissolution of the blood corpusules and fatty degeneration of the muscles and of the secreting cells of the liver and kidneys.

Symptoms.—Children in whom the symptoms of scurvy are noticed

are often large, flabby infants between twelve and eighteen months oil They usually show the milder phenomena of rickets, such as profize sweating about the head, lateness of dentition, enlargement of the cods d the long bones, and beading of the ribs. In such subjects the course of the scorbutic disease is as follows: The patient shows signs of unusual and extreme tenderness. He dreads being handled, cries if put upon his feet, and if he had been able to walk, is quite taken off his legs. Next in begins to suffer from pains which seem to be constant. The child .ss moaning in his cot, and screams if touched or even approached. Ven soon swelling is noticed of a limb, usually a thigh—one or both. The affected part is enlarged by a cylindrical swelling which although not as tually brawny to the touch is yet firmer than natural. In many cases at a distinctly odematous, but it may not pit under the finger, although a often gives the sensation of containing infiltrated serosity. In the lower limb the swelling usually occupies the whole length of the thigh and often of the leg. There is no perceptible fluctuation, and no enlarged tens can be seen, but the tint of the skin is often livid or faintly lead-erdoned, and in a case recorded by Fürst its tint was red and glistening. There's no effusion into the joints, but these are usually swollen from enlargement of the articular ends of the bones. The upper limbs are less affected than the lower. The forearm just above the wrist is here the part in which awelling is most commonly noticed. In such a case if the swelling is not extensive, it is difficult to distinguish it from the ordinary epiplesed as largement so commonly present in the rickety child. But besides the parts which have been mentioned, swellings from local periosteal extravasation may be found at the upper part of the humerus and on the shoulder-blades, and sometimes similar extravasations are noticed in the skin and subcutaneous tissue. Petechie, bruise-like patches, and even small blood-tumours may be met with. There appears also to be the same tendency to the formation of ulcerating sores on the cutaneous suface which has been remarked in cases of scurvy affecting the adult. In one of Dr. Cheadle's cases—a little boy aged sixteen months—there were two unhealthy looking sores seated the one on the right wrist, the older on the fore-finger.

At first, when the swellings begin, the child keeps his limbs flexed but later a new phenomenon is noticed. The patient ceases to flex his less and allows them to remain stretched out straight in the bed, as if he had lost all power of movement. It will now be noticed on examination that a soft crepitus can be detected in the neighbourhood of the joints from separation of the epiphyseal ends of the bones, and the wrist may dep from fracture of the carpal end of the radius. At this stage the joints can be examined without the child appearing to suffer pain from the many

ment of the articulations.

In many of the cases in which the symptoms are well marked, spead ness of the guins and other minor manifestations of the scorbutic taust are entirely absent. Sometimes, however, the guins are red and soft at gelatinous-looking, and may be so swollen as actually to protrude between the patient's lips. They bleed at the least touch. The swelling may intend to the mucous membrane of the palate, and this may be so spongate almost to touch the dorsum of the tongue when the mouth is open. In Cheadle has reported some cases in which the affection of the guins we unaccompanied by signs of deep-seated extravasation in the limbs but the two conditions may be present together. The child appears at this time to be the subject of marked cachexia. He is sallow and very emacated

his temperature is often raised, reaching to 101° or 102° in the evening; his appetite is poor, and his bowels may be relaxed. Often profuse perspirations are noticed. If the mucous membrane of the mouth or guins is affected, the breath has a most offensive odour. The weakness is usually very great. The child ceases to be able to support hunself in a sitting posture, and when placed in that position falls on to his side at once if elt done. The urine may contain albumen and sometimes is reddened The abdominal organs seem to be healthy, and no cuburgewith blood, ment can be detected of the liver or spleen. There may be cough, but the physical signs of the chest are usually normal, or consist merely in a few arge bubbles heard here and there about the back. In one of Dr Gee's cues -a child aged one year-a curious recession of the chest was noticed. At each inspiration the whole of the front sank inwards, the ribs bending on each side at a point much outside the costochondral articulation, and tie breast-bone receding instead of protruding as in rickets. Dysphoca s ad, however, mentioned in other recorded cases of the disease in early

As the illness progresses it is often found that the swelling first noticed because after a time somewhat to subside, and another limb becomes affected in a similar way. Thus, in Furst's case the earlier swellings appeared in the left femair and the tibiar of both limbs. Next, enlargement was noticed in the right forearm, and afterwards in the left forearm and the make arm. At the time when these secondary swellings appeared the parts tool aftered began to recover, and the fever abated. Even after apparently complete recovery the disease is still liable to recur, under the influence, two day, of the same causes which provoked the original attack. Thus, in its Thomas Smith's case the child was said to have suffered eleven months foreastly from like symptoms which had lasted over a period of two another.

beer is not always present in cases of scurvy in the child. Sometimes, as has been stated the thormometer marks an elevation of 101, 102, or ever higher, but the disease may run its course without the occurrence of pyraxia. Still, if the hiemorrhagic effusion is great and the tension of the periosterial correspondingly severe, a certain amount of fever is usually to be moticed.

When the patients recover, as they will usually do if suitable treatment is a lopted in time, the temperature falls, the tenderness subsides, the swellings disappear, the appetite improves, and the strength and colour relates. A degree of thickening is left at first around the bone at the site of the swelling, but this after a time is no longer to be detected. Even the strength and colour related epiphyses will, under favourable conditions, become again considered with the shaft of the bone.

In grows —In all cases where a young child presents symptoms of the kets, and it is discovered that his feeding and management have been such as to favour the special deterioration of the blood which gives rise to actainly, the symptoms of that disease should be looked for. These always the event upon a state of ill-health, and never occur, as is the case with parpura, in a child whose condition is not in other respects unsatisfactory. It is a suspicious symptom. In relative tenderness, even in a case of rickets, is a suspicious symptom. In relative of the disease are pronounced. If the symptom is noticed in a child who, although showing signs of rickets, is evidently suffering from the disease only in a mild form, it points very decidedly to scurvy

When the swellings occur in the limbs the great enlargement without

fluctuation, or redness, or local heat of skin, is unlike ordinary periodicand, indeed, this disease is not a recognized complication of nebrolishes, the patient be suffering from rickets, the probability of the additional phenomena being due to the supervention of scurvy should be consider.

In many cases, especially if separation of the epiphyseal en is of a bone has occurred, with the symptoms of pseudo-paralysis, the different to exclude syphilis; and if, as may happen, there is a history of more riages on the part of the mother, or of doubtful symptoms in the millioniself shortly after birth, it may be impossible to exclude a syphilit taint. Still, the diagnosis of scurvy may often be ventured upon. Symple pseudo-paralysis is usually accompanied by enlargement of the space and all the signs of a profound syphilitic cachexia. The child is greatly wasted he is hourse and snuffles, the cranial bones have the characteristic that ing, and the skin has the pseuhar dry, parelment like appearance so cannon in the inherited disease. In scurvy the patients are not as a rangreatly emaciated. Often their general nutrition is fair; and the special characteristics of syphilis are absent. If the gums are spongy or sate of hemorrhage can be noticed in the skin or elsewhere, the evilance strongly in favour of scurvy.

Prognosis.—If the child be seen in time and measures are at once the to improve the quality of his food and supply the backing constituent is his blood, recovery may assuably be counted upon. When children do in this disease they die from exhaustion. Much will therefore departupon those who are entrusted with the care of the child, for scurvy is the of the maladies of which the treatment consists almost entirely in upon

and judicious nursing.

Treatment. - In all cases of infantile scurvy it will be found that is child has been deprived of fresh milk and fed upon Swiss milk and other kinds of tinned food, which are deficient in the material necessary in maintaining all the constituents of the blood at a normal standard. As immediate change must therefore be made in his diet. He smuld 🖛 given fresh cow's milk, diluted, if necessary, with harley-water or the least with a proportion of potato-gruel. If he be twelve mouths old now matter pounded in a mortar and strained through a fine sieve, may be given every other day alternating with raw meat-junce," or if the meat be not will digested, meat-juice can be given every day. If the child refuse this famil the juice may be sweetened with sugar, or what is much better with tarnip or carrot. Orange-juice is well taken as a rule, even by young balks. and is a valuable anti-scorbutic. If the patient be in a very exhausted state, twenty or thirty drops of brandy can be given every three or four hours; or he may have one or two teaspoonfuls of burgandy or the Raphael Tannin wine, diluted with an equal proportion of water At the? some time care should be taken to furnish a proper supply of fired, ar 13 the weather be suitable the child may be taken out frequently lying at hall length in a little carriage. If he be confined to the house, open wild we should be insisted upon, every precaution being taken to keep the rol of of the line of direct draught. The best medicine is cod-liver oil. The may be given with a few drops of the tracture of perchloride of iron, or 42 a draught composed of three of four grains of the citrate of iron and que nine dissolved in a teaspoonful of lemon-juice, and sweetened with spinis .

To make raw meat juice. Put two ounces of lean raw mutton very finds at anto an earthen vesse, and pour upon the meat enough cold water to cover it small finder before the fire for two hours, then strain through a stove

Microform. An occasional powder of rhubarb and aromatic chalk can be

given if there is an unhealthy state of the bowels.

When the gums are spongy and bleeding, they may be painted several times a day with a solution of glycerine of tannin and glycerine of carbolic acid, fifteen minims of each to the ounce. This application was used by Dr. Cheadle in his cases with the best results. For the swellings of the timbs Dr. Barlow recommends surrounding them with wet compresses throughly wrung out, and covered with dry cloths closely applied. An opention seems to be unnecessary, although Mr. Herbert Page has reported a case in which he made an incision through the periosteum and timed out the extravasated clots without ill consequences. Still, it seems probable, from the results in other cases, that eventual absorption of the blood will take place if the child be put under favourable conditions for necessary. If separation of the epiphyses has occurred, the limb must be hept perfectly quiet in splints.

Part 5.

DISEASES OF THE NERVOUS SYSTEM.

CHAPTER I.

GENERAL CONSIDERATIONS.

The diseases of the Nervous System in childhood present many difficulties. In early life the excitability of the reflex centres is normally in excess; and can even be heightened by causes which rapidly modify the general nutrition of the body. ('onsequently slight irritants may give rise to symptoms of tumult in the nervous system which are out of all proportion to the apparently trifling character of the lesion which has produced them. On account of this excessive irritability of the nervous system many pathological states in the child express themselves by convulsive movements which in the adult are accompanied by much less striking symptoms. In the young subject signs of nervous disturbance may arise quite independently of actual disease in the nervous centres; and the apparent violence of the commotion is not influenced by the seat of the irritant, and bears no proportion to the severity of the lesion of which it is the expression. Indeed, the same violent spasmodic movements may be the consequence of lesions so various in situation and in gravity, that in a case where such symptoms are noticed it is often by no means easy to discover the position of the irritant or to say at first whether or not the nervous centres are free from disease.

In children investigation of disease of the cerebro-spinal system is carried on by means exactly the same as are employed in the case of the adult. As, however, the young child cannot describe his sensations we have to trust much to objective symptoms, and are dependent upon the memory and observation of others for important information as to peculiarities of manner and changes in temper and disposition.

Of the symptoms to which cerebral disease gives rise some are peculiar to a centric lesion, while others are present in every case of nervous disturbance, however it may have originated. In every variety of acute illness in the young child the impressionable nervous system shows signs of distress. This is well seen in a case of acute indigestion. The skin becomes burning hot; the child is restless, cries and talks widly; he twitches and starts in his uneasy sleep and, if an infant, may be violently

convilsed. These symptoms indicate nervous disturbance but are not dismetive of cerebral lesion. So, again, a child may scream out with pain, and frequently carry has hand to his forehead or ear, without his headache

emr necessarily a sign of disease of the brain.

There are other symptoms which are more directly indicative of cobral origin; but which may still be present without owing their rase to any discoverable lesion of the nervous centres. Thus, squanting is a sgn waich should always be viewed with great suspicion. It is frequently mesent in convulsious, whatever their cause, and may even continue after the mercous serzure is at an end without being necessarily a sign of anything more serious than derangement of function. Sometimes the defect because a permanent one, and yet after death from some accidental cause a metanorican examination of the body discovers no lesion within the skull. Madagnus is not therefore necessarily a grave symptom. Still, it is so frequently a consequence of serious disease of the brain and membranes Uni its persistence after a convulsive attack should always give rise to unseness. An external squint, when it occurs without having been preedel by spannishe movements, is often a sign of pressure upon the corre-roading crus cerebri, and may be an early symptom of cerebral tumour. Statusmus may, however, occur as a consequence of hypermetropia; and a intermittent squart is not unfrequently a symptom of chronic digestive derugement. Therefore, in all cases, careful search should be made for further evidence. In the case of cerebral tumour external squint is usually secreted with ptosis and dilated pupils; headache and vomiting will troubly have been complained of; there may be tremors or spasmodic waterents in other muscles; the sight is often impaired, and an ophthalto-copic examination may reveal the presence of optic neuritis.

Vistaginus, or small consensual oscillations of the eyeballa, very often interest the presence of cerebral disease. It is common in the second and thard stages of tubercular meningitis, and is then accompanied by stere and obvious symptoms of intra-cranial mischief. It is not unfrequently seen in chronic hydrocephalus and even in simple ædema of the brain, and is sometimes present as a consequence of cerebral atrophy. It cases of tumour of the brain nystaginus often precedes paralysis of the arise muscles as an early symptom of a growth within the skull. Nystaginus is not, however, always a consequence of cerebral mischief. If it recurs in an infant in whom no other sign of nervous disturbance has seen noticed it should suggest a congenital cataract; for this lesion if left intratact is apt to induce oscillatory movements of the eyeball from alterate contractions of the recti and oblique muscles of the eye. Even in object children the symptom may be due to a congenital cataract which has been overlooked. In rare cases nystaginus is the consequence of a local

chorea.

The condition of the pupils should be always noted. During sleep in a healthy child the pupils are contracted but they dilate when the child sakes up. They are contracted in the early stage of meningitis, either the simple or tubercular form, and are also small if opium has been administered in too large quantities. In the later stage of meningitis and in main forms of cerebral disease the pupils are large and equal. If they are sliggish and contract imperfectly or not at all under the influence of light, the ugn is a very grave one. If they are unequal on the two sides, the eyes themselves being perfectly free from disease, we can have little hope of the patient's recovery.

impairment or loss of sight is another symptom of importance. In

tumour of the brain it occurs early, and if combined with headache ad vomiting is very characteristic of a cerebral growth. It is often observed in meningitis and in thrombosis of the corebral sinuses. In these cases optic neuritis may perhaps be discovered by the ophthalmoscope

Debrium in the young baby is indicated by sudden screams, stand-the eyes, and a frightened look. In the older child by restlessues a random talking, as it is in the adult. The symptom is comparated rarely the consequence of cerebral disease, although it may occur in every of tubercular meninguis. As a rule, debrium in the child is evidentifier of digestive derangement, of the febrile state, or of some above condition of the blood such as obtains in the acute specific fevers. In comparation of the blood such as obtains in the acute specific fevers. In exceptional cases a transient delirium may be due to mere weakness, at may be seen on the subsidence of pyrexia at the end of an attack of subfebrile disease. In such a case it disappears at once when the class spoken to and he answers perfectly rationally. Early and pronounced delirium, accompanied by a high temperature, is very commonly indeed by croupous pneumoma; and in any illness beginning with such scale toms it is to this disease that our thoughts would naturally turn.

Procesiness, with dilated pupils, passing into super, is often a signal intra-cramal mischief. After a fit of convulsions from reflex irritation are child may be drowsy for an hour or two; but unless congestion of the brain have supervened and effusion of fluid have taken place into the state cavity, it is a symptom which in such a case soon passes away. If the frare frequently repeated, and in the intervals the child is heavy and store, with large singuish pupils; if he takes no notice of familiar faces, and especially if the temperature is high, and there are signs of headache, the

case is probably one of meningitia

It must, however, be borne in mind that drowsiness approaching we to stupor may be present without being due to a cerebral lesion. Certain cases of pneumonia in the child are accompanied by stupor without the temperature being extraordinarily elevated, and may give rise to strong suspicions of cerebral disease. In such cases there is often little to attract attention to the chest, and all the symptoms point to the brain as the partiaffected. So, also, at the beginning of certain fevers, in urienna, and continues to some cases of severe gastric disturbance there may be great drowsing.

and stupor, although there is no lesion of the brain.

Loss of consciousness is not easy to detect in infants. The popular tests the capability of recognising a familiar face. If the baby no long "takes notice," he is thought to be unconscious. But it must be remembered that impairment of eight is an early symptom of tumour of the brain, and may be present in other forms of cerebral disease. A child therefore, may cease to recognise objects and faces because his eight and not his intelligence is defective. In all cases of unconsciousness or supposed unconsciousness it is important to notice if the child still takes lapposed unconsciousness it is important to notice if the child still takes lapposed unconsciousness it is profound, or if he is suffering pair the head or elsewhere, refuses his food; while, if he is only stupil as drowsy, without being completely comatose, and is in no pain, he we often take his bottle with avidity. In corebral homorrhage and serveffusion a child sucks well from the bottle. When he is tortured with each or abdominal colic, he refuses all food while the pain lasts, and child suffering from meningitis can only be fed with great difficulty.

Changes of temper should be always inquired for. At the beginning of many cerebral diseases the child often seems unaccountably wayward at capricious. He is fretful without cause, or spiteful, or sullen and more

These symptoms are not, however, confined to cases of brain affection. The same change is often noticed in chronic abdominal derangements, and have be a symptom of epilepsy.

Termore, spasme, and paralysis are symptoms which derive their value

from the connection in which they are found.

Tremors are sometimes a result of mere weakness, as when they occur is the late period of typhoid fever. In such a case they are general, and the condition of the patient is one of extreme debility. When they result from cerebral disease they are often confined to one limb or to a group of susseles. In such a case, if they are repeated, and occur always in the same part, they should excite suspicious of tubercle of the brain. If the thraical, they would suggest disseminated sclerosis, although this is a care disease in childhood.

Systems or conculsive movements, both clonic (intermittent contractions) and tonic (persistent contractions) may be general or limited, like the tremors to one side of the body, to a group of muscles, or even to a single muscle. As a result of cerebral disease they are often so limited. Thus, if a child be subject to epileptiform convulsions which affect exclusively one half of the body, some lesion (often a mass of cheesy matter) may be suspected in the opposite hemisphere of the brain. Still, a general consulsion, as has already been remarked at the beginning of this chapter, is necessarily a sign of disease of the brain; for in certain subjects a term trilling and passing irritant is able to induce it. This subject is treated of at length in a separate chapter (see Convulsions).

Paralysis is commonly a consequence of disease of the brain or spinal cord; but even this symptom may be sometimes referred to a less serious origin. Thus a temporary loss of power may follow a severe and prolovinged attack of convulsions, and is then attributed to exhaustion of nerveforce as a consequence of the seizure. This form of paralysis soon passes
off. If it persist for a week or longer, it is probable that a lesion of the
brain has actually occurred. Again, facial paralysis may be the result of
causes acting upon the facial nerve after its point of exit from the temporal bone. An infant may be born paralysed on one side of his face
from pressure of the forceps upon the trunk of the nerve; and in older
challen rheunatic inflammation of the nerve-sheath from a chill may be

followed by the same deformity.

Even paralysis due to cerebral or spinal disease is not always permanerat. When the patient survives, power in the affected limbs is often recovered more or less completely. Thus, paralysis due to myelitis affecting the anterior cornua of the spinal cord (infantile spinal paralysis), at first very extensive, may be found in a few days or weeks to have limited itself to one limb, or even to a single muscle. Again, a paralysis from carefully humorrhage is often recovered from if the child survive; and the mixturous form of paralysis which sometimes follows an attack of diphtherin generally passes off completely after a time. The loss of power is often very partial, and affects special muscles. In cases of cerebral tumour it may be limited to the muscles of the eye or face.

The various forms of paralysis in children which result from clot, embolism, or other shock to the brain, are usually accompanied by aphasia. With regard to this symptom it may be noted that loss of speech is of less value in early life, as indicating the seat of the lesion, than it is held to be in the adult. Indeed, in the young subject aphasia may be present although the brain itself is free from disease. It must be remembered that in a child of five or six years old the power of talking is a comparatively recent ac-

complishment, and that the utterance of any but the most simple requires a distinct intellectual effort. In many weakened state body—whether produced by general disease or special injury to brum—the necessary effort cannot be made. Consequently, any the system will in many children take away for a considerable

faculty of articulate speech.

Registry may be noticed in the affected parts. If the paralysis manent, rigidity and contraction may eventually ensue. Rigidit ever, is often a neerely temporary phenomenon which affects various and comes and goes irregularly. This is often seen in cases of to meningitis. Other forms of rigidity of the joints are seen in children contractions may occur in the extremities from reflex disturbance nervous system (see page 274); the limbs may be the seat of specify from disease of the spinal cord; and in girls of ten or two old the so-called hysterical contractions of the joints are by a rare.

A common form of rigidity is that which affects the muscle nucha and causes retraction of the head upon the shoulders. The tom is a common one in cases of cerebral disease, and is a certain intra-cranial lesson. Mero stiffness of the neck is not here related the many be due to many causes, such as cervical carries, rheumal In the retraction of the head so often induced by brain affection is drawn backwards upon the shoulders by rigidly contracted in the back of the neck. This condition may be associated with rightness, epileptiform fits, and hydrocephalus. It is often due to be ingited and may be the consequences of mere distention of the ventricles with fluid. It is a grave symptom, although not necessarily approximately approximately.

Besides the symptoms connected especially with the brain, or rived from disturbance of distant organs may furnish signs not to lected of a cerebral origin. So great is the sympathy between the organs of the body in early life that disease in the central nervoor is invariably associated with more or less general disorder of functions.

Comiting is rarely absent in cases of cerebral disease. It has only after meals, but at other times; and when retching occur empty stomach, or is excited by merely raising the child up from it is a very characteristic symptom. Constipution, also, if obstitutes a very characteristic symptom. Constipution, also, if obstitutes in a child in whom gradual failure of health has been noticed suspicious of tubercular meningitis. Even the amount of tensor abdominal wall is a matter not to be disregarded. In tubercular gits the softness and loss of elasticity of the parietes is sufficiently to the touch, and at the same time the wall is depressed and retrigion.

The state of the breathing must be noticed. In many forms lesion the respirations become very irregular, and this alteration of may be sometimes a very important sign. In tubercular mening civily, great irregularity of breathing, with frequent sighs and o long pauses during which the chest-walls are not seen to move, is a

[&]quot;It is important not to confound the involuntary contraction of the head for contracted muscles with the voluntary bending back of the head which is fairts who are suffering from the pressure of an absects upon the larynx is are accompanied by livility of the face and urgent dyspnia; and a swelling the folt at the back of the pharynx.

be to diagnosis when the nature of the disease is doubtful. There is a peaker form of breathing, called from the writers who have drawn attention to it the "Cheyne-Stokes' type, which, although not peculiar to cerebralise so, is yet often noticed in such affections. It consists of a series of my rations gradually increasing in depth and strength, and then as a tenly diminishing until the movement of the chest-will is hardly personal. There are many theories as to the pathology of this peculiar requirement. In most of them a supposed diminution in the excitability of the assuratory centre is a prominent feature. This type of breathing is sten associated with headache and delirium, and may be found in disorters of the heart and kidneys as well as of the brain. Still, when it is touch that ever be the disease, some nervous complication is usually to the disease.

Information can also be derived from the state of the circulation. In the exter period of meringitis the pulse often falls in frequency and at the more time becomes intermittent. If a child with a temperature of 102 have a pulse of 70, especially if its rhythm be irregular, we should suspect the resence of tubercular meningitis. It must not be forgotten, however, the slaw pulse is not uncommon in children during convilescence from the disease, and that this slow pulse may be irregular or even completely turned at times, especially during sleep. We must not, therefore, attach to great importance to this symptom alone, unless the temperature be

beard, and the child's state be one to excite anxiety.

Arun, a remarkable modification in the vascularity of the skin is often to an assort subscream meningitis. The child often flushes up sudscir, and slight pressure upon the skin, especially that of the face, the base on and the front of the thighs, produces a bright redness which remarks many minutes. This cerebral flush (called by Trousseau, who has less attention to it, trene o'ribrates, although perhaps more vivid and pussent in this disease, is yet not peculiar to tubercular meningitis. It tau be often produced by gentle pressure in sensitive children, especially fluer are the subjects of pyrexia.

In the cases of paralysis in the child a careful examination should be bale of the heart. Children, like their elders, are subject to embolisms, a 11' saiden hemaplegia occur in a child who suffers from valvular disease of the heart, we have reason to attribute the paralysis to this cause.

lastly, the state of the urine must not be forgotten. Come and contains from Bright's disease are not uncommon in children. If, in such access oslema, however slight, be discovered, and an examination of the aver reveals the presence of albumen, we can have little hesitation in

walning the pervous symptoms to a toxic cause.

In make a complete examination of a young child in whom we suspect the custone of a cerebral lesson, all these points should be taken into constitution. In addition, it is important to study the face and expression of the patient, for by this means we may often exclude serious disease. A time g child who has just had a fit seldom looks ill—that is to say, his has not the weary, haggard look which severe acute disease imprints as from the first. If the child's face looks pinched and distressed we have sure, however apparently trifling the symptoms may be, that the has a serious one.

In connection with this subject of nervous symptoms in children it is most to remember that in them even in children three and four Par 41 -we must be prepared occasionally to find the peculiar functional discreters of the nervous system which in the adult are called hys-

teria. These disorders are found both amongst boys and girls, and have no necessary relation to puberty or the establishment of the catamental function. Sensitive children, if frightened by the shock of a fall or other nervous impression, may be seized with convulsions of hysterical type and have various modifications of sensibility of the skin, combined, perhaps, with impairment or disorder of motor power. Aphonia, blindness, deafness, anaesthesia, analgesia, hyperesthesia, rigidities, and paralyses may be all met with from this cause. It is possible that in some of these cases the child is addicted to excessive masturbation, and some instances have been published in which there can be httle doubt that debility and exhaustion of nerve-power induced by this means were the cause of the nervous disturbance. Often, however, there is no reason to suspect any such agency. The patient is a strong, healthy-looking child with firm muscles and well-developed limbs. In not a few such cases the derangement can be referred to a fright or other shock to the nervous system.

Cases illustrating these various conditions are published from time to time in the medical journals, and all busy practitioners must occasionally meet with them. They are usually readily cured by the application of a

moderate galvanic current.

The diagnosis is not difficult. The decangement being purely functional, no nutritive changes can be detected. Thus the paraplegic child has full, firm limbs with no sign of muscular wasting. In the child who professes that he cannot see, and gropes his way like a blind person, the retina shows no change to the ophthalmoscope, the cornea is bright, and the pupils contract normally. Moreover, in almost all instances we may suspect the mature of the case, partly from the character of the symptoms themselves, partly from the general appearance of the child, and partly from the absence of other signs of serious organic disease.

CHAPTER II.

LARYNOISMUS STRIDULUS.

Larvoysurs strategies (child-crowing, spasm of the glottis, internal convision) is very common in England. The complaint is a form of convulsive source which is limited to the muscles of respiration. Sometimes it affects exclusively the muscles of the glottis; in other cases it may implicate also the disphragm and other muscles concerned in breathing. The disorder must not be confounded with laryngitis stridulosa, in which there is inflymmation of the glottis with spasm superadded. Laryngismus, as it affects the vocal cords, is a pure spasm, arising, as other spasmodic attacks are so apt to do in the child, from reflex irritation.

Consistion. The complaint may be met with under two different conditions. In new-born infants in whom no other deviation from health can be observed, and in rickety children between the ages of six or eight

months and two years.

The spasm appears to be predisposed to by foul air and hot, ill-ventihted rooms. It is a remarkable and suggestive fact that the disorder is essentially a winter complaint, being prevalent when windows and doors are kept closed for the sake of warmth. It is rurely seen in summer, when every window is open to admit the air. Still, the derangement may occur wit hout our being able to attribute it to any impurity in the air. In these

to the individual infant,

Few writers now hold the opinion that laryngismus is the result of pressure upon the vagus or its branches by an enlarged thymus gland. Were this so, cases of laryngeal spasm would surely be much more numerous thran they actually are. Moreover, M. Hérard has reported that in six chaildren who had died from this complaint, the size of the gland presented that liter who had died from this complaint, the size of the gland presented that liter was impossible to connect it with the produce that pressure of the faryngismus from which they had suffered. It is equally like probable that pressure of any other kind set up on the pueumogastric or it is recurrent branch can produce the disorder. The effects of such pressure the case of unlarged bronchial glands are well known. Hoarseness of the case of unlarged bronchial glands are early symptoms, and if spasm is it as lined it occurs, usually, at a late period, when the existence of the discussion is beyond a doubt. Spasm occurring alone without warning, and as the dealy subsiding without other syn ptoms being noticed, is not a characteristic of enlarged bronchial glands.

The association of laryngismus with rickets is indisputable. It was first pointed out by Elsusser, and was dwelt upon by Sir William Jenner in his lectures on rickets in 1860, and more lately by Drs. Gee and Henoch. For many years I have paid attention to this matter, and can call to mind but few cases of laryngismus occurring after the age of six months in which the child was not rickety in some degree. It is important to remember, in in-

restigating this point, that the patients do not always show a marked degree of rickets. They may do so; but as often, perhaps, as not, the child is fat, although pale and flabby-a big child, although a weak one. This connection with rickets-a disease in which the irritability of the nervous centres is known to be exalted—as a strong argument in favour of the reflex origin of the spasm. It also serves to explain the cases where many children of a family have suffered in turn from the complaint; for when a first child is rickety the others who are brought up under similar conditions usually hecome so too. Moreover, the tendency to laryngismus is often combined with a tendency to tonic and clonic spasm. In the same family one shild may suffer from spasm of the glottis, another from general convulsions; or in the same child attacks of larvngismus may alternate with general eclamptic seizures, or may even be complicated by them. That the latter disturbance is often a pure neurosis is universally conceded; it seems therefore, needlessly creating a difficulty to search for a different explanation for the former. Still, many other conditions have been said to be capable of causing the complaint. Various lesions of structure connected with the cerebro spinal system have been discovered in children dying in a spasm, and in all of these cases a connection has been supposed to exist between the symptoms observed during life and the morbid appearances found in the dissecting-room. Thus the laryngeal trouble has been referred to chronic hydrocephalus, to exostosis in the skull cavity, or to actual pressure of the pillow upon a softened occiput. It seems highly probable that in all these cases the special pathological condition has been a pure coincidence, or at any rate has had only an indirect influence in inducing the nervous commotion. That no evident tissue change is recded to excite a perfect and even fatal spasm is proved by the numerous cases on record in which, after death in laryngismus from apmea, no lesion of the cerebrospinal system or of the glottis could be detected. It is equally certain that under ordinary circumstances intracranial inflammations and effusions do not produce spasm of the glottis, and there is no evidence that pressure upon the substance of the brain or spinal cord will have any such

The exciting cause of the seizure is usually some peripheral irritant, as in the case of reflex convulsions. There may be disorder of the digestion or other unitation of the stomach or bowels, or a swollen, tense gum. The child may have been exposed to a sudden chill, and according to Herech cold and catarrh of the air-passages are the most frequent source of this form of reflex irritation. In the few cases which have come under my notice of laryngismus attacking a child some time after birth where symptoms of rickets were completely absent, the spasms appeared to be due to slight larvingeal estaith occurring in a nervous, sensitive child. I was asked sen.e. time ago to see a healthy baby, seven months old, who had cut two teeth and was cutting his upper incisors. The little boy was peculiarly precocious, and had the bright, intelligent face of one twice his age. There was no enlargement of the ends of the bones or other sign of rickets. The child was brought up at the breast, and his general health was good although his bowels were habitually costive. Some days before my visit the child had eaught cold and had begun to cough. His voice also had been husky. Since that time he had alarmed his parents by occasionally making a noise in his throat "like the crowing of a cock." He did not suffer from dyspuces, nor was there any lividity of the face. The sound was evidently due to a slight spasm of the laryax, which passed off almost immediately and seemed to cause little inconvenience to the infant himself.

The chill's lowels were attended to and he was given half a grain of

and twice a day. The symptom then soon subsided.

In cases where there is great irribibility of the nervous system cough er on swall-wing may induce a paroxysm. Anything which frightens or emates the patient may produce the same result. Thus in a young child sh is subject to the attacks a fit of crying may bring on a seizure. Section 3, again, the complaint is a relic of pertussis, the spasm remaining at sigh the other symptoms of the disease have passed away.

S - plons. - We may often notice in rickety babies an occasional crow corak in their breathing which seems to cause them little or no inconnamete. In some children this symptom may continue for weeks and the disappear without being followed by anything more serious. In others, after it has continued for some time the child is suddenly seized

and a decided attack of laryngismus stridulus.

la a pronounced form of the seizure the child becomes all at once we staring, and his expression haggard and frightened. After a few see. Is the spasm relaxes, the breath is drawn in with a crowing or was langual; often he goes to sleep.

la the more severe cases the spasm is repeated several times at short intervals. Still, actual closure of the glottis is seldom prolonged beyond a few seconds. There is no pyrexia. At the end of an attack the child often counts, and sometimes he has a good fit of crying.

The above is the simplest form of the complaint—that in which the

species is limited to the muscles of the glottis. Even in these cases, how-THE MELIN Of tonic spanns in voluntary muscles are often to be detected. The fagers are forcibly elenched upon the thumbs, and the toes are flexed where the feet. This tendency to carpo-pedal spasins may continue bets on the attacks and even for some little time after the seizures have cased to appear. The number of the spasms and the frequency with and they are repeated vary considerably in different cases. Generally 31 attacks are not very frequent at first, and sometimes after occurring stral times they cease to appear. But if the child be the subject of thed rickets he seldom escapes so easily. The seizures, having once be.us, sooner or later return. In the beganning they may be seen at experience or intervals, and perhaps only after waking from sleep, or then the chall is irritated or frightened; but in bad cases they may new so frequently that the patient is in constant peril. Dr. Roberton has alerred to a case in which the spasms were not absent for more than by minutes, day or night, for ten months. Sometimes they cease complates for a time, but return at the end of some weeks, or even months, * a sufficiently powerful exciting cause is again in operation.

As an illustration of the length of time during which these attacks this continue, I may instance a little rickety boy, aged twenty months, The was an in-patient under my care in the East London Children's Hos-Nine months before the clubt had an attack of whooping-cough the the cough had subsided the bryngeal spasms still continued, and of the repeated eight or nine times in the twenty-four hours. He tal ben treated as an out-patient three months before admission with benefit, for the paroxysms had been greatly reduced in number, at they returned on the slightest provocation. If by any chance he of he always had an attack immediately. During the first few days after singuston the child had three paroxysms daily. In these attacks,

which came on quite suddenly, his lips turned blue, his breathing was excessively difficult, his inspirations were croupy, and his whole body was agitated, although there was no general convulsion. Then the spasm abruptly relaxed and he heaved a deep sigh. After the seizure he was always very pale, but the breathing was natural and there was no hourse-tiess. The child had all the signs of well-marked rickets. He had only tax teeth; the joints were large; the fontanelle was open; the ribs were very soft and the lower part of the thorneic wall receded deeply at each breath. The spleen was enlarged, reaching nearly to the level of the navel. There were no signs of swelling of the bronchial glands. The child's bowels were loose and his motions very offensive. There was no fever. In this patient the spasmodic attacks were cured almost immediately by

bathing him three times a day in cold water.

A more complicated form of the complaint is that in which the spasm is not limited to the glottis, but involves also the disphragm and other respiratory muscles. These cases assume much more the characters of general convulsions, for there is often more or less tonic spasm of the lumbs, and consciousness may even be interfered with. Thus the child hes backwards with dusky face, hulf-opened evelids, and upturned eyes; breathing is laboured and inspiration difficult and crowing; the diaphragm acts irregularly; and there are often convulsive contractions of the muscles, causing profound recession of the lower ribs and soft parts of the chest. Sometimes for a few seconds the glottis is completely closed; the face then becomes lead-coloured, and the limbs are agitated by convulsive movements. According to Rilliet and Barthez, the pulse is small, frequent, and irregular, and the heart's action also irregular and tumultuous. If the child be markedly rickety a general eclamptic attack may supervene, or there may be tonic contractions of all the voluntary muscles, the body becoming stiff, the limbs contracted, and the fingers and toes forcibly flexed

In new-born infants, on account of the feebleness of the child—for it is in weakly or prematurely born infants only, as far as I have noticed, that laryngismus occurs so soon after birth—the symptoms are quieter. In the cases I have seen crowing-breathing was absent. The hips were noticed to turn blue and the face to become livid; the baby stretched himself out suffly and remained for a few seconds perfectly motionless, with flexed fingers and toes. There was complete immobility of the respiratory muscles, and he seemed as if dead. Then he drew a deep sigh and the attack was over. In these cases the spasm appears to be seated in the diaphragm and external muscles of respiration, leaving the glottis unaffected; for no symptom is noticed of narrowing of the rima. Obstruction to breathing seems to be complete. The seizure is abort and rarely lasts longer than five or at the most ten seconds.

In an uncomplicated case of laryngismus stridulus, i.e., in a case where the complaint consists of pure muscular spasm, there is no fever. Sometimes, however, laryngismus complicates an attack of pneumonia. The temperature is then high. These cases are very serious and usually end

fatally.

Even in an uncomplicated case death may ensue. If this happen during a paroxysm, the face assumes an expression of the utmost terror; the eyes are widely open and suffused, the pupils are dilated, and the eyeballs seem to project; the complexion grows more and more dusky, sweat breaks out on the forehead, and the pulse grows feeble and small. Inspiratory efforts are at first violent, then cease; the heart stops, and the child falls

ack dead. Death may be preceded by general convulsions. This is the solt of asphyxia from too long-continued spasm of the inspiratory musses. According to Dr. J. Solis Cohen, incarceration of the opiglottis is pt to occur in the more violent paroxysms, and may produce death by affection. The epiglottis is drawn forcibly down by the spasmodic action the ary epiglottidean muscles, and its free edge is cought between the location face of the laryax and the wall of the plaryax, so as to cover the base has a lid and completely occlude it. In such cases it can be felt by being a passed deeply into the child's throat. Sometimes death takes have still more suchenly, and the end then resembles an attack of fatal troops. The dusky face assumes a ghastly pailed hue, the muscles generally relax, and the patient is found to be dead.

In other instances, where the seizures have been violent and persistent, spend, of they have been complicated by general convulsions, the child in he more slowly. In most of these cases extensive collapse takes been the lungs. The spasmodic symptoms subside but the child's face things dusky. His has are blue, his nostrils work, he has very quietly be that with rapid, shallow inspirations which expand the chest very importantly; he gets more and more hvid, and after some hours dies quietly

a a and convulsion.

Sillen death from asphyxis may take place early, even it is said in the second tree. The slower death from collapse of the lung is seldom seen that it severe cases where the child is exhausted by repeated and violent problems, or where the complaint has been complicated by general continue. In mekety children who are left untreated for that disease the procedure as long as the faulty nutrition to which the disorder is to make unremedied. The seizures may therefore go on for months, the parent we are ignorant or careless, and the child is becausely reared. In ordinary cases the patient is treated early and the recovers. Children after the second year rarely suffer from the complete. I have, however, met with it once in a rickety little girl of four and all rears old.

In new-born babies laryngismus, especially if it be of that the ty which is manifested by spasm of the diaphragm and intercostal we without closure of the glottis, may be mistaken for infantile tetative. We may distinguish the two diseases by remarking that in laryngistic the temperature is normal, and that between the attacks the muscles is presently relaxed. This complete relaxation of the muscles is the most transmitty distinguishing mark, for the temperature in very young children may be raised by many triffing and temperary conditions. Sometimes, owever, there may be a more serious complication that gives rise to take. Thus I once saw an infant of two weeks old who suffered from the attacks, and in whom there was pyrevia dependent upon pericarditis

the copions offusion into the sac of the heart.

In the clutchen the case may be mistaken for laryngitis stridulosa. In the the absence of fever is a very important distinction, if the distance of the absence of fever is a very important distinction, if the distance of quite uncomplicated. But children while cutting their teeth are expected for elevations of temperature from the natural process of larger and this in the subjects of rickets, who cut their teeth late, may believed for beyond the end of the second year. We should then be reful to satisfy ourselves that the gums are not swollen, and that there is standards or other complication capable of giving rise to fever. It have, the history and course of the two diseases are different. In largesmus the space comes on quite suddenly, lasts a few seconds or a

minute or two, and then subsides. Laryngitis is preceded by couch ad hourseness; the attacks of dysphera are much more prolonged, at descin the intervals the breathing is more or less oppressed, the voice have and the cough loud and clanging. Again, stridulous laryngitis is an action disease, while laryngismus strudulous is apt to take on a very scute commendaryngismus there are often tonic spasms or carpopedal contractions at the disorder is often complicated by general convulsions. In laryngismus are rare and tonic contractions are very rarely seen. Lest laryngitis stridulosa, as a rule, attacks children after the age at what they are most susceptible to laryngismus, and is not common in ulars under two years old.

Prognosis. In new-born infants the prospect is very serious for the attacks at this early age are very apt to end fatally. Persistent limiter the face or other sign of collapse of the lung is a symptom of very la-

gerous import.

In older children, if the spasm remains limited to the respiratory nascles, the prognosis is less serious than in cases where the convulsions a first local, afterwards become general. The percentage of mortality as been put very high by some writers; but statistics gathered from published cases alone are apt to be misleading, as only the worst cases as likely to be placed on record. The prognosis depends in great measure upon the strength of the child and the degree of rickets which may present. If there be much softening of the ribs and consequent interfrence with respiration, there is great danger of pulmonary collapse takes place, and the case is a very serious one. If, under these circumstates general convulsions ensue, the child's life is in very imminent dates. Even in the slightest cases we should speak guardedly of the patients chances of recovery.

Treatment.—If the child be seen during an attack, attempts should be made to excite vomiting by passing the finger into the fauces. Afterward a sponge wrung out of hot water may be applied to the throat under the clim. According to M. Charon, who first proposed the remedy, the inhelation of ammonia is almost invariably successful in arresting an attack. This physician advises all mothers whose children are subject to spass of the glottis to carry a small bottle of ammonia—ordinary "smelling sale about with them. He relates the case of a lady whose child was always

rapidly relieved by this means. Unfortunately one day the child was seized with an attack at a time when the remedy was not at hard and while the mother was hurriedly searching for it the child fell loss

dead.

If the suffocative spasm be very intense, it is well to thrust the first deeply into the child's throat, so that the epiglottis, if incarcerated, as described by Dr. Cohen, may be released. The seizure, however, in new cases, is over so quickly that there is little time to adopt measures for abridging it. But we can at any rate take steps to prevent a return of the paroxysms. For this object cold water bathing is indisputably the new important and most immediately successful. The child should be placed maked in an empty bath or large basin, and be then rapidly sponged over the body with cold water. In winter he may be made to sit as he water during the process. The bath should be given three times a lar Very few cases of laryngismus will be found to resist this treatment. I have used it in obstinate cases, and to children suffering from rickets, with the most satisfactory results. Next to cold bathing fresh air is of the greatest service. The child, warmly dressed, should be taken regularly

out of doors, and even in cold weather should spend many hours in the

While these measures are being carried out, search must be made for any source of irritation which may serve as an exciting cause of the pisms. Tense swollen gums should be lanced, the chetary must be repastructed upon sound principles, and the condition of the digestive with relaxed shiny motions. If this be so, a dose of rhubarb should be given, and the child should take for a few days five or six grains of bicarbonate of so,la dissolved in an aromatic water sweetened with glycerine. Of special drugs musk and belladonna are the most useful. The former can be given to a child of twelve months old in doses of one-third of a grain every six hours, and will be found to have a powerful influence in checking the tendency to spasm. Belladonna to be of service must be given in sufficient doses. A baby of twelve months old will take well fifken drops three times in the day. Mr. Stewart of Barnsley, speaks lighly of chloral in the treatment of spasm of the glottis, and recommais two and a half grains to be given to a child of twelve months old Lire times a day.

In new-born babies, for whom cold sponging is inadmissible, musk is a very unportant remedy. One-fourth of a grain can be given three times also, suspended in mucilage. It can be combined with ten drops of time-

ture of belludonna if thought desirable.

If the child is markedly rickety, iron and cod-liver oil should be given a son as the state of his digestive organs is sufficiently improved to make the use of the tonic desirable. Iron wine is, perhaps, the best form in wash that drug can be administered, for the alcohol it contains is an addition of great value to weakly children. Great care must be taken in these cases that the child is not overfed with farinaceous foods which continue hitle to his general nutrition while they overload him with unleastly fat. They are also very apt to turn acid in the stomach and favour cutarrhal derangements. No mention has been made of bromide of potassium for in this complaint I hold the drug to be of very inferior value, and place it for below musk in its powers as an autispassmodic.

18

CHAPTER III.

TONIC CONTRACTION OF THE EXTREMITIES.

Toute contraction of the extremities, or felany, is sometimes met with a young children, most commonly in the subjects of reflex convolution of laryngismus strictulus. The contraction occupies the muscles of the large especially those of the hands and feet, and may be continuous, remutes or intermittent.

Causation -Tonic contraction appears to be one of the many forus reflex disturbance to which rickety and excitable children are so permain prone. The disorder rarely attacks a sturdy subject. It is most comment met with in young patients whose nutrition is imperfect either from a judicious management or natural delicacy of constitution, and appears to be predisposed to or excited by digestive derangements and other form. of irritation. Thus a little girl of five years old, who had recovered upler my own observation from tubercular peritonitis, but had remained un delicate and hable to gastrie and intestinal troubles, one day small ment part of an orange. She was seized shortly afterwards with severe part in the belly, and passed a few loose, unhealthy motions. At the same unthe fingers became firmly clenched, with the thumbs inverted and the west flexed. In this state she remained for forty-eight hours, in space of active treatment by injections and laxatives. At the end of this time a age enems brought away a mass of orange pulp. The child was at once > lieved, and the rigid contractions of the muscles ceased from that moment Similar instances have been recorded in which a constituted state of the bowels has been a cause of the phenomenon, and other sources of diturbance and excitement, such as pleurisy, pneumonia, diarrhora, intestea, worms, the irritation of uric acid calculi, and teething have been quoted as exciting causes of this painful affection. The age at which children are most liable to be attacked is between the first and third year. The discoder is said sometimes to affect young girls shortly before pulerty, and a such cases is attributed on the continent of Europe, where telany seems to be more common than in this country, to the influence of cold and damp

Symptoms. A child who has been for some time in a weakly state, and is, perhaps, in the majority of cases, the subject of mild rickets, all at one cross with pain in the extremities, and it is noticed that these parts at contracted. Often the contraction is found to succeed to a fit of convisions or an attack of laryngeal spasm; but it persists after these are at an end. The muscular spasm may affect both hands and feet, or be noticed first in the fingers, and spread thence to the hand and wrist, the ankle and the toes. When fully developed the hand is found to be flexed at the wrist, and the thumb to be firmly inverted into the palm. The fingers may be rigidly elenched upon the thumb, or slightly separated and patterly straight except for some slight flexing of the last joint. The ankles are often extended and the toes firmly flexed. In a few cases reduces to swelling in the neighbourhood of the joints have been noticed. The case

traction in most cases seems to be painful. Infants cry repeatedly, and older children complain of pains shooting along the course of the nerves. The muscles are in a state of rigid contraction. In pronounced cases, not only can the muscles of the leg, such as the gastroneam and peronen, and of the forearm be felt to be firm, but the act of manipulating them increases their tendency to become rigid. Pressure may even induce tonic contractions in muscles otherwise free from rigidity, such as the pectorals, the muscles of the neck, and those of the abdomen. In a severe case recorded by Dr. Chealle—in a boy two years old—even the muscles of the face were in a state of abnormal excitability, fowirritation of the skin just in front of the left parotid region caused twitching of the orbicularis palpebrarum, the levitor also nasi, and the levator anguli oris. The same phenomenon was also seen, although to a less degree, on the right side of the face. There was, in addition, some difficulty in swallowing, especially

when liquids were taken.

When the attacks follow a convulsive seizure they may be accompanied by a temporary paralysis, such as is a not uncommon consequence of ectampsia (see page 280). Sometimes the contractions are more exten-Thus the muscles of the trunk are occasionally affected. Rilliet niers to the case of a delicate little garl, aged twelve years, in whom the tour rigidity of the extremities was accompanied by opisthotonos with extreme retraction of the head, and at times intermittent contractions kanted to the back were noticed, closely resembling tetanus in character. but the jaws were not affected, as they invariably are in that disease. The decoder lasted for a month. In other cases, according to the same autornty, the spasms may be more limited and affect the hip or one side of to neck. The disease appears to be more severe upon the continent of Las pe than it is in England. In the milder form common in this counby the contractions are invariably bilateral, and affect the corresponding missions of the two sides. As long as they continue, walking is impossible, al the child can hold nothing in his hand. In the slighter forms the contractions are remittent, and occasionally cease completely. In severe cases attle variation is seen in the rigidity, and it persists during sleep, East complete anosthesia from chloroform produces no relaxation of the tone spasm. Sensation is unaffected; reflex excitability is normal; the the positure is natural or even below the level of health and the child's satchigence remains perfect. In Dr. Cheadle's case the muscles responded ach to both the continued and interrupted current. The tonic contractions are rarely the only nervous symptoms present. Often they alternate with other forms of nervous spasm. The child may be subject to larvagismus stratulus, or may be readily thrown into convulsions by any passing irritation. In many cases, as has been said, the contractions succeed to some such form of nervous seizure, and sometimes an intermittent squint is noticed.

In most cases, in addition, symptoms of intestinal or other derangement are present. Diarrheaus one of the commonest of those symptoms, and, indeed, the nervous desorder has been known to disappear as the condition of the bowels improved. The duration of tetany is very variable. It may last a few days or persist for weeks. It usually becomes intermittent before it mailly disappears. After ceasing for a time it not unfrequently returns.

Degrees —This form of nervous spasm is readily recognised. Tonic contractions occur in a child whose nutrition is impaired either from injudicing management, from gastro-intestinal derangement, or from the recent presence of acute disease. Often he is the subject of rickets, and has already shown a tendency to other forms of nervous derangement. Tetany

is bilateral and symmetrical. It occasions no elevation of temperature of is accompanied by no clouding of the intellect. These qualities, control with the tendency to nervous spasm, and the evident connection of the start with some form of peripheral urritation, will serve to exclude cerebral scase. In the severe form, which is accompanied by opisthotonos and temperature and the condition of spasms, the history of the attack, the normal temperature and the turn absence of stiffness of the jaws will be sufficient to exclude tetazure.

Prognoss.—Tetany is merely a symptom which has no gravity that ever; and the prospects of the putient's recovery of health depend on a causes quite independent of the nervous spasm. As the children in what tetany occurs are often the subjects of a chronic intestinal demagnent and are in many cases distressed by frequent attacks of lary negations stately, they may possibly succumb; but in estimating the patient's charge of recovery the tonic rigidity of the extremities may be quite exclude

from our calculations.

Treatment.—Our first care in the treatment of this complaint must be to attend to any disordered condition which may be present interfent, with natrition, and acting as an irritant to the nervous system. Gastrointestinal derangements must be checked; constipated bowels must be relieved; the diet must be regulated to suit the needs of the system are Infantile Atrophy, Chronic Diarrhora, etc.); and if rickets be present, assures must be taken at once to arrest its progress. In all cases, add the general treatment recommended for laryngismus stridulus and robust viz., fresh air, good food, cleanliness, and the administration of free war and cod-liver oil, is of equal service in this disorder. Frictions and wars

baths seem also to have a beneficial influence.

In obstinate cases special steps are required to relieve the tonic right This form of spasm will often refuse to yield to measures which have the power of readily controlling the nervous disorders with which tetar is allied. Chloroform puts an immediate stop to an eclamptic seizus, but has no power of relaxing the rigidly contracted muscles of teta; and chloral which is so valuable in arresting the spasm in larrages and stridulus is given in this neurosis without any beneficial result. Bracile of potassium and musk appear to be equally useless. In Dr. Cheadles case, before referred to, chloroform, chloral, and bromide of potassium was given without any success; but the contractions yielded after the treatment had been changed to Calabar bean with cod-liver oil and iron was One thirty sixth of a grain of the bean was given three times a day dose was gradually increased to one-eighth before any effect was produced A notable diminution in the stiffness was then observed. Afterwards we dose was increased to one-fifth, later to one-fourth, and lastly to one-third of a grain three times a day. The boy was well seven weeks after beguning to take the remedy.

Although the bean appears in this case to have had a decided influence over the spasm, it must be noted that the child began at the same time to take iron wine and cod-liver oil; and that although the principal improvement occurred after the dose had been pushed to one-sixth of a grun, it followed two days after the important addition of pounded raw ment had been made to the child's diet. The Calabar bean, no doubt, descress a more extended trial in these cases of tonic rigidity. Still, in the interesting case referred to it is doubtful what degree of improvement can be controlly attributed to this remedy; for the alcohol, the cod-liver oil, and the improved diet must have taken a sensible share in bringing about the

child's recovery of health.

CHAPTER IV.

CONVULSIONS.

In commotion in the nervous system which goes by the name of eclamps, or a fit of convulsions, is a common phenomenon in infancy, and is maximes seen in early childhood. The seizure depends upon an examines seen in early childhood. The seizure depends upon an examines to either the reflex centres seated in the pons and medulin obtorate but is seldom attended by changes in those parts capable of being detected on examination of the dead body. The disturbance is essentially a suptem, and may be produced by a variety of causes. Irrespective, there of the immediate danger to life, the phenomenon may be of serious a next or of trithing consequence according to the cause which has induced it. It is, therefore, of great importance to ascertain its mode of our for only by this means can we speak with any certainty as regards the influence which the attack is likely to have upon the future well-

It is during the first two years of life that the tendency to this form of serious derangement is most active. At this period of childhood the ner-ton-watem of the infant, although immature, is undergoing rapid development, and the rollex centres respond briskly to every form of peripheral artistion. The tendency to echimpsia is not, however, confined to this acc. Convulsions may even affect the infant in the womb. Early death of the fetus and premature labour can be sometimes attributed to this mass and it is to this accident that some varieties of congenital deformity has been referred—those which are characterised by permanent contraction of special muscles. After birth the proneness to convulsions may continue for a longer or shorter time, according to the natural sensitiveness of the pervous system to external impressions. It is therefore much more present in some children than in others, and may endure in exceptional case to the ninth or tenth year.

tristion. There are certain conditions which predispose a child to conditions. Thus the liability to eclamptic seizures sometimes runs in tables, so that all the children born of certain parents are found to suffer to, these attacks. In other cases the tendency is confined to certain intuals of the family, or even to one sex. Thus all the boys may have nearly one while the girls escape. Again, in rickets there is a special product tendency which is very remarkable, and a large number of the of reflex convulsions are found to occur in children with this constitutional condition. When the predisposition—may induce the attacks.

Within certain limits the state of a child's nutrition does not appear to bet his susceptibility to convulsive seizures. A strong child and a weak may be equally prone to suffer from this nervous disturbance. When, werer, an infant is greatly reduced by long-continued interference with tration, a remark able difference is noticed in his sensibility to nervous measions. Not only is there no exaltation of reflex function, but the

normal excitability of the reflex centres is diminished or annulled. Therefore in a child so enfeebled convulsions are seldem of reflex origin, but usually indicate grave cerebral disease.

The exciting causes of the nervous commotion are very various:

True reflex convulsions arise from peripheral irritation. Injuries to the skin from pricks, burns, and wounds; irritation of the alimentary conal from indigestible food, hard freeal masses, or parasitic worms, of the gums from inflammation and swelling during the cutting of a tooth; of the ear from collections of wax, the presence of a foreign body in the auditory meatus, or inflammation of the tympanic cavity; retention of urine; sudden chilling of the surface from exposure; violent emotions, such as ter-

ror-all these causes may set up convulsions in certain subjects.

Irritation affecting the mucous membrane of the stomach and intestine. and according to some authors irritation within the ear, seem to be the most common exciting causes of reflex convulsions. In hand-fed bulius inducestion is a familiar occurrence, and the disturbance set up by a mass of undissolved curd or other critant may speedily culminate in an attack of eclampsia. Again, otitis is a more common disease of infancy than is usually supposed. It is often a direct consequence of dental irritation, and occurs with such frequency as to constitute one of the more common complications of dentition. According to Dr Woakes the inflamed and swollen gum is a source from which irritation is conveyed to the offe ganglion, and thence is deflected to the vessel supplying the tympanic membrane. Acute congestion of the membrane thus occasioned is a source of extreme pain; and if the irritation persist, suppuration in the tympanic cavity may follow. Inflammatory tension of the gum alone may set up the eclamptic attack; and the secondary disturbance in the ear is a fruitful source of such seizures.

Eclamptic attacks are common in the child at the onset of acute illness, and correspond to the rigor which usually introduces the febrile movement in older persons. These seizures must not be attributed directly to the pyrexia, for it is improbable that the mere elevation of temperature is sufficient to produce them. The more severe the attack and the younger and more impressible the patient, the more likely are convulsions to be seen. These attacks are seldem dangerous, but the eclamptic fits which occur at a later stage of the same diseases arise from a different cause and

Lave a far graver meaning.

Another class consists of the convulsions which are induced by imperfect airmaion of blood. These constitute the less serious attacks which sometimes arise in the course of pertussis after a prolonged paroxysm of cough, and often precede death in cases of extensive collapse of the lung

Congestion of the brain is often quoted as one of the causes of convulsions, and no doubt fatal fits of eclampsia are frequently associated with a hyperamic state of the cerebral vessels. The chief factor in such cases, both of the congestion and the fits, may, as Dr Bastian has suggested, be minute embolisms or thromboses in the small arteries and capillaries of the brain. In the fatal convulsions which sometimes abruptly terminate an attack of whooping-cough congestion of the brain is generally present, and is often dependent in such cases upon thrombosis of the cramal sinuses.

An exactly opposite state of the cerebral vessels may induce the same symptom. The analmia of brain which results from profuse hæmorrhale or exhausting discharges, such as an attack of acute diarrhapa, is often indicated by a convulsive seizure. It is, however, worthy of note that an equal degree of prostration slowly established by a chronic intestipal de-

rangement is not followed by the same consequences, the excitability of the nervous centres being then diminished instead of exalted.

Lastly, toxic causes may induce convulsive seizures. Uramic convulsions belong to this class, and also the eclamptic attacks which are common in children who live in malarious districts. Lead in the system may produce the same result. Infants seem to be very susceptible to the influence of lead given medicinally. I have long ceased to make use of this remedy in the treatment of the distributes of young children, as I have several times seen convulsions follow its employment, and the attack has appeared to me in some cases to be directly excited by the use of this agent.

Convulsions arising from cerebral disease have been omitted from the above classification, as partaking more of the nature of epileptic attacks that of true columpsia. Reference must, however, be frequently made to them in discussing the subject of convulsive sciences, for it is of the utmost importance in every case where a child is taken with a fit to be able

to exclude centric causes from consideration.

Symploms. - The convulsive seizures may come on suddenly or be preredel by symptoms of nervous excitability which are more or less obvious. Seek phenomena are often called by nurses "inward fits." They are not sarrably followed by a convulsion. Indeed, as a rule perhaps, they pass of after a time, especially if they are the consequence of digestive trouble, and the infant's placedity of manner returns. In other cases they become more and more pronounced, and culminate in an attack of eclamptic Thus the child is unusually disturbed in his sleep. He often sats and twitches. His eyelids may only partially close, and he wakes starting up at the slightest touch. When awake he is restless and It is senses seem unusually acute, so that loud noises frighten has He changes colour frequently. His face has a curious expression, the eyeballs are often directed upwards, and his thumbs may be twisted Man is across the palms. After these symptoms have continued for a rande time-often for several days-the child is all at once noticed to be musially quiet. He stares with a peculiar fixed look, and his attention must be diverted to his toys. Then, suddenly, the fit begins. The child * spute stiff, his head is retracted, his arms and legs are rigidly extended, to tree are turned upwards, and he ceases entirely to breathe. In a few words the tome rigidity is replaced by clome spasms. The face becomes thusely congested, the eyelids are widely open, and the eyeballs are have upwards and to one side, and are twitched rapidly in different direc-The muscles of the face work, the tongue may be seized and bitthe teeth, and froth, perhaps tinged with blood, may appear upon the 4s. The muscles of the limbs are thrown into the same spasmodic saten, and more or less pronounced twitching affects the arms and legs, boxetimes even down to the fingers and toes. Consciousness is completely lat. The skin is often covered with a profuse sweat, and in many cases the planeters are relaxed, so that there is involuntary passage of urine and During the clome spasms the breathing is not suspended, but the are jerking movements of the respiratory muscles. After some time the spasms become less violent. The face then changes from dusky red loa deathly pallor, the muscles relax, the child often gives a long sigh, the attack is at an end.

The specimodic movements are usually general and involve both sides of the body, although one side is often more actively convulsed than the sides. Sometimes they are partial, and may be limited to one or both habs on one side of the body, to the two arms, or even to one side of the

face. The eyes are almost always involved in the convulsion. The fit lasts for a time varying from a few minutes to several hours. In the longer fits there are intervals of more or less complete remission, and sometimes the so-called fit consists of a series of eclamptic seizures with short intervals of quiet. In rure cases death takes place in the fit from asphyxia. As a rule, the child sleeps after the seizure has come to a close, and may wake to all appearance quite well. When the fit is repeated several times the child is drowsy for a time between the attacks, but the sleepiness passes off in a few hours. As long as any signs of abnormal excitability of the nervous system continue, and symptoms characteristic of the condition described as "inward fits "remain, we may anticipate a renewal of the convulsive seizures. It is not until all restlessness, startings, twitchings, etc.

have disappeared that our apprehensions can be laid aside.

Some loss of motor power may be noticed after the fit is at an end, In cases of pure eclampsia this is a very temporary phenomenon, and only occurs when the seizures have been very violent and protracted. It is probably due to exhaustion of nervous power and disappears completely after a day or two. Any signs of permanent interference with nerve-force, such as local muscular weakness, contractions, or chorcic movements, are usually taken to indicate some organic central cause for the convulsion. It is possible, however, that these symptoms may be the consequence of the sezure; for severe corebral congestion induced by intense and protracted columnsia may give rise to he morrhage into the brain or arachnoid. Certainly I have known cases of convulsions occurring in children as a result of some temporary irritant to be followed by paralysis with contraction of muscle, and have thought that in such cases the cerebral lesion might have been secondary to the columptic attack. There seems little reason to doubt that sometimes congestion of brain, with serous effusion sufficient in quantity to flatten the convolutions, may result from an eclamptic attack, and give rise to squinting, drowsiness, and death.

A rickety little girl, aged twelve months, who had cut only two teeth, was quite well until January 7th, when she was weared. She then became very fretful and vomited her food. At the same time an cruption of small red spots appeared on her arms and face. On January 9th the child had two fits, in which she "went stiff and worked her arms about." On January

ary 11th she had a third fit and then began to squint.

When I saw the child, on January 17th, she was lying with her eyes closed; the right eye was turned inwards with convergent squint; the pupils were equally dilated, and acted well with light; there was no discharge from either ear; the face was pale, but flushed upon pressure of the skin; there was no paralysis or contraction; the thumbs were not twisted inwards, nor were the toes flexed. When the abdomen was compressed the child made uneasy movements. She was evidently not unconscious, but seemed drowsy. The heart and lungs were healthy. The child was preparing to cut the upper incisors, and the gums were very full and tense. Pulse, 160, regular; respiration, of Cheyne-Stokes type, 40; temperature, 99.

The patient was ordered a mercurial purge, and bromide of potassium was given; but the drowsness deepened into stupor, and she died on January 19th. Her temperature rose every night to 101. Half an hour

before death it was 99.4.

On examination of the body the dura mater was noticed to be very tense, and the brain bulged through slits in the membrane. There was great venous congestion of the pin mater, and the convolutions were flatand On removing the brain about two ounces of sanguinolent fluid are left at the base of the skull, and on section much fluid escaped from the lateral ventricles. Nothing but congestion of the brain was noticed. Ton was no loss of consistence; the membranes were not thickened, nor lattley lost their pearly appearance; there was no lymph effused, and no graginalistions could be detected. There was a mass of enlarged glands at the bifurcation of the trachea. The lungs and heart were healthy. Tabermattely the cranial sinuses were not opened.

In this case it seems clear that the post-mortem appearances were secondary to the convulsions. The nervous symptoms themselves seem to have been the consequence of reflex irritation from the state of the gums, and itself with irritation of the stomach from unsuitable food, both occurring in a child of rickety constitution. The red spots spoken of were

groundless, resulting from the indigestion

Sometimes loss of speech and even imbecility have been known to follow upon an attack of convulsions. In such cases, no doubt, some profound

calrd lesion has induced the fit or been caused by it.

by asset. In every case of convulsions we should examine the patient are carefully for signs of disease of the brain or its membranes, more carefully as the first question usually asked by the parents after their first customent and alarm have subsided relates to the possibility of any affective of the brain. In infants of twelve months old or under, if the child is fit as I robust, the fit is in all probability reflex; if he be under-nourised, acakly, and wasted, i.e., in that condition where all reflex excitability a practically in abeyance, the convulsion is no doubt the consequence of a unfractional lesion. In a weakly wasted infant by far the most common crosse of a convulsive seizure is general tuberculosis with secondary bearing menuncitis.

The character of the fit itself will give some indication valuable in diag-Desa Cerchril convulsions are often partial. Therefore, if the spasms are heatel to one si te of the body or one limb, we should search carefully for Ensil corebral disease. Paralysis of the face remaining after the end of at stack is indicative of a cerebral lesion. Thus, drawing of the mouth to or ale, ptosis, or inequality of pupils are symptoms never seen in true arough ated eclampsia. A squint persisting after the convulsion has Post off must be regarded with anxiety; for although not necessarily a symptom, it is often indicative of a serious lesion; and if accompanied by sens of heaviness, or tendency to stupor, must be looked upon as an salar anable omen Again, convulsions, general or partial, without loss of consciousness, should lead us to suspect disease of the brain. Another uncreant symptom is the condition of the child after the attack. In true compan consciousness is recovered quickly after the seizure; and if any howsness remain, it is over in a few hours. Signs of persistent stupor or alacss of the senses would point to a cerebral lesion. Mere temporary of power in a limb is no proof of centric origin; but if the paralysis betwee longer than a few hours or a day or two, especially if contraction muscle occur, we may conclude that some centric lesion, either primary secondary, is present. Even if unmistakable evidence of a cerebral lesion seen when the convulsion is at an end, it does not follow that the lesion withe cause of the fit. One consequence of eclamptic seizures is congesof the brain, and if the nervous attack be prolonged, serous effusions, d perhaps minute capillary hamorrhages, may occur and lead to alarming parquences A case in which death took place from this cause has raily been narrated.

It has been said that convulsions taking place at the end of the exathemata and other februle diseases are commonly attributed to embed congestion, although it seems probable from the observations of Dr Ratian that embolic plugging of minute cerebral arteries takes a large date in their production These attacks never come on except at an idensed period of the illness, when the state of the patient is evidently very areas and they quickly put an end to his sufferings. It is right here to master that a fit may be the first sign of secondary tuberculosis meningitis, when it occurs in the course of an acute illness, has its own early symptoms masked by those proper to the primary disease, and our reveals its presence by the more violent phenomena which are characteristic of the third stage of the intracranial lesson. Appearing in this ca -as a part of a general formation of the grav granulation all over the body—tubercular meningitis is not uncommon in babics of only 1 by months old. If, then, in a child of any age suffering from an acute uflammatory disease, such as an attack of acute catarrhal pneumonia, ctvulsions come on, we should strongly suspect tuberculosis; and if the time followed by squinting and irregularity of pupils, with or without rigiday of joints, we can speak confidently of the existence of tubercular inflammata in the skull cavity.

In cases where no serious cerebral lesion is suspected, it is importantly distinguish an eclamptic attack from an epileptic seizure. At the time that is impossible, for the state of the patient requires all our attention, and only to quiet the alarm of the relatives, it is urgent that something should be done. When, however, the subsidence of the spasms gives us lessured make inquiries, we should try to discover some source of irritation to with the convulsion may be attributed. We should look for signs of ricket-the condition which especially predisposes to eclamptic seizures—and in-

quire for any convulsive tendency in the family.

The age is of importance. Up to the time of completion of the first detition the disturbance is probably not epileptic; and if the gums are tensor hot, or the child has lately swallowed some unsuitable food, we may feel satisfied that the case is one of pure celampsia. Again, high feet not a characteristic of epilepsy; therefore, if there be pyrevia, the mais probably reflex, or is a nervous disturbance announcing the cost of one of the exanthemata or of an acute disease. But irrespective of these considerations, under the age of two years epilepsy is rare, while reflex convulsions and the other forms of pure celampsia are very converge.

In older children it is more difficult, often it is quite impossible, to evelude epilepsy. If, however, the fit is a prolonged one, and leasts for a hour or more without intermission, we may conclude that the attack a eclamptic, for the duration of an epileptic science rarely exceeds tou manutes, or at the most a quarter of an hour. When the urine can be of tirely it should be always examined for albumen, as urasmic convulsions in earlier are not uncommon. For the same reason the whole body should be carefully inspected for signs of pecling of the skin, as uncome convulsions towards the end of the desquamative stage of scarlatina are far from rate. The attack of scarlatina is sometimes so mild as to be overlooked by mattentive or unobservant parents; and even if it be known to have occurred, the past illness may be looked upon as immaterial to the present distribution, and may not be referred to. In all cases we must remember that after the age of three, or at the most four years, eclamptic attacks from reflex irritation are rare. Convulsions occurring in a child of this age, if

or due to epilepsy or cerebral disease, are generally either urremic or are

remuters of some neute febrile dise ise.

As long as any cause can be discovered for the attack the fit is probable clamptic. It is the convulsion occurring without evident reason at 13 so suspicious of true epilepsy; and if a child of four or five years it or upwards, be visited while in apparent health by such a seizure, we are pushed in fearing the beginning of epilepsy. It must be remembered, assert, that convulsive seizures, at first eclamptic, may pass into true pilepsy. There is no doubt that this does happen in cases where there is song neurotic inheritance. Where there is no such predisposition I have that epilepsy only follows in cases where the eclamptic attack has based a secondary cerebral lesson. In such a case, although the first tank or series of attacks, may have occurred as a result of some approximately, the after convulsions may arise without anything being discov-

nd to serve as an explanation of the morbid phenomenon.

Propose - Edampus is a symptom which may be serious or not acsort as to circumstances. In estimating the importance of the symptom remar consider the age of the child, the nature and severity of the atbet and the probable cause which has induced it. Infants of a few weeks Morten die even from purely reflex convulsions if the scizures are viobut Older children have a better chance of recovery. After the first for works of life much depends upon the cause of the attack. Purely res tots and the untial convulsions of acute disease rarely end otherwise the avoncably. Again, the convulsions which arise from imperfect acrader of the blood, such as may occur in pertussis, are often recovered from; but when the cause is collapse of the lung they are generally fatal. In set set however, convulsions may be of several kinds, of which some are Those due to cerebral congestion and throm-Eclampsia arising from congestion and amenia whe brain are especially serious, because they usually take place when Occurrent is already in a state of great exhaustion. When convulsions or reports the close of the cruptive stage of measles or scarlation, they we be looked upon as a very dangerous symptom. Ura mic fits often me away without producing serious consequences. Whatever be the wof the attack, stertorous breathing, great lividity of the face with Haves of the nails, or a very rapid pulse should excite the gravest ap-Post-rous. As a rule, the prospect becomes more unfavourable in proportion to the rapid succession of the eclamptic seizures and the severity The occurrence of a large flow of urine, according to M. in a is a sign of good omen, indicating that the convulsive movements or along to cease,

b consulsions from cerebral disease it need not be said that prognosis as at unfavourable; and if the fits are followed by stupor, squinting, or relative and sluggishness of the pupils, we can have little hope of the

Ment a rescurery.

The influence which the attack is likely to have upon future brain-dependent is a point of importance, and much anxiety is usually manifested a the subject by the child's relatives. In the commonest case, that in the attack to be usually unimportant; and familiar as is the experimentary to be usually unimportant; and familiar as is the experimentary when the patient to suffer from any after ill-consequences. So in the case of the other forms of purely reflex convulsions, the chapter sequence is due to some temporary condition, or set of conditions, that may pass off, if the child survives, leaving the brain unharmed. If,

however, the patient belong to a family in which nervous disorders are common, convulsive serzures assume greater agnificance. If the attacks are often repeated, the prospect as regards the mental development of the child is unfavourable, for such cases may end in epilepsy or even idiocy. In all cases, too, where the convulsions are connected, either as cause or effect, with some intracranial lesion, and where they are followed by signs, more than merely temporary, of muscular weakness, there is no doubt that for the time the brain is injured by the illness. In cases of recovery especial care would then have to be exercised in the child's education so as not to

put too great a stmin upon his faculties.

Treatment. When called to a case of convulsions the practitioner should lose no time in questioning the attendants, but should at once have the child placed in a warm bath of the temperature of 90 Fah., and apply sponges dipped in cold water to his head. This is the time-honoured remody: it is certainly an innocent one: it may tend to quiet the nervous system, and it is one the efficacy of which is so generally recognised amongst the public, that it would be unwise to court unfavourable criticism by neglecting to employ it. The bath must not be continued too long. In ordinary cases the child should be allowed to remain in it for ten or twenty minutes, according to his age. If, however, the patient be an infant who has lately been reduced by an exhausting diarrhoa, he should not be allowed to remain more than two or three minutes in the warm water, and cold applications to the head may be dispensed with. If the convulsions have ceased when the case is first seen, the bath need not be used; but we should not omit to have the child completely undressed, and then to see that he is placed, lightly covered, in a large cot, and that the room in which he lies is well ventilated and not too light. Care should be taken to unload the bowels by a large enema of soap and water; and if the child be noticed to retch, his stomach may be relieved by a teaspoonful of ipecacuanha wine. In the case of a teething infant opinions differ as to the propriety of lancing the gums. There is no doubt that this operation is a useless one if employed with any hope of hastening the evolution of the teeth; but if the object be to relieve pain and tension, I consider the practice judicious, and never hesitate in such circumstances to have recourse to it. If it be desirable to remove all sources of irritation, surely such a source of irritation as a swollen and inflamed gum should not be disregarded. Lastly, if it can be discovered that the child has had pain in the ear, or if the tympanic membrane can be seen to be red, the ear should be fomented with hot water; and if thought desirable a leech may be applied within the concha, the meatus being first plugged with cotton wool.

If in spite of these measures the convulsions return, or signs are noticed of continued unitability of the nervous system, it is best to administer a dose of chloral. Two grains can be given to a child between six and twelve months old, and if the patient be unable to swallow, half as much again may be administered by the rectum, dissolved in a few teaspoonfuls of water. If necessary the dose can be repeated several times a day. Bromide of ammonium, and belladonna, are also largely employed in these cases. The former may be given in three or four grain doses every two hours to a child between six and twelve months old; the second in ten, fifteen, or twenty drop doses two or three times a day. In the convulsions of pertussis, where the spasm of the glottis is extreme, treatment by bromide of ammonium or potassium and belladonna is especially indicated. The bromides are well borne by quite young children, and we should not

ar ill consequences from what may seem a very large dose. Chloroform

Nitrite of amyl is a very useful agent in arresting convulsions, and may employed without fear of danger even in young infants. The remedy ar be administered by the mouth or by inhalation. In the case of an at at of six to time months old, one-fourth of a drop of the nitrite may given in muchage and glycerine three or four times a day; and if the and be actually convulsed the inhalation of a drop on a morsel of lint a lusually put a speedy end to the spasmodic movements. Even in cases the convulsive seizures are due to cerebral disease the symptom may be outrolled by the same means Dr. A. E. Bridger has reported some we in which this plan of treatment was followed by the utmost benefit in far as the muscular spasms were concerned; for although the nitrate anot of course exercise any remedial influence upon the centre disease, had no small advantage to be able to control a symptom which of all Were is chatressing to those to whom the patient is dear. Dr Bridger had that it was necessary to increase the dose every twenty-four hours a shout one-third.

If the child have been lately the subject of exhausting discharges, warmth

be boush Pharmacopona must be given energetically.

If the convulsive attacks are followed by symptoms indicative of intragradualschief, such as stupor, squinting, ptosis, etc., the child should be highquet and an ice-bag be applied to his head. In such cases the treatact a set be conducted according to the conditions from which the con-

men is supposed to have arisen.

When the convulsions have ceased, and signs of irritability of the nerone stem are no longer to be observed, we must take steps to improve
the paral condition of the patient. His bowels should be attended
to ad his diet carefully regulated. If rickets be present, it must be
traced according to the directions laid down for the management of these

CHAPTER V.

RPILEPSY.

EPILLESSY, a disease which may vary in severity from the most transent uconsciousness to violent convulsions and profound coma, is not unconsciin children. It has been estimated that nearly one-third of the case are with in the adult have begun under the age of ten years. The inslands one of peculiar importance in early life, on account of its tendency to info

ence injuriously the development of the brain.

Causation.—In a large proportion of cases of epilepsy there is a best itary neurotic tendency. We often find a family history of epilepsy insanity, or of some form of nervous derangement. If this is the case of the side of both parents the child's prospect is a sad one, and is set families every child may be afflicted with some form of neurotic distintance. If abitual intemperance in alcohol on the part of the latter of mother is said to have a determining influence in the causation of epileps in the child. Lancereaux insists upon the importance of this cause and states that a tendency to convulsions in their offspring is a common acceptance of alcoholism in the parents.

Cachectic conditions resulting from imperfect nutrition or disease so as anoma, chlorosis, and scrofula, have been said to favour the development of epilepsy; but I can find no sufficient foundation for this statement. Buckets contributes largely to the occurrence of columptic attacks it as fancy, but it does not, according to my experience, especially precisive to epilepsy unless there be strong hereditary neurotic tendency; for was the disease passes off, as it will do readily if the causes exciting it be re-

moved, the propeness to convulsive seizures also subsides.

Amongst the exerting causes of epilepsy violent criotions, such as terms and fright, take a prominent place. Injuries, such as blows or fells upon the head, are answerable for many of the cases. It is also common to the the paroxysms attributed in the first place to eclamptic attacks occurred during childhood. It seems probable that in many cases of infantic extractions some change takes place in the brain during the course of the till which afterwards induces a return of the seizures without discoveries cause.

A bright, healthy little boy, aged cleven months, in whose family I could discover no neurotic history with the exception that his father at I one of his uncles had had fits in infancy, was taken ill on August 31, 1871. Some pustules appeared on his legs and he was feverish. On the best morning he was seized with a convulsive fit which hasted with occasional internassions for several hours and left him paralysed on the right said. During the next three days he remained in a drowsy state and was feveral at night. I saw him for the first time on September 4th. The chill a healthy-looking boy, had but three teeth. Still, although backward it the respect for his age, he showed no other sign of rickets. He was lying with

closed eyes on his mother's lap. His pupils were equal and acted well was light; his pulse 146, was regular in rhythm but not in force, his breathing was irregular and interspersed with sighs, although without long pauses; the temperature in the rectum was 101.6°. Both legs were ceived from the knee to the ankle with an erysipelatous blush. Power our them was, however, being restored, for the child moved the right am readily and the leg a little. At first they had been completely paragred. His lungs and heart were healthy. The child seemed stupid but was not unconscious, for he watched a light passed before his eyes, at I during examination of his chest cried and twisted hunself about. When the teat of his fee ling-bottle was given to him, he seized it eagerly

and put it into his mouth. There was no paralysis of the face.

The convulsions in this case had been evidently an initial symptom of the crysipelatous inflammation, and must have led to a small extravasation or that structural lesion in the brain; for although the child quickly record the use of his himbs, he became subject from that time to frequent start two or three weeks without discoverable cause and lasted for one or two minutes. The boy was said to become suddenly very quiet; then, in a mont, his checks flushed, his lips became purple, his eyes, although not exactly fixed, had an unnatural look, and he lost consciousness completely. He did not twitch. When the fit came on he never fell, for his more seeing his sudden quiet and anticipating what was to follow always took him up in her arms. In spite of treatment these attacks became confined, and in 1882—the boy being then twelve years of age—were still 2007 on. Occasionally he had a more perfect seizure, but usually the attacks were of the character which has been described.

The above illustration I believe to be typical of a class, and am strongly of opinion that the origin of many cases of epilepsy in the child can be referred to a similar accident. In other cases where there is a strong neurone predisposition, and the gray matter of the brain is in a highly explosive state, it is possible that columptic attacks originally induced by some trifling irritant may become perpetuated as epileptic seizures without discoverable cause. Where no such predisposition exists, and no lesion is pressent in the brain, I know of no proof that convulsive seizures can be so

perpetuated.

Pathology. - No anatomical characters have been discovered by which the occurrence of epileptic attacks can be explained, and hence the nature of the disease is still a matter of speculation and doubt. The seizures ince been attributed to both amemia and congestion of the brain, the sent of the faulty action has been referred to the medulla oblongata and the upper part of the spinal cord, to the ganglia at the base of the brain, and to the cerebral convolutions. We have learned by experiment that lesions of the convolutions will induce muscular spasm, and that irritation of the cortex in the motor region will have the same effect. Nothnagel, too, has pointed out on the floor of the fourth ventricle a limited area, which he calls the "convulsion centre," on irritation of which all the columntary muscles of the body are thrown into tonic and clonic spasms. Any or all of these parts may then be concerned in the production of an (pulptic seizure. It can hardly be doubted that sometimes the convolu-Les is may be the seat of the nervous discharge, for in a certain proportion I come where at the beginning of the fit the patient is conscious of his coo litiou, the discharge occurs in a centre of special sense; also in cases water the aura is intellectual the hemispheres are probably at fault.

When the attack is distinctly reflex, the medulia oblongata and porsumar contain the seat of diseased action; and the fact that in all cases there is more violence of spasm on one side of the body than on the other series

to point to some controlling influence of the corpus striatum.

The loss of consciousness has been explained to be the consequence of anomal due to spasm of the cerebral arteries and capillaries, and cased by an extension of the discharge to the vaso-motor centre. According to another theory, consciousness is arrested as the result of an influence which radiates from the part affected to the sensorium. The after-symptoms have been ascribed to carbonic acid poisoning from partial astrona and this was long held to be a sufficient explanation, although lately count have been expressed as to its correctness. At present, however, no explanation has passed out of the region of hypothesis, and although lifterent theories may have different degrees of plausibility, none can be said

to rest upon any very solid foundation.

Symptoms.—The symptoms of epilepsy are very various. Although the convulsive movements are the part of the seizure which most form attracts the attention, they are not essential to the nature of the discrete The most characteristic feature is the loss of consciousness, and the stthough often transient, is very rarely completely absent. A severe fit f epilepsy is much the same in the child that it is in the adult, and it will be unnecessary to describe minutely the characters of a seizure with with everyone must be familiar. The main features of the attack are similar to those already described as characteristic of eclampsia. It is preceded by a prodromal period of variable duration, in which some change is noted a the character, manner, or expression of the patient. The convulsion self seldom lasts longer than a few minutes. It is followed by a stage of coma, which is usually more protracted, but sooner or later the child recovers consciousness, although he may remain more or less stud for some hours. Often recovery is marked by a profuse discharge of hazel urine. In many cases the onset of the fit is announced in the child, as it is in the adult, by an "nura." In others the first symptom is vertigo, of a sudden flushing or pallor, or a twitching of some particular muscle. ever this initial symptom may be, it is usually repeated before each attack

The more severe seizures (epilepsia gravior or haut mal) seldom appear in all their gravity when the child first becomes subject to the disease. They are usually preceded for months or years by a milder form of the affliction (epilepsia mittor, petit mal, or epileptic vertigo) which present

itself in very many different forms.

In all varieties of epileptic vertigo, loss or clouding of the consciousness, which may be momentary, is the main feature, and is sometimes the only symptom. Thus, a child while engaged at his lessons or his play stops all at once in what he is doing and rests for a time perfectly quiet with dilated pupils and a strange fixed gaze; then after a few seconds he recovers himself and continues his occupation. Instead of being perfectly still, he may mutter some incoherent words or may perform some curious or unexpected act. Sometimes his face may lose its colour, or a twitching may be noticed in one cheek, lip, or cyclid, or his head may be drawn to one side. In any case, when consciousness returns the child is quite ignorant of what has passed, and immediately continues the action a which he was engaged. In other instances he merely seems for the two to be puzzled and confused, and does not recognise his friends. In other cases, again, an ordinary peaceful and affectionate boy will suddenly do

some savage or spiteful act which is strangely foreign to his real disposition, and which afterwards he is quite ignorant of having perpetrated.

A little boy, aged twelve years, well nourished and healthy looking, had always been well until September, 1877, when he had an attack of pertussis. During this time he noticed that objects "looked small" to hea for a moment. On recovery from the whooping-cough he returned to his day-school, and one evening, when doing his lessons, he seemed all at once to be "puzzled and confused, and did not know his father."

Suce then he had lad some well-marked epileptic fits.

The boy was brought to me in May, 1878. He then complained of shight but constant shooting pain in his right temple. I was told that he sellom had a genuine epileptic fit, but that he was very subject to attacks of mental aberration in which he did strangely spiteful things. The attacks were such to last from a few seconds to ten minutes and to end in a super of about a munute's duration. On recovery he was always quite mount that anything extraordinary had occurred. While standing beho me the boy had an epileptic seizure. He turned his face away over held shoulder, remained for about thirty seconds perfectly motionless, and then fell backwards into his mother's arms. His face continued perfeely placed and did not change colour. The eyes were closed, and when the hil was raised were seen to be turned upwards and to the right. Then was a faint twitch noticed twice in the fingers of the right hand. To pulse was full and regular. After being in his mother's arms for short sixty seconds, he suddenly changed his position; and then in wither minute sat up, looked about lam, and seemed quite recovered.

Attacks of epileptic vertigo may come on suddenly, or may be preceded by certain premonitory warnings, which soon come to be recognised by the friends as likely to be followed by a seizure. The warning may be a bracker, a pun in the body or a limb, an attack of sickness, the contraction or spesm of a muscle, or some curious change in the habits or deposition of the patient. It may precede the attack by several hours or a day or two. Sometimes it occurs without being followed by a fit. Epilepte vertigo often in time develops into the more pronounced form of the disease. Usually, as in the case above narrated, rare attacks of gentace type pay are separated by long intervals, during which the patient is extent fits occur only at night and may be thus overlooked for a time. Epileptic vertigo always recurs much more frequently than the genuine that seizures, and the patient may suffer from many such attacks in

the course of a single day.

between the attacks, whether of the graver or lighter form of the discrete the child may seem perfectly well both in mind and body. He may be atmated, intelligent, active, and seem in no way harmed by his afflication. In other cases, especially if the attacks have dated from infancy, three is manifest interference with mental development, and the child may either have the numer and intelligence of one much younger than his graph or be dull an I stupid even to idiocy. In the case already referred to the little boy in whom the attacks began at the age of eleven months when four years old he was intellectually on a level with a child of half his years. He sat on the floor and played with his toys with the manner to baby, and had only learned to fend himself during the previous six mentis. Although he understood all that was said to him, he could only say a few words and could not pronounce the letters at large of five years he began to have daily lessons from a governess, who re-

ported him as "not difficult to teach." At twelve years of age the five in continued, although they were, as a rule, mild and infrequent, and curred at intervals of aix weeks two months, or longer. His father sate at this time, in answer to a letter making inquiry as to the law, in that his mental power was below the average, and that the lad was behind other boys of his age.

The severe convulsions which occur at comparatively long interiseem to have a less disastrous influence upon mental development that imilder epileptiform scizures which occur more frequently. Also, a labera before remarked, the age at which the scizures begin is a very untant matter. If the child has been subject to them from before the pletion of the first year of life, his mental development is almost certain be injuriously affected.

Sometimes choreic movements occur in epileptic children for the appears to be an association between the two diseases. A choreic may develop epilepsy; and a child subject to epileptic fits may be choreic. Dr. Gowers has published some interesting cases illustrated connection.

Inagrosus.—An eclamptic attack in infancy and early childhood to sents exactly the same characters as a fit of genuine epilepse, there is a very important to decide in every instance to which class of court consease the attack is to be referred. This question has already because

cussed elsewhere (see page 282).

Epileptic vertigo, when it takes the form of loss of consciousness ** out muscular spasm, is liable to be mistaken for an attack of system especially in those cases where there is great pallor of the fare I sciences, indeed, are constantly spoken of by the parents as fantacing and we must be on our guard against this interpretation of the plant non. But syncope, although not uncommon in young people is a seen except as a consequence of weakness, prolonged and exhauster . ease, or flatulent accumulation occurring in an anamic child. It is children are often robust and generally appear to be well not as a Again, slight twitching of muscle, combined with complete loss to sciousness, would point to epilepsy. In syncope there are no twice and and if any muscular movement occur insensibility is not cor-Listly, an epileptic attack is sudden, and when the child recovers ignorant of what has passed; syncope is preceded by a very distinct saw of "funtness," and after the attack is at an end the patient is quite and that he has been unconscious.

Cases of cerebral disease with partial convulsions may be mistaken this disorder, but in such cases there is a history differing wider of that of epilepsy, and other symptoms of cerebral disease are present is sides in the attack we do not find the peculiar interference with respirate

which is so characteristic of an epileptic scizure,

the hysterical simulation of epileptic seizures both on the part of love at parts. These false attacks can be usually recognized without difficulty. It buy, eleven years of age, was admitted into the East London Character Hospital under the care of my colleague, Dr. Donkin, with a history of the way supposed to be epileptic. There was no neurotic tensory of the family, and the patient had always been healthy until the beginning July, when he was noticed to look pale. He was said to have been expensionally before to a hot sun, and also to have received a heavy blow of the head of which for some time he seemed to feel the effects. On July 19.

he had a fit in the night, which was supposed to be a faint. During the next fortnight he suffered frequently from the attacks, often passing through as many as eight or nine in the day. The description given was that he felt guidy, fancied he saw "things going round him," made a clutch at some imaginary object, and then with a cry fell backwards. He was said to foun, at the mouth, but not to bite his tongue although he clenched his teeth firmly, to make convulsive movements with his arms as if fighting; and sometimes to be motiouless with closed eyes. The mother thought he lost consciousness. The fit sometimes lasted half an hour. It was not followed by stuper, but the boy remained for some time oppressed and weary,

and stammered when he attempted to talk,

The first day be passed in the hospital he had eight attacks. In these is struck out with his arms, dashing his hands against the bars of his bed, but always striking with the firsty part of the fist, never with the knuckles. He also kicked out with his feet as if keeping off some enemy. He threw test his head, and his face was much flushed by his exertions. It never be one blue, nor was there any arrest of respirations. The eyelids were closed and he resisted opening them. When the conjunctiva was touched to whated. The pupils were not dilated. He did not injure his tongue was if he crught it between his teeth, and all his movements had a certic soluntary character. There was no stage of tonic contraction. After his to over he lay down with closed eyes as if to sleep.

On the second day a sharp galvanic current was applied to the boy's

After this experience he had no more attacks of convulsion.

Enleptic fits which occur in the night only are often overlooked. In schoolse the fact that a child suddenly begins to wet his bed at night is experious and if a neurotic tendency exist in the family, the symptom

best lead us to make further inquiries.

Property — Cases where the attacks are well developed and occur infrelightly are more hopeful than the modified seizures which continually reter. Certainly they are more amenable to treatment. The age at which
the affection first maintests itself has less influence on the curability of the
hispler than it is said to have at a later period of life. On account of
the difficulty in following out these cases (for if no immediate improvetent is noticed the patient is very apt to be lost night of), my experience
of the matter is too limited to enable me to speak positively; but I am intack to believe that the appearance of the disease during the first two
tent of life is of less favourable import than when it begans later. There
is solvable that at this age its influence upon the mental development of
the patient is more hurtful, especially as such early appearance implies in
large cases a strong neurotic predisposition.

The earlier treatment is begun after the onset of the disease the more two rable is the prognosis; for while the affliction is still recent, we may two topes of putting an end to the attacks. In confirmed cases, espently if there is strong hereditary tendency, the child's prospect is but a

THEY OHE.

To downt.—It is so seldom possible to discover and remove the cause of spileptic seizures that little hope of curing the patient by this means can be extramed. It is not, however, the less desirable to relieve the child fall criticists, and to shield him from all influences which experience has some to be injurious. Worms should be inquired for, the state of the maste should be regulated; evil habits, if included in, should be consistent in the child's whole mode of life should be arranged according inte laws of health. All sources of excitement, whether in games, chil-

drens' parties, or public amusements, should be strictly forbidles, all although monotony of life is to be earefully avoided, pastimes which is not over-excite the brain are to be preferred. The influence of quet us of healthy recreation upon the disease is often seen in hospital patents. A child who has been admitted with a history of severe epileptic segues occurring daily for months, may pass several weeks in the wards and le eventually dismissed without any symptom of his disease having best detected. Careful gymnastic exercise is of value in promoting health change of tissue, but care should be taken to stop short of actual fatigue With the same object pursuits which occupy the mind while they gre employment to the hands should be encouraged, such as gardenic wi carpentering. A useful plan is to send the child, under proper superise to a farm-house, where the tending and feeding of animals, and all the jusuits incidental to healthy country life, will be found of infinite server. him. At the same time the patient should be kept under strict centre any taste he may have for music, drawing, etc., should be cultivated and without fatiguing the mind by mental labour, much valuable instruction may be conveyed by conversation and the reading to him of suita a books. Dr. West recommends simple chants, such as are easily sequent as a useful means of improving imperfect articulation, and suggests of ing to the accompaniment of music as valuable in correcting slovenium of guit and aiding the child to regulate voluntary movement.

The question of food is a very important one, as the frequency elemrence of the attacks may be determined to some extent by the point with which his diet is selected. It is a generally recognised fact that a abundant meat diet is injurious to epileptics, for the brain-tissue where the helps to build up is of a more highly irritable composition than if a less stimulating dictary were enjoined. Butcher's meat must be taken againgly, and the food should consist principally of milk, vegetables, positive.

game, and white fish.

The drugs which I have found the most useful and which I believe have a decided influence in checking the number and diminishing to a verity of the attacks are strychnia, belladonna, and the bromides of one num and potassium. For a child five years of age I begin with two days of liq. strychnize (P. B.) and twenty drops of tinct, belladonnae twice a dr and give at night half a drachm of brounds of potassium with car per-water sweetened with simple syrup. This treatment should be contained for months together, increasing the dose of the strychnia solution in our drop and of the belladonna tineture by three drops every two weeks by this way large doses of the drugs may be administered without dancer A little boy, four years of age, under my care took for a long time severier drops of the strychnia solution (or about one-seventh of a gran of teralkaloid) twice a day with great benefit. Another child-a little gui un years of age by gradual addition to the strength of her medicine, resched one-fourth of a grain of strychnia twice in the day. An important put of the treatment consists in the administration of a weekly or business aperient, for it is essential that the bowels be regularly relieved. Actor mulation of feeal matter is a powerful excitant of convulsive seizures " a child of epileptic tendencies. Moreover, the continued use of the brown

In all cases where the brouide salts are being taken, however small the owner practitioner must be prepared for the occurrence of the brounde rash. Some desired have a curious sensitiveness to these salts. A few small doese of brounds of present will produce in such subjects an abundant cruption which, if their idosyncemy a less recognised, may excite considerable perplexity.

to many children to produce constipation which may assume an character. In such cases it is useful to combine the strychnia of one or two drachms of infusion of senna, so as to maintain a digentle action upon the bowels. The addition of chloral to the said to increase the efficacy of this treatment, and it has been at used in this combination a smaller proportion of the brounder

ad to produce an equal effect.

the above remedies, other drugs have been employed in the control of this disease, such as the bromide and other salts of arsenic; but, bromide, and oxide of zinc; the oxide and nitrate of silver; to five. Very good results are sometimes obtained from the use. This salt may be given in doses of one grain for each year of bufe. Borax is best administered directly after food, for if given the contact it may excite vomiting. There is one disadvantage d with the use of the remedy. In certain subjects the drug has a to cause psornans which may prove obstinate.

ttack may be sometimes arrested by the inhalation of chloroform. den shock is occasionally useful to attain the same object, such as ammonia to the nose or pouring cold water upon the head. Dr.

a Browne advocates the inhalation of nitrite of amyl.

CHAPTER VI.

MEGRIM.

Means, or migraine, is a functional nervous disorder which gives not onever headache and other nervous phenomena, and often to now and bilious vomiting. The derangement is a not uncommon one is ellihood, especially amongst growing boys. Treatment is of peculiar approaches at this age, for if the complaint be allowed to continue and attacks become frequent, the patient may be almost entirely incapable from pursuing his studies, and his education may suffer greatly in expension.

sequence.

Causation.—In many cases megrim appears to be hereditary. We the find on inquiry that one or the other parent suffers or has suffered for the derangement, or that there is a tendency in the family to see a fix of nervous disease. Sometimes, however, this is not the case. The corder then appears to be acquired. In excitable children it may be duced by continued mental effort in crowded, ill-ventilated school-not and the common practice of pressing forward the education at a very stage no doubt helps to engender the disposition to suffer from the oppoint.

Anemia and debility, from which children often suffer soon after a second crop of teeth begin to make their appearance, probably also with the production of megrin, and an exhausting illness, such as typhorities sometimes seems to predispose towards it. One of the most powering the exciting causes appears to be confinement in-doors combined with the exciting in a weakly child. The complaint is much more common and the children of well-to-do parents than amongst the children of the post

who pass so much of their time playing in the streets.

Megrim is not seen in early childhood. It rarely begins to slow its? before the beginning of the second dentition, at about the sixth year

have, however, known it to occur in a little boy five years old.

Pathology. The view formerly held that the head symptoms were the consequence of gastric disturbance is now practically abundance. In Latham refers the source of the affection to the sympathetic nervous attent. He believes that if by anxiety, fatigue, or other depressing case the regulating influence of the cerebro-spinal system of nervous is in paired, the sympathetic system, no longer controlled, runs riot, cases contraction of the vessels and consequent aniemia of the brain. It is this aniemia that he attributes the disorders of sensation which provide the cephalalgia. Afterwards the excitement of the sympathetic substantial is followed by exhaustion, and the vessels becoming chlated present the headache.

Dr. Edward Living differs from this view. This authority ascales the phenomena to the irregular accumulation and discharge of namedov. He believes that a "nerve-storm traverses more or less of the same

tract from the optic thalami to the gauglia of the vagus, or else radiates in the same tract from a focus in the neighbourhood of the quadrigenumal bodies."

Symptoms. The chief symptom of megrin is headache. Sometimes it appears to be the sole source of discomfort, but it is often preceded by a general feeling of illness and certain disorders of sensation. In many we are told that the child wakes up with a severe headache, and that has continues for several hours, during which he has growing and meapathe of any exertion either of mind or body. The pain in young subjects is more often bilateral than it is in older persons, and is comparatively sillom limited to one spot or one side of the head. It may extend across the forehead or over the top of the head or the occiput. It is of a very were throbbing character, and is increased by light, by noise, or by securit. The child feels and looks excessively depressed. His face is de and haggard. He cannot cut, and usually prefers to lie qually on a a in a darkened room. His head is often hot, but his feet and hands fedeabl to the touch, and he complains of feeling chilly and may shiver. Le pulse is small and weak and may fall to 60 or 70. In exceptional cases the child feels sick and may vomit.

the headache does not always occur in the early morning. Sometimes the patient wakes up in his usual health, and it is not until several hours at reards that the pain begins. The cephalalgia is that often preceded by arous disorders of vision. Some chaldren will say that objects look at the them, others that everything appears to be larger than natural, as times stationary objects seem to be in movement, or there is partial as bulty of the return so that the patient cannot see the whole of an est at once. Thus in looking at his mother's face he may see only the ast or the left side, not the whole. In addition to the sight, other seemay be affected. There may be noises in the head or impairment thering, or the taste or smell may be deficient. The child complains the leasant odoors, or if offered milk remarks upon the peculiarity of

us ficeur.

These earlier symptoms usually subside when the pain comes on. The beds he lasts a variable time, from three or four to eight or ten hours, to the gradually subsides. As his suffering becomes relieved the child usually fulls asleep and wakes well, but wearied and weak. The frequency will which the attacks come on varies in different subjects. Often they were no lical and return with remarkable regularity every week or fortable. Sometimes a child after one attack has no return of the complex for months. If boys at school suffer, the attacks are often very

troy . tit

The pure time ago I saw a school-boy, twelve or thirteen years of age, who we salpect to daily headaches to such a degree as to be almost incapacitivel from pursuing his education. The pure begin in the morning on the from be I and listed all day, only subsiding towards the evening. It was led the whole of the head, and although not at first very severe, was the worse by exercise, by head-work, and by a bright light. It was not attended by sickness. If, as sometimes happened, the boy awoke free free pure, the cephal dgir came on in the middle of the day, and in this in light subside as usual in the evening. The boy was subject about the attended by light light about the attended by the light and the light and the second light of the day, and in this will not subside as usual in the evening. The boy was subject about the attended by the light light and the latter, objects always looked large to him.

There was no doubt about the truth of the boy's statements. They are a probotated by his mother, who assured me that the severity of

her son's suffering during his attacks was perfectly visible in his face. To boy himself was found of his studies and accused very anxious to be one: He first took ten-grain guarana powders, but without relact. He was no ordered to take twice a day a dose of liq. strychnize (\mathbb{P}_1 ii) and a set extract of ergot (\mathbb{P}_1 x.), and in a few days the headaches had entraced.

In some cases, in addition to the cephalalgia pains apparently of a ter-

ralgic character are complained of in the limbs.

A well-grown boy, nine years old, was sent to me from the life Wight by Dr. Gibson, with the history that for six months he had be suffering from frequent attacks of pain in the head and often in the least The boy used frequently to cry with pain which attacked him at make the right hip and knee. He was noticed to drag the affected leg sugar in walking, and seemed to have a difficulty in placing the foot fairly in the side of the other. It was thought, too, that the leg was a little shortest. His temperature at that time was between 99° and 100°. The pain was not, however, confined to that limb. Sometimes it shifted to the other extremity, and sometimes was complained of in the back and shalls? The temperature for a month was about 100°, but the boy second selected for the pains, and strongly objected to any restriction in his dec

When the patient came under my own notice he was in good couding and had a healthy appearance. The lungs and heart were normal, and to organs generally gave no sign of disease. The urine was acid, of special gravity 1.014, and contained no allumen. No petechiae or signs of land ing were seen about the body. There was no swelling of any of the rate nor any excess of fluid in the knees. The attacks of pain were sail come on at variable intervals. Often be woke in the morning with a co vere frontal headache, but sometimes the cephalalgia came on dung the day. It always lasted many hours. He rarely vonuted. When the past first began in the course of the day, he was noticed for some time beforhand to look white, with eves "drawn," and his sight would be affected He would see only half an object, or objects would look unraturally state to him. In the limbs the pains were chiefly at this time behind the knew but sometimes they affected the thighs and calves of the lega. Ther were increased by exercise, and he could not walk long without fatigue. Ilappetite was good and his bowels were regular. The boy was ordered. take two minims of liq. strychnize and fifteen of the hand extract ! ergot three times a day, and the nurse was directed to employ uppers frictions to his limbs before he went to bed. Under this treatment the distressing symptoms began to moderate, and as long as the box remarks in London - a period of several weeks—he had no return of the heads 🐦 or pains in the lumbs. Before his return home he was said to have great. improved in his power of walking.

Diagnosis.—Periodical attacks of headache, preceded by disorler of sight—these attacks lasting several hours and passing off completely, lessing the child well until the next recurrence—may almost always be usually to megrim. Children comparatively rarely suffer from dyspeptic best aches, although sometimes during attacks of acid indigestion in years subjects dull pain in the temples and soreness of the eyeballs may a complained of. These attacks are, however, very different from no print. The pain is much less intense and is preceded by symptoms of gastro leaves, and his complexion is usually sallow. In megrin the pain is named and throbbing, the face is white, and vomiting, if it occur, is a late symptom.

tom, coming on towards the end of the attack. The attacks, too, often occur in the night, so that the patient, when he wakes up, finds the healache fully developed, although he had retired to rest in perfect health.

Children who are much exposed to vitisted air, especially to air made unwholesome by gos-jets, often suffer from headaches, but in these cases the pun can be traced to the evident cause of the attack. Again, hypermetropia is a not uncommon cause of cephalalgia in young people. This torm of headache is not noticed until the education of the child is entered upon and he begins to pursue regular studies. He is then forced for some hours together to exert the full focussing power of his eyes in order to remedy his natural defect, and the consequent strain upon his muscles of accommodation gives rise to a frontal headache which is often very distressing. But this headache always comes on at about the same time in the day, and is evidently connected with the act of reading. It ceases at once directly the hypermetropia is remedied by the use of suitable glasses.

In headache due to cerebral disease, such as tumour of the brain, there are usually other symptoms connected with the brain which continue between the attacks of paroxysmal suffering. Squint, or nystagmus, is often an early symptom, and persistent lesions of special sense soon begin to be observed. These are not limited to the seizures, but continue after the

headache has subsided.

The thment,—During the actual attack the child should be allowed to be quartly in a room shaded from a too bright light. If he be chilly a thin coverlet may be thrown over him, and if his feet feel cold they should be warmed by a hot-water bottle. The best remedy at this stage is the guarana powder, which is to be given in a dose of ten grains (to a child of ten years old) in a little sweetened water. This remedy is said to succeed best in cases where there are very distinct premonitory symptoms, especially disorders of vision, but even in these cases the administration of the powder is often followed by no rehef. Other remedies which sometimes have the effect of cutting short an attack are the bromide of potassium (gr. x.-xx) with sal volatile, chloride of numionium (gr. x-xv.) with spirits of chloroform, and compound tincture of lavender. Various antispismodies, as valerian, assaferials, tincture of henbane, and the fetal spirits of ammonia, have also been recommended. In many cases in most, perhaps, occurring in young subjects—the attack is very decidedly shortened by a dose (M xv.-xx.) of the liquid extract of ergot given with spirits of chloroform in camphor-water.

If sickness occur and prove obstinate, it may be often arrested by a saline effervescing draught containing a couple of drops of dilute hydro-

cyanic acid (P. B.).

After the attack is at an end the child should, if possible, avoid close rooms and healwork, and should be made to spend as much of his time as possible in the open air. In the case of school-boys, however, it is important that their education should be proceeded with, and we must endeavour to arrest the tendency to the attacks without any intermission of study. If we cases will be found to resist the combination of strychnia and extract of ergot already referred to in the treatment of the two cases which have been narrated. I was led to employ these reme lies in this complaint from noticing their useful effects in some cases of epilepsy, and since beginning to trust megrum in the young subject by this method I have met with very few obstinate cases. Often from the time of beginning to take the

medicine the attacks have ceased altogether. I usually order two or three drops of the strychnia solution (P. B.) and ten or fifteen of the liquid extract of ergot with spirits of chloroform to be taken three times a dry. I believe the combination of the two drugs to be more efficacious than either given alone, but in some cases strychnia given with iron has been found of value.

The child's bowels must be kept regular with some mild aperient, such as the compound liquorice powder, and the diet should be regulated, taking care that he does not take an excess of sweets or fruit.

CHAPTER VII.

CHOREA.

Choice is essentially a disease of the second dentition; for although it is seen simally met with in children under five years of age, and sometimes even in adults, yet an enormous majority of the cases are found between

the ages of five and fifteen years.

Constion.—Children who are likely to be attacked by this complaint are those in whose family there is a tendency to neurotic disease, and who, perhaps as a consequence of this tendency, are born delicate and sensitive, with a highly impressionable nervous system. Perhaps the mother may herself in childhood have been afflicted in the same way. Girls are truch more prone to it than boys, and a child who has once passed.

Lough an attack is very likely to suffer from it a second time.

The outbreak of the disorder may be determined by an attack of Pheamatism, or by some shock to the nervous system, as a fright, or by any cause which reduces the strength more or less suddenly and sets up Ansemia or some eachectic condition. There is an indisputable connection Intween rheumatism and chorea. It is common to find a family history of rhoumatic attacks. Often the patient has herself suffered from it, either In its acute or subacute form. Out of forty-two cases mine boys and thirty-three girls) of whom I have notes, I find distinct history of rheumatic attacks in sixteen. Others came of rheumatic families, although it could not be discovered that they had suffered from the disease themselves. There was a heart-murmur in twenty-seven, and in many cases the rheumatic disease had left evident traces of its passage in a harsh cardiac murmur with some hypertrophy of the heart. Still, there is no doubt that we find many cases of choren in which no history of rheumatism can be discovered, and many rheumatic children never have choren. Rheumatrem alone will not set up the complaint, for a peculiar instability of the nervous system is no doubt essential to the production of the disorder. Rilliet states that in Geneva, where rheumatism was a common disease, chores was almost unknown, and according to the investigations of Dr. Weir Mitchell, it appears that amongst negro children, in whom rheumatism is not uncommon, chorea is very rarely seen.

Dr Anstie was of opinion that the hereditary rheumatic tendency was associated with a hereditary tendency to neurotic diseases of various kinds, and especially to chorea. In support of this view he instanced the case of nine families with decided rheumatic history. In each of these several of the children had suffered from rheumatism, to his own personal knowledge. In all of them, also, there was a strong neurotic inheritance, which showed itself in many cases in the form of chorea. The striking fact consisted in this, that although many children suffered from theumatism and many from chorea, it was not the victims of rheumatism who were especially prone to chorea. As often as not those children who had

suffered from rheumatism escaped the neurosis, while others who had never had rheumatism fell victims to chorea.

Other conditions appear to influence the incidence of the disease. The rarity of chorea amongst the little negroes seems to show that the degree of cerebral development may constitute an important element in the tendency to the disorder; for the brain in the black race is no doubt less perfectly developed than it is in whites. Again, monotony of life and absence of mental excitement must tend to impart immunity from chorea, for Dr. Weir Mitchell's researches show that the disease is far less common in rural districts than it is in towns, and in small towns than in large cities.

In a suitable subject any irritant may set up the complaint. Worms in the intestinal canal, and, of course, the practice of masturbation, have been cited as frequent causes of this as of all other nervous disorders. Still, I cannot but think that the influence of the two causes just mentioned, of masturbation especially, in provoking nervous derangements in the child has been greatly exaggerated. Chorea is sometimes associated with grave diseases of the nervous centres. It has been seen in connection with cerebral tubercle, cerebral hypertrophy, and softening of the brain; and Dr. Jacoby has reported a case in which violent choreic movements were induced by meningitis involving the membranes of the cervical part of the spinal cord.

Pathology. The pathology of chorea is still a matter of debate. In some fatal cases obstructions have been discovered in the minute arterica ramifying in the corpus striatum and its vicinity, with little points of softening and congestion resulting from them. Hence Dr. Kirke's view, since supported by the authority of Dr. Hughlings Jackson, that chorea is a consequence of minute emboli swept out of the heart and arrested in the small arteries of this part of the brain. This theory, if correct, would only explain the cases which have been preceded by rheumatism, and would throw no light on the many cases where the heart is to all appearance

Dr. Dickinson has proposed another explanation. He believes that the faulty part of the brain is not limited to so small an area. In his opinion the disease depends upon a wide-spread hypericinia of the nervous centres "not due to any mechanical mischance, but produced by causes mainly of two kinds one being the rheumatic condition, the other comprising various forms of irritation, mental and reflex, belonging especially to the neryous system." Dr. Dickinson has found, as the result of post-mortem examinations of fatal cases, that all the small arteries both of the brain and spinal cord have a general tendency to dilatation. As a consequence, exudations and sometimes minute bemorrhages occur in the ussues immediately surrounding the dilated vessels—shown by the presence of bloodcrystals and patches of sclerosis. He has noticed these changes to be most advanced in the corpora striata, the vicinity of the trunks of the middle cerebral arteries, and in the posterior and lateral parts of the spinal cond -principally at the upper part; and states that they are equally distributed on the two sides. This theory has the advantage that it explains the wasting of muscles, rigidity of limbs, and occasional permanent paralyses which sometimes follow an attack of chorea.

In opposition to the above theories based upon morbid anatomy, Dr. Sturges has advanced an ingenious explanation of the phenomena attendant upon chorea, founded upon intimate acquaintance with the peculiarities of childhood. Dr. Sturges regards chorea as a purely functional complaint, arising, in the majority of cases, from some strong nervous impression.

Sarting from the fact that in every child placed in an embarrassing position and donal restlessness (or temporary chorea) is produced, he argues that exaggerated limb-movement is the natural expression in young subpose of emotional states; that disordered movement is increased by the attanks being diverted, as it is by some strong emotional shock; that the cuscounters of this partial loss of control deepens the mental impression and intensities and extends its consequences; and, listly, that want of success in directing movement impairs the child's confidence and entails further fadure. The little treatise is well worthy of perusal, for although it may ext offer a full explanation of all the phenomena connected with the descler, no one can refuse admiration to the ingentity of its reasoning will be graces of its style.

Dr Havelon, of Dublin, has started another theory. Like Dr. Sturges be refuses to accept any special organic lesion as the exciting cause of the complant. He believes that the attack begins with a vaso-motor paresis, the consequence of a profound emotional impression, and that the essential appropriate are due to defective polarity or dynamic instability of the moto-nerve tracts, both intracramal and spinal. This hypothesis would either the post-morten appearances noted by Dr. Dickinson, and would accept for the phenomena common in the graver cases of the disorder.

Semploses.—The phenomena of chorea consist in an inability to guide and control the muscles, so that while there is excess of motion there is above of ordered movement. The infirmity begins gradually in most case. At first the child is noticed to be stupid over her lessons; she have less than her usual alacrity at her games, and is emotional, nervous, and along the strange in manner. Soon she begins to fidget, scraping let let as she sits on a chair, or restlessly moving one of her hands about the strange in the she is found to drop articles from her hand, and to the she walks. These symptoms are always at first and tied to carelessness, and the child is admonished and reproved; but there are usually from some eccentricity of movement or facial contortic it draws upon the parents that the child's control over her muscles is appared, and the matter is referred to the medical attendant.

In exceptional cases the symptoms do not come on in this insidious we but begin with some suddenness as a consequence of fright or other to the nervous system. But however the disorder may have begun, what fully developed the symptoms are the same. The power of the will to take I muscular action appears to be completely lost, and we find the same spasmodic movement, inco-ordination of voluntary movement,

a certain degree of muscular weakness.

Learn trived case nearly all the voluntary muscles of the body seem to the train share in this desorder of movement. The child is never quiet. It are group of muscles, then another, contract in a jerky spasmodic attack which is very characteristic. Volition is evidently not concerned their production. They occur not only without the influence of the last in spate of it. The face is curiously worked, as if the muscles attempting, but unsuccessfully, to simulate all the passions of the last. The eyebrows are suddenly bent into a from; but it is not last. The mouth expands abruptly into a smale; but conveys no impression of mirth. The eyelids are opened widely; then quickly squeezed laster; the eyes are rolled upwards, downwards, and from side to side; the case's twitch, and the angles of the mouth are contorted with strange theres. The head is jerked backwards and forwards, and then pulled saliently down to one side. The arm may be thrown abruptly forwards

by a peculiar movement of the shoulder; the hand and wrist are violently promited, then as suddenly supinated, and the fingers work convulsively. Sometimes, by a strong effort of the will, the hand may be kept quiet for a few seconds, but soon, with a convulsive jerk, it is thrown again into motion. The lower limbs, although less violently affected, are not inactive. They are thrown one over the other, or are suddenly drawn up and again extended.

Sometimes the muscles of the trunk may be affected, and spasmodic contractions of the respiratory muscles may take place; or the patient may be suddenly jerked upwards from the bed, or even thrown out of it upon the floor. In the worst cases the child has a wild, frightened look, or sometimes a half-dazed expression; speech may be impossible, and even

memory may appear to be almost lost.

In the milder cases an effort to execute a voluntary act increases the contractions; and even the exertion of standing makes control of the muscles more difficult. The more completely the child is at rest, the quieter she becomes. The movements are also increased by mental emotion and nervousness, so that the child is always at her worst when observed; and no doubt, as Dr Sturges suggests, the consciousness of failure increases her helplessness. During the height of the complaint the ungovernable eccentricity of movement makes the commonest actions difficult or impossible; for an attempt to direct any special group of muscles is immediately frustrated by violent contractions of antagonistic groups, so that the patient does anything but what she wishes. The child can only speak indistinctly; she cannot button or us her clothes, or perform any act in which accurate co-ordination of movement is required. For this reason it is often quite impossible for her to feed herself, as she can no longer guide the spoon or fork to her lips. Even when fed by the nurse, mustication may be difficult from uregular movements of the tongue; and sometimes the contractions of the guilet are interfered with in the process of swallowing. In bad cases natural sleep is almost impossible. Even in a milder form of the complaint the child finds a difficulty in going to sleep; but when she does at last sleep the movements cease.

Sometimes sensory disturbances can be noticed. Painful spots may be found in the course of the nerve-trunks in the affected parts; there may be tenderness on pressure over the spinous processes of the vertebra; or the child may complain of hyperaesthesia or amesthesia of the skin. Occa-

sionally sight is impaired.

The choreic movements are not always general; sometimes they are limited to one-half of the body (hemishorea). In these cases either side may be attacked; but even in hemichorea, according to Dr. Broadbent, muscles bilaterally associated in their action are affected to some extent on the two sides. When the disorder is unilateral, the muscular weakness, which is seldom completely absent, is more easy to recognise, as we have in the sound side a standard of comparison. When sensation is impaired in hemichorea, it is impaired on the same side of the body as that on which the muscles are affected. This fact is relied upon by Dr. Broadbent as a proof that the sent of the disease is not in the cord; for if it were so, sensation would be impaired on the side opposite to the affected muscles.

The constant movement seems to cause wonderfully little muscular fatigue. In ordinary cases, if the movements are not exceptionally violent the general health is but little affected. The child may complain of giddiness and headache, but appetite is usually good, and the digestive functions are well performed, although the bowels may be costive. In bad

cross appetite is often capricious and digestion impaired, and partly for this reason, partly from the difficulty in feeling the patient and the want of shop, nutrition may suffer and the child become pide and thin

The urine has always a Light specific gravity at the height of the dis-

case, and contains abundant uren and phosphates.

The mental condition may vary, according to the severity of the disorder, from more depression or irritability to taciturality, obstuncy, violence of disposition, or even furious debrium. In the milder cases intelligence does not appear to be enfeebled, and although the patient often has a silly vacant expression, this is no more than can be accounted for by the childs own feeling of helplessness, and her consciousness that her contortions and grimaces may be the subject of ridicule.

The temperature in chorea is normal unless the complaint be complicated with a rheumatic attack, or be symptometric of organic disease of the

Lervous centres.

Weakness of the muscles has already been referred to as an essential stantom of the desorder, but as a rule it is insignificant, and may not be . Littled without special inquiry. Sometimes, however, the muscular weakbess assumes great prominence, and may even throw all the other symptorus into the shale. Thus a form of the disease is sometimes met with which a paralysis or paresis of one or more limbs as the only symptom complained of. For instance, a little girl is said to have gradually lost the use of her arm. The hand hangs down and is evidently very weak. The put ent may perhaps by a great effort of will be able to raise it, but when tries to grosp with the fingers the pressure is very feeble. The leg of the same side is sound, and there is no paralysis of the face or tongue. sometimes the other arm is also weak, although to a less degree. In other the paralysis involves the leg as well as the arm of one side, but the face and tongue always escape. In all these cases, although to a casual glaces there may appear to be no movement at all, careful inspection will as mally discover occasional slight twitches faint clopic spasms in the a to tel limb or on the sound side. Sometimes this is al. that can be botteed, and the muscular power returns after a time without the occur-Tenne of any confirmed disorder of movement. In other cases the clome pasms become more and more marked as the paresis improves, so that wat the power of the affected limb is almost restored the motor disorder

There is another form of muscular weakness which occurs later, and sometimes remains as a permanent condition after the disease has passed if It affects the muscles which have been previously implicated, and is probably due to degenerative changes in the spinal cord. The muscles

teurun weak and become wasted, and perhaps contracted,

The state of the heart in chorea is very interesting. In a large proportion of cases, at least of those occurring in young children, a natral nurmor becomes developed in the course of the illness. This murmur may disappear as the symptoms of motor disorder decline, or may remain as a primanent condition. The temporary murmurs are often very variable in intensity; coming and going; heard with some beats of the heart and not with others. These are probably due to some irregular action of the papillary muscles of the heart, the consequence of clonic spasm similar to that which takes place in the voluntary muscles of the body. Temporary murmurs, when not thus interrupted, may be the result of anumin—a condition in which the blood is watery and the tissues of the heart relaxed, so that the left ventricle is dilated and the mitral ordice is insufficiently

closed by its valve. In these cases there is often a basic pulmonary nurmur. We cannot say positively that a murmur has disappeared und we have examined the chest after exertion as well as when the heart is quet. It is important, therefore, before pronouncing an opinion, to excrete the heart's action by making the child run round the room. If the heart-wands after this exercise still remain clear, we can say decidedly that the murral has gone. Temporary murmurs are much more common in girls than a boys.

Permanent murmurs are in all cases, probably, the result of calcanditis, which may be due to coincident rheumatism, or may arise in the

course of the illness without rheumatic taint.

The choreic disorder runs a chronic course, but in the large majorith of cases ends in complete recovery. Its progress is, however, often recount, and the child may be better and worse again several times before control over muscular movement is completely restored. After all a voluntary spasm has subsided, a certain abruptness of executing voluntary acts may continue for a time before all traces of the disorder pass away Relapses after an interval of months or years are very common.

The duration of chorea varies greatly. If left to itself it lasts from ento two months, seldom longer, although cases are recorded in which according disturbance has continued through life. As a rule, the discuss of permute the discuss of recording influenced by treatment. When the complaint passes off recording in most cases is complete. Sometimes, however, the mind runsus more or less enfectled; the patient becomes slovenly, careless, and driving her habits, and may even drift into a state of permutent weakness of mind. In other cases the contrary happens, and the intellect seems brightened by the attack. Sometimes, although fortunately very rarely, some of the affected muscles undergo atrophy and contraction.

Death from the disease is very uncommon in children, but it sometime occurs from the violence of the disease, the patient being worn outly want of sleep, insufficient nourishment, and nuscular exhaustion. Deat is usually preceded by delirium and coma. In the bad cases the classes of the skin produced by constant friction becomes a source of great is

comfort, and may induce an attack of fatal ervsipelas.

Diagnosis.—In a well-marked case of chorea the absence of menetry and rhythm in the movements, their abruptness and variety, their couplete independence of the will, and their occurrence in spite of all effect to restrain them, make mistake impossible. The cases which began will puresis, and in which the muscular movement is a subordinate and as a mitcant feature, are less immediately recognisable. In such cases care in observation is often required to ascertain the existence of muscular specific According to Dr. Gowers, whenever a child of the choreic age suffers far gradual loss of power in the arm, and presents no weakness of fact tongue, or leg, the disease is invariably chorea. If the nature of the couplaint be suspected, we must look for confirmatory evidence, and shight exceptional spasm will be usually detected in the weak arm or in the sentatione.

Prognosis.—The immediate prognosis is almost always favourable and very severe cases in children under twelve years of age seldom do the wise than well. The worst cases are seen in girls who have monstructed and it must be remembered that the catamenia sometimes appears at a very early age.

The influence of the disease upon a child's future life has also to be considered. If the patient have strong neurotic tendencies derived to the

inheritance, we may feel less sanguine than we otherwise should be as to the after-effects of the illness. In such cases much will depend upon the moral advances which may be brought to bear upon the child. The form of the complaint in which muscular weakness is the prominent and early supplied, seldom passes into very severe general chores, but it often

genes an obstinate adment and difficult of cure.

Treatment.—Chorea is a disease which is decidedly influenced by treatsex in the wider sense of the word, as distinguished from mere drugmag. Our first care should be to see that the muscles are spared all unpressury exertion; and that the child is kept as quiet as possible in well We should then attend to all the bodily functions see that the lovels are regularly relieved; that any worms present in them are rea red; that the skin and kidneys act well; that the diet is reguided with a proper proportion of animal and vegetable substances; and the child does not take too much farmaceous matter or sweets. In most cases the subjects of chorea are anamic and weak, with flabby musde; not unfrequently the skin is dry and acts imperfectly. To resore the skin to its natural condition the body should be oiled all over staght, and in the morning the child should be thoroughly washed with some and hot water. After a few days the normal softness and suppleness of the skin will be restored. A cold douche may be then added to the treatment. If the child be not weakly, the douche may be given after her country bath as she sits in the warm water. In the case of a weakly chal it is better to separate the ordinary washing from the invigorating dracks. The patient may take her usual both in the evening, and in the coming the douche may be given as the child sits in hot water, after complete preparation of the skin by vigorous shampooing (see Introduction. In this process the shampooing, besides preparing the skin to resist the shock of the cold water, seems to have a directly beneficial effect upon the muse less.

Moral treatment is of the utmost importance. The child is, as a rule, weakened and demoralised by the new conditions in which she finds herself and much may be done by kindness, firmness, and vigilant attention to the wants to restore the balance of her mind. At first she should be assumed as much as possible, and endeavours should be made to anticipate by wishes, so that she may be spared the constant sense of failure. When the symptoms begin to improve, the child may be allowed to leave her bed, and games which involve thy thinical movement, such as the skipping-pe, should be encouraged. Benedikt recommends a weak constant current along the spine. The child should stand up during the application, and the current should be just strong enough to be distinctly felt.

With regard to drugs, the whole pharmacoparia has been ransacked for reaches for this complaint. The disorder has been attacked with autitionatic remedies, on account of its connection with rheumatism; with ma, cod-liver oil, and tonics generally, on account of the weakness and pillor with which it is usually associated; with phosphorus and other perime tonics and stimulants, to strengthen the nervous system; and with the whole long list of antisposmodies, sedatives, and narcotics, to reduce across excitement. Where there is great and mis iron is very useful, and should be always given. In these cases, too, alcohol is of great service, and the child should take a wine-glassful of sound chiret, diluted with an origin quantity of water, with her dinner. Of all the drugs which have been recommended as specifics in this complaint the only one from which have ever seen any decided benefit has been arsenic, and with this only

in large doses. Children bear arsenic well. I have been in the habit of prescribing for a child of five or six years of age ten drops of Fowler's solution of arsenic, directly after meals, three times a day. In this dose it is rurely found to disagree. If the child complain of discomfort at the epigastrium, and vomit a short time after taking the remedy and these are the only unpleasant symptoms I have known the medicine to produce it can be given for a time twice a day or in smaller doses. In every case the dose should be as large a one as can be borne without discomfort, and given thus immediate benefit will usually ensue. In cases where arsenic is ill borne by the stomach, or where it has been given without producing benefit, the drug may be administered hypodermically. Dr. W. A. Hammond, of New York, speaks in high praise of this manner of treating the disease, and states that thus administered the remedy can be tolerated by the system in doses considerably larger than if it were given by the mouth. Dr. Hammond directs that the injection should be made slowly at a spot where the skin is loose, such as the front of the forearm; that cure should be taken to conduct the fluid into the subcutaneous tissue and not into the skin or underlying muscles; and that Fowler's solution should be used diluted with an equal proportion of glycerine. The injection should be made once in the twenty-four hours, beginning with ten or twelve drops of the solution, and increasing the quantity by one drop each

Almost every writer on this subject has his favourite remedy. Trousseau advocates the claims of morphia and strychnia; Sir Thomas Watson speaks in high praise of turpentine. Sulphate of zine is said to be a specific by some; others prefer brounde of potassium or chloral. Without going through the list of drugs specially recommended, it may be sufficient to say that it is now generally held that the broundes are most useful in cross where the movements are violent and exhausting, especially if there be any reason to suspect ovarian excitement; that zine should be preferred for florid children and the more acute cases, iron for the pallid subjects weakened by chronic illness, and that arsenic given by the mouth effects its most rapid cures in the simpler forms of the disease where the muscular disturbance is not extreme. In cases of acute chorea dependent upon meningitis or medullary congestion or inflamination, and accompanied by a high temperature, Dr. Jacoby recommends the liquid extract of ergot given in half drachin doses to a child five years of age, three or four times

a day, and continued for many weeks in succession.

In very bad cases, where the movements are violent and incessant, where the child cannot sleep, and takes food with the utmost difficulty, the best plan is to put the patient under chloroform at stated intervals and feed her through an elastic entheter passed down the gullet. In such cases a sofficient quantity of stimulant should be supplied with each meal. At night-time, in order to insure sleep, a full dose of morphin should be given hypodermically. Much benefit is sometimes derived from Jaccould's plan of spraying with ether the whole length of the spine twice a day. Dr. Anstie records the case of a boy, aged six years, who had been reduced by the violence of the disease into an almost hopeless condition. At length the ether spray was begun. The boy at once began to improve, and in a fortinght the disease was at an end.

Obstunate cases of chorea may be sometimes cured by the plan originated by Dr. Weir Mitchell and abty practised by Dr. Playfair in cases of aggravated hysteria in women. The plan consists in vigorous slumpoung or "massage" of the muscles, so as to excite excessive muscular waste, and

in supplying the waste so induced by regular and excessive feeding. The shampooing must be carried out energetically. It consists in kneeding the muscles and making passive movements of the joints. This should be done several times daily for half an hour on each occasion. At the same time the patient is fed with large quantities of milk, meat, eggs, and other nourishing food. By this means all the more violent movements are quickly controlled, the extremities become warm, the child sleeps soundly and rapidly puts on flesh.

In every case where the movements are violent care should be taken that the patient receives no injury from knocking or bruising or chafing the skin. The sides of the cot should be padded; and the child should be confined to the bed by a folded sheet passed over the chest and tied

underneath the cot.

When the disease has passed off, means must be taken to discipline the mind by a judicious system of education, both moral and intellectual, and the shild should be encouraged to take part in active games and out-of-door exercises. A change to the sea-side is often useful to complete the enra.

CHAPTER VIII.

IDIOPATHIC TETANUS.

Teranus or lock-jaw, as it attacks new-born children, is a disease of wire in England we know little by actual experience. A few cases are, bowen seen from time to time, and it is not unlikely that but for the tender report of the infant attacked, and the rapidity with which the disease horrowing close, more examples of the malady might come under observation. Us tamly, at the east end of London, in the Irish quarters, where square alpoverty are often extreme, it is strangely common to hear of several mixture of a family having died a few days after birth from "convulsions." Some cases have probably come under the notice of no more expenenced observer than an ordinary midwife, and it is quite possible that many cased infantile tetanus may thus escape recognition.

The disease consists in an intense unitability of the spinal cord and a motor nerves which proceed from it, throwing the whole body into use tonic spasms. Infantile tetanus runs a very acute course and general ends in death. It is common in the West Indian islands, in South Angra and in the southern portion of the United States. In these warm chartistatacks by preference the new-born children of the negro populate it is also occasionally found in more temperate zones. The island of Kilda in the Hebrides has long been notorious for its enormous mant the tality from this cause, and sometimes in other parts of Europe the discontinuous that the tality from this cause, and sometimes in other parts of Europe the discontinuous in the cause.

occurs sporadically or even in occasional epidemies.

Canadian. - Much speculation has been bestowed upon the etiolog the disease as it occurs in new-born infants, and many theories have bydevised to account for it. The fact that the symptoms appear within a be days of birth seems to point to some traumatic cause for the illness ul suspicion naturally fell at once upon the remnant of the newly divided we brlical cord. Hence the disease has been ascribed to phiebitis of the bilical veins. The explanation has however, been proved to be errore-Dr. Mildner, of Prague, has collected forty-six cases of inflammation of the numbheal vessels which ended fatally. In only five of these did convicte form part of the symptoms, and in no instance did the convulsions is a any resemblance to those characteristic of tetanus. Again, phtchara if is umbilical veins, although an occasional accompaniment of infantile tetal in is more often absent than present. Inflammation, then, cannot be a cause of the disease, but still it does not follow that tetanus is independed of the condition of the cord. Even in the adult inflammation of a weath is not essential to the production of traumatic lockjaw, for the male is her been known to occur in cases where the wound had undergone made cicatrisation.

Mechanical causes for the disease, such as blows or accidental injuries and the use of too hot water for the bath, have been suggested by some authors. An eminent American writer has attributed the disorder to prose

are on the medulla oblongata and its nerves, through displacement occurring either during labour, or after birth from the child being allowed to

he for days together with the back of his head upon a pillow.

Although the disease may arise from these or other traumatic causes, it seems likely that an explanation of the phenomena is to be found in general rather than in local agencies. The influence of sudden changes of temperature in producing tetanus hardly admits of doubt. In all countries where the complant is prevalent there are rapid alternations of temperature the heat of the day passing suddenly into the cool of the evening. On the secount interruption to the functions of the skin has been suggested to the immediate cause of the disease. In the same way chilling of the surface by exposure to coll and wet has been said to be capable of exciting the tetamic convulsion. Of all causes, however, to which the disease has been attributed foul air generated by fifth and imperfect ventilation is, perspy, one of the best established. The often quoted case of the Dublin Lyng-in Asylum seems to prove this conclusively. Before 1772 nearly one in every six of the children born abve in the asylum died, and the cause of death was almost invariably tetanus. In that year Dr. Joseph Clarke introdecel a complete system of ventilation into the hospital. The consequence was that the mortality immediately fell to one in nineteen. Later, the portion of deaths was still further reduced to one in fifty-eight, and of thre who died little more than a ninth died from this disease.

In St Killa the high rate of mortality may with much probability be ambuted to a similar absence of fresh air and cleanliness in their homes. That some cause is there in existence which does not obtain in the neighbourng islands is evident, for children born of natives of St. Kilda out of the short of the affection can-

5 t be attributed to intermarriage or any hereditary influence.

Dr. Holland in his "Summary of the Diseases of the Icelanders," receis the frequency of trismus basecutium in the island of Heimaey, one of a group situated on the southern coast of Iceland. He states that almost very infant born on the island died of this disease, and that consequently be population was supported almost entirely by immigration from the suband. It appears that there was no vegetable food upon the island, and that the natives lived principally upon sea-birds which they salted and tarrelled. Dr. Holland attributes the disease to irritation of the bowels used by the practice of feeding the infants shortly after birth upon a strong and only animal food. He fortifies his opinion by the fact that at Kills, where the diet and mode of life of the natives resembled those possible at Heimaey, the disease was equally prevalent and equally futal.

Tetanus is occasionally seen in older children, as a consequence of some on bruise, or other injury, as is the case in the adult. Sometimes it

is thopathic, and is then probably rheumatic in its nature.

Morbel Anthony — Extreme injection of the small vessels of the spinal and its membranes, with extravasation of blood into the cellular tisme around the theca, and also into the cavity of the spinal arachnoid, has used by been described as a common consequence of infantile tetanus. In a case which died in the East London Children's Hospital, under the care of my colleague, Mr. Parker, there was a striking absence of congestion of accord and its membranes. On opening the spinal canal the loose consective tissue around the cord was found to be exchymosed in patches from the middle to the lower end of the dorsal portion of the cord. On spening the spinal dura mater, the pia mater did not present any unusual appearance. It did not appear abnormally congested. The cord itself

was firm to the touch. On cutting into it, the gray matter was deals mapped out by its pink colour when compared with the white substance

There were no extravasations into its substance at any point.

In some cases in adults Rokitansky and Demme have observed ad-

velopment of connective tissue in the spinal cord.

Symptoms.—The disease generally begins on the third, fourth, or \$k_1. day after birth. It is rarely delayed longer than the tenth. The are symptom mentioned by the mother is usually that the child carnet to the breast, or that if he attempt to do so he quickly abandons the name. Sometimes the milk is noticed to run out of his mouth, as if he had a life culty in swallowing it. Soon the jaws become stiff and the face has rigid, pinched look. The spasms extend from the muscles of the jay t the neck, the back, and finally the limbs, so that in a short time a general muscular rigidity is observed, which comes on in paroxysms, lasts for variable time, and then remits to return after a short interval. The intail may utter a pitiful whiteper when the paroxysm begins but at once to muscles become stiff and hard, the eyes are tightly closed, the passing set, with the mouth a little open, the head is drawn backwards the huar are clenched, and the feet are flexed upon the ankles. Sometimes that opisthotonos. If the paroxysin is short respiration may be suspended and the face become dusky, but in the longer attacks breathing group, continues. Euch attack lasts from a few seconds to half a minute, wi the intervals between them may be a few minutes or longer val the spasm does not completely relax, there is some livelity of the far the head often remains more or less retracted, the hands continue cleached and the thumbs are twisted inwards. At this time a touch will frequest excite the recurrence of the paroxysm. If milk is put into the mouth to child may be unable to swallow it, or if he attempt to do so the edd may bring on a return of the spasms. The want of nourishment and to exhaustion induced by the convulsions cause rapid emaciation. In me cases the interval between the attacks becomes shorter and shorter. the child sinks exhausted, or dies asphyxiated from spasm of the masses of respiration. From the very beginning of the attack the child comentirely to cry. Occasionally he may whimper faintly, but a lead on . never heard. The temperature usually varies from \$11.5 to 101 or 103 It may fall below the normal level before death, or may rust to 108 ? 105°. In a case recorded by Ingersley the temperature in some of the attacks reached 107. In this case albumen and casts were found in to urine, and the kolneys, after death, showed marks of acute neptimis will extravasations of blood.

Death usually occurs at the end of a day or two. The infant silice recovers if the paroxysms have appeared before the third day after total If the child live six days after the appearance of the first symptoms is

case may terminate favourably.

In Mr. Parker's case, before referred to, the arms were noticed to be stiff immediately after birth, and they could not be flexed. For a divitwo the child sucked without difficulty, then the milk was observed to run out of his mouth. On the fifth day, soon after the navel structel of he began to have slight spasms. If the apple was put into his mouth the spasms were immediately excited. On admission on the fifth day is cranial bones presented no abnormality. The child lay with the comscrewed up. His month was not quite closed, but any attempt to open wider brought on a tetanic spasm. There was no risus sardomens. Was stripped, the child's body was seen to be covered with hemorrhage deThe umbilicus was slightly red and inflamed, but there was no disciple from it. There were no marks of violence, nor any sores of any helpful the body. The limbs were rigid and outstretched, the legs that he so than the arms; the hands were clenched. The abdomin destinated walls were also rigid during the spasm, but they partially related after the spasm had passed off. The limbs never quite related during the intervals. The spasms were of short duration (a quarter to half a new), and affected the whole body at once. They recurred very rapidly, the slightest touch sufficed to bring them on. Respiration was quite mosted during the paroxysm. There was no opisthotonos. The temperary taken in the rectum, was 103.8°.

The case was treated with the calabar bean extract, of which one-sixth terms was given every half hour by the mouth; but as the infant was take to swallow, probably very little of the remedy was really introduced to the system. Still, possibly some was absorbed, for after several doses to staid opened his eyes and was able to swallow milk. He was then have in a warm bath and the bean extract was given every two hours. It is a warm bath and the bean extract was given every two hours. It is a warm bath and the bean extract was given every two hours. It is a warm bath and the bath, and a few others shortly forwards, but in the course of an hour they ceased entirely and the had so med to be going on well, when suddenly a violent paroxysm came and he died asphyxiated. The temperature varied, after the first, because 190.5° and 102.4°. The child lived only about sixteen hours after same soon into the hospital.

In fatal cases the duration of the illness is usually short. Sometimes a mant dies in a few hours, and in the majority of cases all is over better the end of the second day. More rarely the child makes a better the for life, and only succumbs on the eighth or ninth day. When he have takes a mill form from the beginning it may ternatiate favour-

he after a more or less serious illness of two or three weeks.

When tetanus attacks children after the age of infancy, the symptoms which are seen in the adult. They are well illustrated a following case of idiopathic tetanus which was under my care in

Last Lon Ion Children's Hospital.

A boy, aged ten years, complianed one day on returning from school ich live sa, and shivered. For the next three days he seemed poorly and sa, laned constantly of feeling cold. On the fourth day, in the evening, ack became stiff, and the stiffness extended to between the shoulders that he held his head backwards. On the following day (the fifth) he is to get straight' from the hips upwards, and the stiffness soon exist to the feet. Although very ill, he would sit up in a chair during lay and on one occasion, on being raised to his feet at his own reject to became perfectly stiff so that his mother could not bend him or bear him in his chair. After about a minute the rigidity subsided and resided his seat. He complained of no pain except from his tongue, has often bit in these attacks. After this the stiffness returned whenever he moved. His mind was quite clear, but except for asking for what writed he did not talk. The bowels were much confined.

The boy was admitted into the hospital on November 12th, two weeks to inscomplaint of clindiness. It was noted that he had no marks of certal injury. His face was drawn from contraction of the muscles, and he was risus sardonicus. Occasionally his body became quite stiff, his use and legs rigid and extended, the abdominal muscles hard and the case of the nucha contracted. There was no opisthotonos. These attacks generally came on at night. On the night of November 14th he had

nine of the spasms, on the 15th, ten. He often bit his tongue. the first few days his pulse was 80; temperature, 99-101, respectively.

20-24. The lungs and heart were healthy.

On the 16th, at 6 r.m., he began to take calabar bean extract, of a grain every half hour. This reduced his pulse in a few how. On the 17th it was noticed: "Abdominal muscles feel hard, and much rigidity of the back of the neck. No stiffness of joints of legs. Can only partially open mouth, when he does so the muscle the chin become very stiff, but are painless. Keeps his eyes closed light is not distressing to them. Checks and eyelids rather red. has a peculiar drawn expression; nostrils widely open. Tongue thing. Has no difficulty in swallowing. When asleep, the musuch less rigid than when he is awake, unless during the actual Temperature at 9 a.m., 98.2°; pulse, 72, small and compressible in force but not in rhythm; respiration, 22"

During the whole of the 17th the boy had only one paroxysm course of the following night he had three attacks. At 10 nr night (the 17th), his pulse being only 48, the medicine was order given every hour instead of half hour. After this the spasms fewer and less severe and the rigidity of the muscles gradually. The spasms still continued to occur at times during sleep, but I ally subsided at once when the child was roused. The bean extraorded on the 25th. His improvement continued and the parpronounced convalescent on December 12th. The last muscles to

completely relaxed were those of the abdominal wall.

Diagnosis.—Infantile tetanus is a disease which it is not easy to Violent paroxysms of tonic rigidity in which the jaws are set, the fixed, the muscles generally are still and hard, and the face become and drawn—these seizures occurring without twitching or sign a spasm, and followed by intervals of only partial relaxation, are a acteristic.

In older children it is important to distinguish between tet the symptoms of strychnia poisoning. According to Sir Robert Cl tetanus does not kill so quickly as a poisonous dosc of strychnia. in tetanus the symptoms become developed gradually, in struct soning the convulsions very rapidly become general, and a perfect veloped in an hour, or even more quickly still. If strychina he given in carefully graduated doses, the distinction is less easy, in these cases there are very decided differences. Tetanus begre ally and always runs a continuous course. Sir B Broche declared and never known a case of tetanus to begin, then subside, and the again in twenty-four hours. This continuity of symptoms would cult to simulate even by the most carefully graduated doses of the Again, in stryclinia poisoning the upper extremities are affected tetanus they are implicated late, and the fingers last of all. The too, of tetanus is very peculiar. The forehead is wrinkled perpend and transversely, the eyebrows being drawn towards one another remarkable manner. The eyes are not fully opened; there is a " look" which is very characteristic, and after a time the eyeball painfully sunken from tetanic contraction of its muscles. In d poisoning the evelids are widely opened and the evelvalls protrude

Prognosis.—So few children recover from this disease that demosis is always very unfavourable. Dr. Lewis Smith has collected cases, of which thirty-two died and eight recovered. This is a let

portion of recoveries, but statistics gathered from published cases alone pressably represent but feebly the fatal nature of the illness; for in so mortal a disease it is likely that many more successes than failures would be placed upon record. Early occurrence of the symptoms after birth, great violence of the spasms, shortness of the period of remission, and a very high temperature should excite the gravest appears after the first week has passed. The symptoms are then as a rule less severe, and sometimes deglination is unaffected. The ability or inability of the child to swallow is an important element in the case. If he still continue capable of swallowing milk from a spoon, we are justified in entertaining some hope of ultimate recovery.

In an older child the prospect is more favourable if the disease be the pathic than if it follow upon an injury; but in any case we cannot look forward without serious anxiety to the termination of his illness.

Textment.—In every case of infantile tetanus our first care should be to remore all sources of irritation, whether internal or external. The relations whether internal or external. The relations to be kept quiet in a room carefully darkened, and the bowels should be relieved by a good dose of castor-oil, or if he cannot swallow, by a capt us enema. Next, the rapid emaciation must be counteracted by repear feeding. The great obstacle to efficient nutrition is the spasm of the nuscles of deglutition which makes swallowing so often impossible. In this cannot be nourished per rectum. It is therefore advisable to put the idd under chloroform at regular intervals and administer his mother's man if it can be obtained, or if not, asses milk, cow a milk and barley requal parts), or other suitable food, through an elastic catheter passed down the gullet. In this way three or four ounces of food can be a sumstered every three hours; and with each quantity it is advisable to

my life n or twenty drops of sound brandy.

The third indication is to control the spasms. For this purpose some form of seclative must be resorted to. Opium, alone or combined with anti-quanodics such as sulphate of zinc or assafortida, Indian hemp, and belle nua or its alkaloid have been all employed. Whatever form be used it should be given with the food through the catheter or hypodermusky in frequent small doses. Chloroform checks the paroxysus for a time but they return when the effects of the amesthetic have passed anay. Good results have been obtained from the extract of calabar bean. In Mr Parker's case, previously narrated, even the small quantity of the ready absorbed seemed certainly to prolong the intervals of remission, although the seizures when they occurred were not diminished in severity. To drig should be administered hypodermically if the child cannot swallow The dose should be one-twelfth of a grain by the mouth, or onetweetach by subcutaneous injection, every hour or two hours, watching the feet. It is advisable to produce some decided effect upon the heart and lungs reducing the rapidity of the pulse and the breathing, if any good result is to be hoped for.

Of all the drugs which have been recommended for this disease the most favourable results appear to have been obtained from chloral. Dr. Wilerhofen claims six recoveries in twelve patients by the use of this sent, but the only case referred to in the short extract from his lecture which appeared in the Laucet, was not of a very severe character, as the ampleous came on late and deglutation was not interfered with. In a case which was under my care in the East London Children's Hospital this remain was employed, and although the baby died the effect of the drug

upon the spasms was decidedly encouraging. The difficulty appears to be to regulate the dose accurately so as to dominate the seizures without producing too serious a depression. For the notes of the case I am indebted to Mr. J. Scott Battams the Resident Medical Officer, who watched the

child with great attention.

A little boy, four days old, of healthy Irish parentage, was admitted October 18, 1881. The father and mother with three other children besides the patient occupied one room, which was said to be clean and large. The bed in which the child lay with his mother was placed in a strong draught, of which the woman had constantly complained. The child was born to all appearance healthy, and took the breast well until the day before admission, when he was noticed for the first time to be unable to suck. That night the infant slept badly, crying and drawing up his legs.

The cry was, however, strong even on the morning of admission.

When first seen (October 18th, noon) the baby was dirty but seemed well nourished; navel apparently healthy; cramal bones normal. Every five minutes spasms occurred of moderate severity; they did not arrest the breathing. In the spasms the legs were drawn up rigidly, the forearms were flexed. the fingers were stretched out and widely separated, the lips pouted a little and there was risus sardonicus, the jaw was fixed and the head was slightly retracted. An attempt to open the eyes or month aggrarated the spasms. At this time the person who brought the child refused to leave him without the consent of the mother. At 6 P.M., however, he was brought back and admitted. He had taken no food since 11 P.M. of the previous evening. The spasms had continued all the afternoon and were more severe than at first. The bowels were relieved by enema of a large quantity of curd, and the child was put into bed with an ice-bag to the spine. Between 7 P.M. and midnight three encumera of milk, containing, respectively, four grains, six grains, and six grains of chloral, were administered. After three hours the ice bag was removed. At midnight the child was no better. As he remained unable to swallow, he was put under chloroform, and three ounces of his mother's milk with four grams of chloral were injected through a catheter passed into the stomach. This was repeated at 4.30 a.m., after which the catheter was passed without difficulty and without chloroform, and between two and three ounces of his mother's milk with ten drops of brandy were given every two or three hours. During this time the convulsions had varied in intensity as well as in number. They were manifestly influenced by the chloral, so that from 5 AM. (19th) until 10 AM. he slept quietly.

At 10 a.m. (October 19th) the limbs were quite relaxed, and the child's face was somewhat dusky. Very little air seemed to be entering the lungs. On passing the catheter into the stomach very little spasm was excited.

At 2 r.m. Mr. Battams was sent for, as the infant was thought to be dead. On making artificial respiratory movements the child gave a gasp. From this time until 5 r.m. he continued to breathe eight times per minute. The conjunctive were insensible, the surface was cold, but there was less cyanosis. Some brandy was administered. At 10 r.m. his condition remained unaltered, except that the respirations were now reduced to four per minute. No more spasms had occurred.

On October 20th, at 2.30 a.m., the child was again thought to be dead, but artificial respiration revived him for a time; he, however, finally sank

about 3 A.M.

The temperature was 98° on admission (October 18th), 99° at 9 P.M. On the 19th it was 100.6° at midnight, 99.8° at 2.15 P.M., 94.8° at 5.30

P.M., 95.8° at 7.30 P.M., and 96° at 10.30 P.M. No post-mortem examination was allowed.

In this case the remedy was, no doubt, administered too energetically. It would have been better, after the first dose or two of the chloral, to have given the drug in smaller quantities, even if it had to be repeated more frequently. Had this been done, the result might have been different. I have been unable to find any rule by which the administration of the remedy may be regulated. Whether it be advisable to proceed to actual narcotism, or whether it is preferable to stop short of that point, must be a matter for individual experience to acquire, and in this country such experience is difficult or impossible to obtain. Widerhofen directs gr. j.—ij. by the mouth, or gr. ij.—iv. by the rectum, to be given "at the time of each onset of convulsion." This direction is too vague to be useful as a guide in practice, and can scarcely be intended to apply to a case such as the present, where the intervals of remission were so brief.

Tobacco and woorara have also been recommended, but must be very dangerous drugs to use at so early an age, even when, as in this disease, there is such a remarkable tolerance of sedatives. External applications are sometimes employed. Warm baths and cold packing have both their advocates. In Mr. Parker's case the warm bath seemed to have a decidedly

unfavourable effect upon the infant.

CHAPTER IX.

CONGESTION OF THE BRAIN.

Concertor of the brain is a term which is often used very loosely, and is probably applied to various forms of illness. Writers who have dealt with the subject of disease in early life differ curiously in the importance they attach to the subject of cerebral hyperæmia, some attributing to it most of the convulsive diseases to which young children are hable; others, as Valleix, asserting that this pathological condition is almost unknown in

infancy.

The view formerly held that the quantity of blood circulating within the cranium is constant and cannot be influenced by altered conditions of the body generally, has now been proved to be erroneous. The researches of Robin and of His have shown that surrounding the cerebral blood-vessels are lymphatic sheaths which communicate with the lymphatics of the pia mater, and are several times the size of the blood-vessels they enclose. These lymphatic canals contain a fluid which increases or diminishes in quantity according to the varying distention of the blood-vessels, and must therefore allow of great variety in the amount of fluid circulating within the cranial cavity. There is no doubt, therefore, that hypercoma of the blood-vessels can take place; but it does not follow because evidences of this congestion are discovered in the dead body that it was the cause of the symptoms from which the patient had suffered. It is common in cases of death from convulsions to find engorgement of the vessels of the brain and membranes, but this engargement is probably as often a consequence of the convulsion as a cause of it. Still, every physician practising amongst children must now and again meet with cases in which he finds a group of symptoms suggestive of some temporary increase of pressure upon the brain. These symptoms either pass off after a time and the child recovers, or they increase, the patient dies, and on examination of the skull cavity nothing but a hyperenne state of the cerebral vessels with an effusion of serum is seen to account for the illness. These symptoms are therefore supposed to indicate congestion of the bruin; but there is probably some deeper and less obvious cause of the impairment of function, for although this pathological condition may be invariably present, it cannot be held to furnish a full and satisfactory explanation of the phenomena.

Causation.—Cerebral congestion may occur in two forms: An active hypersemia from increased flow of blood into the brain, and a passive hypersemia from obstruction to the return of blood from the interior of the skull. Many different causes have been enumerated as giving rise to the condition, but it is difficult to accept all of them as determining agents in the production of cerebral congestion. Dentition is usually said to be a cause of vascular engorgement, because the teething process is often accompanied by convulsive seizures; but in these cases, if cerebral hyperse-

min occur, it is as likely that the convulsive seizures are the cause of the congestion as that the congestion determines the fits. The intense congestion of the face, and the swelling of the veins of the neck, which are always present in a convulsive fit, show that there is impediment to the return of blood from the head; at the same time the heart's action is excited, and blood is being propelled rapidly into the cranium. There must the therefore great engorgement of the vessels in this region, and if the fits are frequently repeated and the child remains for hours, as often happens, in a more or less convulsed state, the engarged vessels must relieve themselves by effusion of serum, and perhaps by minute hæmorrhages, Pressure upon the brain set up by this means is sufficient to account for the stupor, squinting, etc., which are often found to follow a convulsive serzure, but the effusions are in all probability like the venous congestion isulf, a consequence rather than a cause of the nervous commotion.

Even in cases where the cerebral congestion has preceded the convulson, it seems probable that something besides mere distention of vessols, unless this be extreme, is necessary to give rise to the eclamptic serzure. Some time ago I was asked to see a little child, aged six months, who had unpetigo of the head. The cervical glands of both sides were enlarged and had set up considerable pressure upon the veins of the neck -enough, indeed, to induce great wdema of the head and face. In this ense, where there must have been serious impediment to the return of blood from the brain, there were no signs of nervous disturbance. So in cases of enlarged bronchial glands with pressure upon the vascular trunks in the chest, adema of the head and neck is sometimes produced, and some heaviness may be complained of; but convulsions are not a symptom of the disease.

It appears probable that in many cases, in addition to the engorged state of the blood-vessels, small embolisms or thromboses in the minute arteries and capillaries of the brain may be agents in the production of nervous symptoms. Dr. Bustian found this condition of the brain in persons who had died whilst suffering from dehrium and come in the course of acute specific diseases, and has recorded his belief that minute and widespread congestions are often a consequence of these obstructions, There is no reason to suppose that young children differ in this respect from older persons; and probably the convulsive seizures which often occar towards the close of measles, scarlatina, and other infectious fevers, may owe their origin not to the accompanying congestion, but to minute plugging of the cerebral capillaries. Such vascular obliterations, if widely distributed, must produce, as Dr. Bastian remarks, "total disturbance in the incidence of blood-pressure, and in the conditions of nutritive supply in the convolutional gray matter of the brain."

Besides the eruptive fevers and convulsive attacks, exposure to extreme heat and cold, or direct violence applied to the head, may be, directly or in breetly, determining causes of acute hypersemia of the brain. A passive congestion may be induced in the child during a difficult labour; it is sometimes the consequence of energetic expiratory effort in whoopingcough; it may be set up by diseases of the heart and lungs, or by other causes which interfere with the return of blood from the head; and it may be induced by the pressure of intracranial growths upon the cerebral

sinuses and venus.

Morind Anatomy.—A congested brain has a swollen appearance. The dura mater is tightly stretched, and if slits are madvertently made in the membrane in the process of removal of the calvarium, the organ bulges through the artificial opening. The convolutions look broad. They are flattened by pressure against the bones of the skull, and their sulci are narrowed. The veins of the pia mater are engorged, tortuous, or even variouse; and the small vessels are filled to their minute ramifications. The cranial sinuses are distended with thick, dark, partially coagulated blood, and the choroid plexuses are also congested. The gray matter of the brain is also darker than natural, and its section shows fine dots from the injected vessels. The white substance also contains numerous red points, and sometimes the 'cerebral tissue is adematous, with excess of fluid in the ventricles. In cases where the congestion has existed for some time, little masses of blood pigment may be found lying outside the vessels within the lymphatic sheath. These are described by Bastian as molecular grains of a dark olive or amber colour.

Symptoms. Signs of general irritability of the nervous system, such as heat of head, fretfulness, dislike to hight and noise, disturbed sleep, startings and twitchings, have been said to constitute an early stage of cerebral congestion. Such symptoms in impressionable infants frequently accompany digestive disturbance and teething, but are more probably due to reflex irritation of the nervous centres than to engargement of the cerebral capillaries and veins. They are often, perhaps, accompanied by increased activity of the cerebral circulation, but are not necessarily induced by it. The so-called "irritative stage" of cerebral congestion, then appears to me to be one which cannot be clinically recognised, at least I know of no evidence to show that the symptoms said to be characteristic

of this stage have any necessary relation to an engorged state of the cerebral circulation.

The common form in which congestion of the brain is met with in practice is that in which an infant who has been taken with violent convulsions from teething, or other form of reflex irritation, is left drowsy and stapped after the fifs have subsided. Instead of clearing quickly away the heaviness continues. The child lies with his head retracted on his shoulders, sometimes he vomits, and he may even squint. In these cases congestion with effusion of scrosity into the lateral ventricles, and perhaps the substance of the brain, appears to be an important agent in the production of the symptoms. In cases of death we find excess of fluid in the ventricles; the volume of the brain, is increased, the convolutions are fluttened, and the vessels of the brain and the pia mater are engarged with blood. Such a case has already been narrated in the chapter on convulsions. Another, which seems to have been of a similar kind, although it ended differently, is the following:

A little boy, seven months old, a strong, healthy-looking child, who was being brought up at the breast, and had cut four of his teeth, was suddenly attacked with vomiting and purging. The symptoms appear to have been severe, for after a few hours the child fell into a lethargic state in which he lay for four days. At the end of this time he had a fit which lasted six hours. For the next ten days he was drowsy and half stapeded. His bowels were confined and once or twice he vom-

ited.

When I saw the child, on April 8th, he was lying in his mother's arms with his eyes half closed. His face was very pale, the pupils were equal, dilated, and immovable; there was no squint; the fontanelle was very elevated and tense; the head was retracted and the muscles at the back of the neck felt rigid. The temperature in the rectum was 99, the pulse and respiration could not be counted for irregularity. The lungs and heart

were healthy. The child took the breast well, and sucked vigorously but

or attaleries

He remained in this state, vomiting occasionally, until April 12th, when the sickness ceased and the patient seemed very much better. When seem a self-th he appeared to be quite sensible. The pupils were dilated as acted imperfectly with light, s.e., when the evilids were suddenly reself the pupils could not be seen to contract. The fontanelle was now reperfectly with light, s.e., when the evilids were suddenly reself the pupils could not be seen to contract. The fontanelle was now reperfectly Pulse, 168, very weak but regular. Skin cool. Head a remeted. After this the child soon became quite well, except that the same time afterwards he had a peculiar stare, the eyes being directed has a rule, so as to show a run of white above the cornea.

It is difficult to say to what these symptoms were due if congestion of the train and effusion of fluid induced by the convulsion were not the case of them. The normal temperature seemed to exclude any inflammative estimate; while the somnolence, the immobility of pupils, the season and tense state of the fontanelle, and the retracted head pointed to see increase of pressure within the skull cavity. If we assume, on the state of Dr. Bastian's observations, that the congestion is the consequence of wide-spread minute emboli obstructing the circulation through than, the frequent occurrence of symptoms such as the above is less

15. It to account for.

(asses have been recorded and attributed to cerebral congestion in with loss of consciousness, with pyrexia, squinting, and general paralysis assured and passed off completely after a few days or hours. It is difficult to understand how a simple local congestion alone can give rise to electron of temperature even in a young child. Such cases are obscure,

and a sufficient explanation of them has yet been arrived at.

Many cases of so-called congestion of the brain are probably the conretice of thrombous of the cerebral sinuses. Dr. Lewis Smith has an this to be sometimes the case in pertussis; and convulsions due to her causes may be accompanied by similar obstructions to the venous passes within the skull. Exact observations upon this point are to be deted, but it is probable that increased knowledge will in course of time smalls diminish the importance of mere fulness of cerebral veins as an

agent in the production of nervous disturbance.

b. poors. When we see a child who is suffering from symptoms indi-Of oppression of the brain, such as drowsiness, unmobility of pupils, stated tense fontanelle, and a retracted head, we have to distinguish rese from one of meningitis or other serious cerebral disease. The hat ar is here of the utmost importance. If the symptoms began with a lave attack preceded merely by signs of irritability of the nervous with a usually usher in a fit of eclampana; if the child be the suband if some cause such as swollen inflamed gums, otalgia, or ignitive derangement, can be discovered to account for the nervous we may consider the symptoms to be due to filling of the cerebral and effusion of serum into the cranial cavity. If the temperature is law if is a confirmation of this diagnosis. Often, however, in these the heat of the body is increased as a consequence of the cause which to peaked the convulsion. Therefore a high temperature is not necesto be interpreted as casting any doubt upon the accuracy of this In sin ple meningitis, which begins with violent convulsions by drowsmess and stupor, there is often a history of chronic detting, and in most cases the convulsion has been preceded by signs A pun in the head. But besides the history, the symptoms in the two

diseases differ in important particulars. In meningitis the child a at once seen to be serrously iil. He refuses his food, and is restless; he contracts his brows, raises his hand to his head, rolls his head from sale is sale, and, although heavy and stupid, manifests every sign of sub-mig. The temperature is high, but the pulse is comparatively slow (1996). The fits continually recur, leaving the child more and more stupided comatose. The pupils become unequal, rigidity of the joints comes on and the child dies.

In cases of congestion and effusion upon the brain the child, although heavy and stupid, is quiet and shows no distress. Usually he takes no bottle well, and this is an important sign. The fits are rarely regard after the drowsiness has become marked. The pupils, although shared are not unequal in size; and although the head may be retracted there is

no rigidity of the joints.

Tubercular meningitis sometimes, although rarely, begins with a mevulsion; but unless the cerebral symptoms occur as a terminal place of acute general tuberculosis, the disease afterwards runs its normal course. which is very unlike that of cerebral congestion. It must be remembered however, that a primary tubercular meningitis is a rarity under the act of two years, while the cases of cerebral congestion we have been considerag are almost limited to the first two years of life. The difference of age is therefore an important element in the diagnosis. Still, apart from other considerations, congestion of the brain may be usually recognised by remarking that although drowsy and stupid the child is not actually upresscious; that he continues to take his bottle well; that his pupils are next unequal; that there is no rigidity of joints, and that loss of power, although it may occur as a consequence of violent convulsions, passes off in a few hours unless there be some cause for it more serious than mere exhaust a of nervous force. The occurrence of squint lasting more than a for hours is very suspicious of a small homorrhage. It occurred, however a the case narrated in another chapter (see Convulsions), without anyther being discovered in the brain beyond congestion of vessels and offusion of

Prognosis.—There is always reason for great anxiety when a year; child shows signs of abnormal heaviness and drowsmess. The matter must not, however, be made of attributing to centric disease natural slope ness due to disturbed rest from digestive derangement. It happend! me once to be summoned some distance into the country to see a child a few weeks old who was said to have congestion of the brain because # was always falling asleep. I found that the child's bowels were disorder! and that it was evidently fortured by frequent-griping pains. Excepter minutes it drew its legs up, bent itself backwards, and uttered a helle cry. After some seconds its features relaxed, its eyes closed, and a seemed to sleep, but almost immediately afterwards it was aroused by fresh attack of pain. This state of things had continued for forts-state hours. During all that time the child had been prevented from obtain the natural sleep owing to the abdominal pains which roused it almost weed as its eyes were closed. After a good dose of castor-oil, which relieved its bowels of the irritating matter, the child enjoyed a refreshing sleep and awoke quite well.

The majority of cases of stupor following convulsions recover; but a c should be careful not to commit ourselves to a too hopeful progress upless improvement begin early and go on space. As long as the child our tinues to take his food well the progress is favourable. If he refuse

is food, if the drowsiness deepen, the pupils become unequal, or squinting our, the child will probably die.

When drowsiness is noticed in children as a result of impediment to be return of blood from the head, the prognosis is determined by the name and severity of the disease which has given rise to the passive conges-

Treatment — When called to a child who has been left heavy and stupid by an attack of convulsions, and we have reason to fear an effusion of fluid to the skull cavity, our first care should be to clear out the alimentary was by a close of calomel and julapine. We should afterwards keep up a beaution of the bowels by frequent doses of any suitable saline aperient. In chall should be kept perfectly quiet in a large well ventilated room seefally should be kept perfectly quiet in a large well ventilated room seefally should be allowed. If he be brought up by hand, milk and barley wast should be given, and but little farinaceous food. If the gums are to saline the perfectly may be lanced; but unless actual irritation arise but this cause the operation is better avoided. If thought desirable cold have applied to the head. In some cases counter-irritation with mustard positions to the chest and spine has seemed to be of service.

In passive congestion the treatment is that of the disease which has

green rise to the hyperaemia.

CHAPTER X.

CEREBRAL ILEMORRHAGE.

Represe of vessels and effusion of blood into the brain is in the child a comparatively rare accident. In new-born babies, however, extravasation into the arachnoid sac (meningeal homorrhage) is not uncommon if the labour has been difficult and slow. Indeed, Cruveillier has stated that amongst still-born children one-third of the deaths may be attributed to this cause. Under three years of age it is rare to meet with any other form of intracramal hemorrhage than that into the arachnoid, or the meshes of the pia mater, although Billiard found a clot in the left corpus structum in an infant only three days old, and Bérard found a similar lesion in a child of eight months. But after the third year a true cerebral hemorrhage is more likely to occur, and sometimes it produces much the same symptoms as are found in the adult to accompany a clot in the brain.

Causation. When meningeal homorrhage occurs during birth it is in cases where the head of the focus is locked in the brim of the pelvis, and the bones of the skull are forced to overlap from the pressure brought to bear upon them. If it occur after the birth of the child it is usually a secondary affection, and may be induced by any cause which is capable of giving rise to severe and long-continued congestion of the brain. Thus it may be found in cases of thrombons of the cranial sinuses; it may be induced by tumours of the brain pressing upon the torcular Herophili and the veins of Galen; it may be a consequence of convulsions or whooping-cough, and it is said to be often found in cases of death from infantile tetanus. It appears to be predisposed to by conditions which lead to debility and cachexia, such as bad feeding and acute exhausting disease.

The same agencies which induce cerebral hemorrhage in infants may cause extravasations of blood into the skull cavity of older children. In these subjects the hemorrhage may take place into the meninges, the ventricles, or the substance of the brain. In hemorrhagic purpura the meninges of the brain, like other parts of the body, are occasionally the seat of extravasations of blood. In many cases, especially when the effusion occurs between the dura mater and the skull, the hamorrhage may be attributed to a traumatic cause. Children, too, like adults, may die from that comparatively rare accident—rupture of an aneurism on the brain. Cerebral aneurism occurs in early life much more frequently than the ordinary forms of ancursm. Out of seventy-nine cases collected by Dr. Peacock no less than four were found in children between the ages of thirteen and fifteen years, and a boy, twelve years of age, recently died of this disease in the Victoria Park Hospital, under the care of one of my colleagues Still, liable as children are to cerebral disease, humorrhage into or on the brain is not common in young subjects, so far at least as can be judged from the results of post-mortem examinations.

Morbid Anatomy. - In young subjects hemorrhage is in general capit-

har Rupture occurs in small vessels and the effusion of blood is gradual. the menuges of the brain the extravasation usually takes place in the are more sac; but it may be also formed between the dura mater and the base in the meshes of the pis mater, and in the lateral ventricles. In the arschnoid sue the blood is either liquid, of the consistence of syrup, mas separated into a solid and a liquid portion. On opening the cranium the lars mater is of a deep violet colour from the presence of the dark de beneath it. On examination this clot is seen to be spread over the safare of the brain. It usually occupies the situation of the posterior lobes and the cerebellum, and may even reach as far as the vertebral canal. It is the test in the centre unless a part of it covers the fissure between the laungheres, in which case it is usually thickest at this spot, as it here de dwn towards the fornix. Towards the circumference it thus off. and is usually continued for some distance as a false membrane which realls from absorption of the colouring matter of the effused blood. This bus memorane near the clot is readily distinguishable, but it fades gradsalv towards the edges and is lost on the surface of the arschnool, and generally adheres slightly to the parietal layer of the arachnoid, although it may be readily separated, and the membrane beneath it has a perfectly normal appearance. The visceral layer of the arachnoid, however, soften thickened and opaque. The clot and resulting false membrane is are cases stratified—an appearance probably produced by succes-* alditions to the original extravasation. Sometimes we find more than occiot, the effusion having taken place at various points. The thickness be from a few lines to an inch or more.

A certain amount of fluid, more or less coloured, bathes the surface of the dot; and if the child live long enough the liquid may become enclosed it a secret of cyst formed by more or less complete adhesion of the edges of the false membrane to the surface of the arachnoid covering. Sometimes the cyst is loculated, and the contents may increase in quantity by a sequent secretion. In a case reported by MM. Rilhet and Barthez a deale cost was found, each chamber containing more than half a litre of that When the collection of fluid is thus considerable, it presses outside the fontanelle and the bones of the skull so as to form a real hydro-

व्या । । । वन

It is rare to find hemorrhage in the ventricles; but it may occur either in the walls of the lateral ventricles or into their cavities. Humorrhage int the substance of the brain is also an uncommon lesion, although it may occur in infants and children of any age. It is seldom copious Usuben it takes place it is in the course of some other form of illness, and perhaps on this account often escapes recognition during life. The basis seen in minute points scattered about the cerebral tissue, or may but I collected in little cavities in the brain-substance. These two The are about equally common. The larger collections of blood vary in from a pea to a walnut. Around them the brain-tissue is normal, or based with rose colour, or slightly softened. The hiemorrhages may be bear at any part of the brain-substance, but are much less common in to crebellium than in the cerebrum. Besides hemorrhages we often find these cases much congestion of the brain; and there may be also other bout such as meningitis and even tubercles of the brain, as in a case to whereards referred to.

Cases of aneurism of a cerebral artery in young subjects are almost inpully associated with endocarditis, and it is generally held that the aranal alatation is the consequence of embolism. It is probable, also, that cerebral harmorrhage in the child is more often the result of aneurism than is commonly supposed, for this may be easily overlooked. As Sir William Gull has observed, "when death takes place from changes around the ancursm, as by pressure or softening, the sac itself may present such appearances that unless a minute dissection be made of it, its true nature may not be discovered." The mechanism by which the aneurismal dilatation is produced is doubtful. Dr. Ogle attributed it to the impaction of the fibrinous clot, and supposed that this afterwards softened and involved the coat of the vessel in the process. Dr. Goodhart has suggested that in many cases the clot is given off from a valve the seat of internative endocarditis, that this poisons the part where it lodges and "leads to acute softening of the arterial wall by inoculating it with its own inflammatory action." This explanation is not, however, of universal applicability.

Symptoms.—The symptoms of meningeal harmorrhage are unfortunately far from being characteristic of the lesion to which they are owing. This form of intracranial hamorrhage, indeed, may give rise to no symptoms at all. According to M. Parrot, in infants reduced by long-continued bad feeding to a cachectic state meningeal hamourhage is not unfrequently found, although during life nothing unusual in the condition of the child had been noticed to excite a suspicion of this serious complication. On the other hand, in new-born babies extravasation of blood into the arachnoid sac may be accompanied by violent convulsions and end in death within a few hours. Such a case is recorded by Valleix. A well-developed, healthy-looking male infant received a violent bruise on the shoulder two days after birth. He seemed to be going on favourably when, on the sixth day, he was seized with strong convulsions, which were repeated with violence, and in three hours the child was dead. On examination of the body a large clot was found in the arachnoid sac; the veins of the pia mater were, swollen with blood; the substance of the brain was injected; and the superior longitudinal sinus was filled with a whitish, semi-transparent, gelatinous thrombus. In this case the convulsions must not be attributed entirely to the hasmorrhage. No doubt the thrombosis had a great share in the production of the symptoms, and it was apparently the cause of the extravasation. Convulsions are, however, a common consequence of arachnoid hemorrhage and repeatedly recur.

Legendre has described a febrile form of meningeal harmorrhage in which the disease begans with vomiting and pyrexia. Convulsive secures soon come on, limited at first to the ocular muscles and giving rise to a slight squint. The child sucks well, probably from thirst, and hus bowels are in a normal state. Soon contractions are noticed of the fingers and toes, and general convulsions follow, both tome and clonic, during which consciousness is lost and the face becomes of a dusky red that For a time the convulsions are comparatively infrequent, and in the intervals the child is heavy and drowsy. After a few days the heaviness deepens into stupor, the intervals between the fits become shorter and shorter, and towards the end of the illness the infant is almost constantly convulsed. The fever persists throughout, and death is often hastened by an intercurrent inflammatory complication of the lungs.

The above is generally accepted as representing the ordinary course of an attack of meningeal hierorrhage in the young child; but if it induces us to look for elevation of temperature as an essential part of the illness it is certainly misleading. Statements with regard to temperature, made in days before the thermometer came into use as an aid to chinical investigation, should be accepted with caution. Moreover, in each of the two

instrations appended by the author to his description of the discuse, a balle catarrhal pneumonia was found to occupy the lungs; and this amplication would amply explain any elevation of temperature which must have been noticed during life. In cases of intracranal his morphage inscremental by an inflammatory condition of other organs the temperature as is shown by a case narrated later, is not raised above the normal lead.

The chief difficulty in assigning to this form of hamorrhage its disundire symptoms arises from the fact that it is rare to find a case in what the hamorrhage was not secondary to, or complicated by, some other midaly. Even in instances where no morbid condition of other organs is to be discovered it is an open question whether the convulsions we be are invariably present in such cases give use to the harmorrhage or the be orthogo to the convulsions. It is worthy of remark that paralysis is selva a consequence of meningeal harmorrhage. The symptoms, miletal, are very much those of meningitis affecting the convexity of the brain. with the important exception that in cases of hemorrhage there is no process. They also differ from them in the fact that there are no signs of Leabshe, and that at first the stupor is not profound. Infants with extransation of blood into the meninges, according to the testimony of all polished cases, take the bottle well for a time. This is no doubt owing to test rather than to any appetite for food. Still, the fact remains that "Libert arachnoid hamorrhage the child takes food with avidity, in simple metagates of the convexity of the brain he makes little attempt to suck, and generally refuses the bottle altogether.

Henorrhage into the meninges or on to the surface of the brain is not excited to infinite. A little girl, aged eight years, was a patient in the Yours Park Chest Hospital, for heart disease and dropsy. The heart was eslarged in all directions; præsystolic and systolic murmurs were bear at the apex; there was much ordema of the lower extremities, and the unne contained one-third of albumen. The child was kept in bed and mais considerable progress for about a fortnight, when some thrombous succeed in the basilic and internal suphena veins of the left side. About a week afterwards she cried out one morning after breakfast with put is her head, and shortly afterwards became convulsed. Twitchings noticed in the muscles of the lower part of the face on the left side, in long the lips, the angle of the mouth, and the left side of the neck. The law was turned to the left. There were also convulsive movements of the left arm, more particularly of the forearm, wrist, and hand. There ware hi movements of the leg on that side. The girl died in the course d the evening after a series of these convulsive movements. The temper-

stare was normal throughout.

On pening the superior longitudinal sinus, after death, the channel to contain a decolourised adherent clot which reached from the lot the anterior extremity to the posterior third. Opening into the saw the arterior extremity to the posterior third. Opening into the saw that with a clot, but less decolourised than the first, and the surface of lectrin in its neighbourhood was the sent of a circumscribed hamorance. The clot was bounded posteriorly by the fissure of Rolan lo, and the belanteriorly over the posterior part of the superior frontal convolution in the right side. These correspond very nearly to the areas described by Ferrier, as connected with the movements of the lips, tongue, and month; also that for the movements of the arm and leg. There were no convolute movements of the left leg, but this was the seat of so

much adema that the child's own voluntary power over it had been very small.

This case, for the notes of which I am indebted to Dr. Lawrence Humphry, the resident physician, bears a very close resemblance to Valleix case before referred to, although occurring in a much older child. It will be remarked that the temperature during the convulsive seizures was not elevated.

When the extravasation of blood takes place into the substance of the brain the first symptom is usually an attack of convulsions. Afterwards the phenomena may resemble those peculiar to an apoplectic seizure in the adult. It is probable that this form of harmorrhage is less uncommon than might be inferred from examinations in the dead-house; for if the amount of blood effused be moderate, the child may recover with a more or less extensive paralysis. In primary homorrhages I believe this is not unfrequently the case. In hospital practice we not unfrequently see children who, as a consequence of a fall or some injury to the head, are seized with headache and convulsions, and are then found to be paralysed in one half of the body. The leg often recovers after a few weeks, but the arm may remain more or less permanently disabled with contraction of the firgers. This was the case with a little girl, six years of age, who was lately a patient in the East London Children's Hospital. In addition the child was aphasic, and could not be persuaded to speak during her stay in the hospital. Otherwise her general health seemed fairly good, and she did not complain of headache. The case unfortunately could not be followed out, as after a few weeks the child was removed by her friends; but I have little hesitation in ascribing her symptoms to a small clot in the

Often the cerebral bemorrhage is only one of several lesions occupying the cranial cavity. It is then difficult to assign to each its due share in

the production of the symptoms.

A little girl, nged lifteen months, with ten teeth, was brought to the hospital on July 13th. According to the mother's account the child, although hand-fed, had walked at the age of ten months, and had always been regarded as healthy until the previous March, when she had had a full down a flight of stairs. The child was not stunned by the accordent, but vomited and "was ill" for a few days. She then began to lose flesh and ceased to run about, always crying to be nursed. On June 4th, she had a violent convulsive seizure which began with hiccough. The spasms were limited to the left side, and lasted nine hours. When they ceased the left arm and leg were noticed to be powerless, and the face was drawn to the right side. The paralysis passed off in about a fortught, but the child remained weakly. She began to have a discharge from the left ear and the nostrils. She seemed to suffer much from pain in the head; often vomited; and the bowels were somewhat loose. On two occasions she had general convulsions of an hour's duration. She took liquid food well.

Towards the end of June the child became much worse. She began to cough; her breathing was rapid; she sighed a great deal; seemed very

drowsy, and at times would scream out suddenly as if in pain.

On admission into the hospital (on July 13th) the temperature was 101°; pulse, 160; respirations, 88. The patient was fretful and screamed almost incessantly until 11 p.m., when she had an attack of general convutsions. At this time her temperature was 104°. On the following morning the was found very pale; the fontanelle was depressed; the eyes were turned constantly to the right; the pupils were unequal and insensible to

the left being the larger of the two. Both arms were convulsed, and be right leg and left hand were rigid; there was no paralysis of the face. To hands, feet, and nose felt cold, although the temperature in the rectum was 102 ft. The pulse was very small, 170. The abdomen was soft and occurrenced. Pressure on the skin produced little flush. On examination of the back dulness was noted on both sides with abundant crepitating ries. After this the child remained insensible and died at 6 p.xt.

On examination of the body much yellow lymph was found covering the right much lle lobe of the cerebrum. There was an old clot, the size of a beverge, occupying the right corpus structum and the superjacent part of the right hemisphere. Scattered caseous nodules, the size of a large pea, were seen in the right hemisphere, and the choroid plexus; and some gray problems were discovered on the vertex of the brain along the course of the ress is, and a larger number at the base. The lungs were the seat of starrhal pneumonia. The liver, spleen, and kidneys contained small relew to lules; and the broughial and mesentoric glands were enlarged and execute.

In this case there can be little doubt that the convulsions and hemiplea noted on June 4th resulted from the apoplectic clot. The afterpapens were, no doubt, the consequence of the meningitis and general traculous. The case is interesting as showing that a copious extravasation is not necessarily fatal; for it is reasonable to suppose that had the

the been the sole lesson present the child would not have died.

Corbrid harmorrhage in the child is not, however, always accompanied by symptoms so characteristic. Violent convulsions and sudden death may be produced by a clot in the substance of the brain; or a child may be seed with repeated vomiting; may then be taken with convulsions; and afterwar is fall into a state of unconsciousness with dilated pupils, rapid being pulse, and cool skin, and die in the course of a few hours. These were the symptoms noticed in the case of a boy who died in the Victoria Part Hospital from rupture of a cerebral aneurism. The notes of the case were kin by furnished to me by Dr. Humphry, the resident physician.

A scrothous looking boy, aged twelve years, was admitted into the hospital in ler the care of my colleague, Dr. Birkett, on March 15th. He had his substitute four years before, followed by dropsy, and there was besides admitted history of rheumatic fever at about the same time. For two the patient had complained of shortness of breath, which had lately gatting more distressing. When admitted, a loud mitral murmur

was less tool, with considerable hypertrophy of the heart.

On Murch 19th the boy vomited a great deal, and complained of headthe the morning of March 20th he seemed very sleepy, but made no
mapping. At 11.30 a.m. the resident physician was summoned to his bedas the boy was said to have had a fit. The patient had vomited, and
pleased to be very drowsy, but he answered questions. The pupils were
the and rather contracted; the conjunctive were sensitive, and there
the squart or other sign of paralysis. Shortly afterwards he had several
the conjunctive were not sensitive. He passed water in the bed.
The pupils were equal. Temperature, 97.6°; pulse, 84, and regular. After
the conjunctive more and more profound, and the boy died at 4 r.m.

On examination of the body the veins over both hemispheres were and congested, especially on the right side. The pia mater over the viale surface was suffused. The left hemisphere was larger than the real and the convolutions were flattened. At the base of the brain all the

spread along the Sylvian fissure on to both surfaces of the cerebrate addownwards along the cord. Both lateral ventricles were compately had with a large clot, as also were the third and fourth ventricles. First the ventricles the blood seemed to have spread by the transverse fissure to the outer portion of the brain, and not through the "ster." The source the hiemorrhage was a small aneurism, of the size of a small peaser to the Sylvian artery about one inch from its beginning. The context aneurism were very atheromatous and brittle. The rupture was extensially along the top of the aneurism, and the blood had burst into the top of the aneurism, and the blood had burst into the top of the sels showed no sign of disease. The mitral valve was much beaded, and the pericardium was universally adherent.

Judging from the variety of symptoms found as a result of cerebric hamorrhage in the child we can only conclude that there are none when can be considered characteristic of this lesion. Symptoms of irritation of the brain coming on suddenly, and followed after a few hours by symptoms of compression, are not peculiar to hamorrhagic effusion within the same and yet, as a rule, we find nothing more distinctive than these. Still the tery fact of profound depression following rapidly upon symptoms, it violent irritation in a non-pyretic patient may give rise to suspicious of cerebral hamorrhage, especially in children over four or five years of age.

Diagnosis.—On account of the indefinite character of the sympton hamorrhage into the brain or meninges in childhood is very difficult to detect. The difficulty is increased by the lesion being so often a secondary one, occurring in infants and young children who are already suffering from other complaints. It must be confessed that in such cases introcranial hamorrhage is very likely to be overlooked. Even when the hamorrhage is primary it is difficult to lay down rules for the detection of the lesion.

If a young child, whose water has been examined and found to be healthy, be seized with repeated convulsions, in the intervals of which although drowsy and stupid, his temperature is normal, and he swall in liquid food with appetite, we may he situte between congestion of the limit with effusion of fluid and intra-cranial hemorrhage. If, now, we notice that after the stupor has become marked the convulsions continue, and especially if any contractions and rigidity, more than merely temperature noticed in the hands and feet, the temperature remaining low, we are justified in suspecting a hiemorrhage.

When hemplegas follows an attack of convulsions, the paralysis is not necessarily a symptom of humorrhage, for the same phenomena recursions and paralysis) are occasionally seen in cases of tumour of the base. In the latter disease, however, we can usually obtain a history of soft and paroxysmal headache; there is often paralysis of ceular muscles, indicating implication of cerebral nerves; and an examination of the eye regenerally detect the presence of optic neuritis. Contractions and regard of the tingers and toos, wrists or ankles, may occur in either case. It after recovery of consciousness the hemplegia persist, but the clader main free from headache, if the retime are normal and the general head seem fairly good, a cerebral growth may be excluded.

A diagnosis between hamorrhage into the meninges and that into the substance of the brain is probably impossible from the symptoms although if paralysis occur this symptom is not in favour of meninged extravasation. The age, however, is here of importance. Under the

and year hamorrhage rarely takes place into the cerebral tissue. In the cases of intracranial hiemorrhage occurring in infants aged three years and under, observed by M. Legendre, in no case was the hiemorrhage other than meningeal. After that age hiemorrhage more commonly takes

bor into the brain-substance, as it does in the adult.

Perpans.—In all cases of cerebral hiemorrhage the prognosis is very prome, and it is especially so if the patient in whom the extravasation as he the subject of disthetic disease, or be weakened by recent acute these. The occurrence of paralysis is not in itself a necessarily unfavourable a.m. Of greater importance is the degree of heaviness remaining that the convulsions have ceased, or the frequency of return of the spassic movements themselves. As long as the child continues to take put food we may hope for improvement. If he refuse his bottle, or case to drink when the feeding-cup is held to his hips, the sign is a very activizable one. The condition of the pupils should be always noticed. It may are distarted and insensible to light the prognosis is bad; if they are uniqual in size death may be considered certain.

Pretonent, -Cases of intracranual hamorrhage require much the same transaction has been already recommended for congestion of the brain. If the child be a rong an ice-bag should be applied to his head, and the basis should be freely acted upon by a dose of calomel and jalap. If the seart's action be violent, and the arteries of the neck are seen to pulticipally, digitalis may be given to control the energy of the cardiac entractions. Three drops of the tineture of digitalis, or twenty of the indusen, may be given every two or three hours to a child of twelve mathe of age. The patient should be with his head raised; and if the last are cold, a hot bottle can be placed at the bottom of the cot. If the pass flag or the fontanelle become depressed, stimulants should be given

The food should consist of milk, freely diluted with barley water, or of water and barley water. It is better in these cases to feed the child with span or at any rate to give him fluid only in small quantities at a time, was act to increase the strain upon the vessels by a rapid introduction of

lup quantities of liquid into the circulation.

In the after-paralysis little can be done. Our efforts must be reten to ordinary measures for improving the general health and propose nutrition.

CHAPTER XI.

CEREBRAL TUMOUR.

Courbres, like adults, are subject to morbid formations in the bost which may give rise to a variety of symptoms according to the situated the growth. In the case of a child, however, "tumour" of the bost usually means "tubercle" of the brain, for it is only in exceptional case that any other form of cerebral growth is to be found. Still, in rare assumes cancerous, glyomatous, and syphilitic nodules are developed in the region, and occasionally we meet with the cysticerous cellulosa or in-

hydatid eyst.

Morbid Anatomy. - Tubercle of the brain is said to be rare under the nge of two years; but I think the occurrence of the disease in mants > more common than has been supposed. It is seldom seen in the cravit without other organs being similarly affected, although in exception cases it may be a solitary instance of tubercular formation in the balt The seat is most frequently in the cerebellum, but it is also consider : the hemispheres of the brain. Next in order of frequency, according to Andral, come the pons, the medulia oblongata, the peduncles of the cerebrum and cerebellum, the optic thalamus, and the corpus stretce. In number there may be one or more, and in size they may be small a large. Usually the more numerous masses are of small dimersors Single tumours may be as small as a pen or as big as an egg, or ever a still larger size; but they are most commonly met with about equal : volume to a filbert or small marble. The masses are almost always at rounded by a fibrous covering which separates them from the brain-substance around. In exceptional cases, however, i.e., where death has two place while the tumour is still growing, the limits of the mass are not thus circumscribed, but its substance passes insensibly into the adjustcerebral tissue. When the tumour ceases to extend itself, an are had connective tissue and vessels forms at its circumference, and deads into a fibrous envelope which varies in thickness according to the age I the growth.

On section the tumours are yellowish white, or have a faint greenst tint, and are found to consist of cheesy matter. Their consistere is more or less firm, but the centre is usually softer than the cromateres and may be converted entirely into a creamy pulp so as to give the apparance, with the firm envelope, of a little bag of pus. Tuberculous name found in the brain is seldom seen in any other shape than that of yellow caseous matter. Lebert and Rokitansky, however, agree that in every tional cases it may begin as the gray granulation; but it seldom remain long in this stage and very quickly becomes cheesy and yellow. Aromithe mass the brain-substance may be natural, or congested, or more of less softened by ordema. Often the collections of tubercle spr., from the pia mater, and are attached to it by a fibrous stalk continuous with the

Cineer of the brain is rare. When it occurs it is usually secondary to sendar growth in the eye; or, as recorded by Steiner, may advance inserted from the skull. When thus secondary, it may appear in several courses. The size of the mass varies from a pea to an orange. These so-

call-I cancerous growths have usually the characters of screoma.

Ghomatous tumours of the brain are solitary growths which increase alonly in size, so that they may be long in producing appreciable effects. They often reach considerable dimensions, and occupy by preference one of other of the posterior cerebral lobes. Their borders are not well defined, and their substance passes gradually into the brain-tissue around. Their consistence is usually firm, and they are rather more vascular than the cerebral substance in which they are embedded.

Cysticerci, the second stage of the tamia solum, when they occur in the brain, are usually numerous. They are generally found in the gray substance or at the surface. They are especially partial to the pin mater, and are usually more or less embedded in the gray matter of the convolutions. They vary in size from a pea upwards. Occasionally they die and become changed into a thick "mortar-like" substance containing booklets.

Hydatids, the second stage of the tenia echinococcus, usually exist, several together, enclosed in an outer sac. The most frequent situation is the centre of the white matter in one of the hemispheres, and the cyst may grow to a large size. The hydatid, although rare at all ages, is not proportionately less common in children than in adults. In twenty-four cases of hydatids of the brain, collected by Dr. Bastian, in which the age was stated, three occurred in children under the age of ten years.

Symptoms. Tumours of the brain, if they grow slowly, if they are situated at a distance from the base of the brain and the large gangha, and if they merely displace the brain filaments without destroying them, may pro fuce absolutely no symptoms at all. This fact, which has been ascribed in a supposed faculty of accommodating itself to pressure residing in the brain, is better explained by Niemeyer to be due to the strophy of cerebral substance which takes place in the neighbourhood of slowly growing tarnours, allowing of increase in size of the growth without interference inth cerebral function. Sometimes the symptoms are so triding as to be ore rehulowed by others arising from disease or disturbance of a different Part of the body. Again, after being a long time latent, the growth may are rise to obstinate headache, to a slight squint, or some other form of "14 Scular spasm; and for weeks or months this may be the only symptom to the detected. In cases where the morbid growth consists of cheesy matter other symptoms may arise not due directly to the cerebral tumour. Thus the patient often dies of a tubercular meningitis, the symptoms of which may quite conceal any special phenomena resulting from the tumour of the brain.

There are no symptoms peculiar to an intracranial growth, for all are the consequence of local destruction of substance, of pressure on the tissue around, and of interference with its vascular supply. A distinctive character is, however, given to the disease by its course, the sequence of its

phenomena, and the predominance of some symptoms over others.

There are certain general symptoms which are found in most cases of cerebral tumour. Headache is usually early to occur, and may remain for a long time the sole morbid phenomenon. Often slight at first, it becomes gradually more intense, and may assume a violent paroxysmal character which is intimtely distressing. Infants show this by contracting the brows, throwing up the hand to the head, rolling the head from side to side, and occasionally breaking out into piercing cries. An older child will place his hand upon the site of the pain it asked to do so. He avoids the light; shudders at a loud noise; and often buries his face in the pillow of his bed, or covers his head with the bedelethes. The attacks of headache are generally accompanied by vomiting, and often by dizzness.

Sometimes complete and bilateral, and resemble attacks of epilepsy. Sometimes they are partial, and are confined to the face, the eyes, or one limb. The convulsions may be preceded by tremours or twitchings without loss of consciousness, and it may happen that these latter are present without being followed by more decided seizures. If attacks of such motor disturbance, of whatever degree, are noticed from time to time in the same part, or persist in it, the symptom is a very suspicious one. Convulsions are said to be more common when the growth is situated in the posterior lobes of the brain, and to be less frequent when the anterior lobes are affected. If the seizures are epileptiform in character, the tumour is proba-

bly in or near the cortical substance of the cerebrum.

The convulsions may be followed by temporary paralysis in the affected museles, and in some cases a permanent paralysis may be observed. This more commonly affects muscles supplied by cerebral nerves than is the case in other diseases of the brain. The external rectus may be affected (sixth nerve), producing convergent squint; there may be prosis, dilutation of pupil, and external strabismus from paralysis of the third nerve; the facial muscles may be paralysed; and there may be impairment of deglistition or articulation. Sometimes hemiplevia is produced. The cerebral nerves are affected on the same side as the growth; the spinal nerves on the opposite side. If, however, there be several tumours present in the brain, nerves of both sides may be involved, and we may find hemiplegia combined with variously distributed paralyses on both aides of the face. Generally the paralysis is developed slowly, and is preceded by pain in the znuseles about to be affected. When it occurs suddenly after a convulsive seizure, the case is often mistaken for one of cerebral ha mornlage. Contractions often occur in the paralysed muscles, and may follow the paralysis very rapidly.

There is usually loss of special sense. Deafness may occur, and impairment of vision is a frequent symptom. Amaurosis is said to be most common when the growth occupies the anterior lobes; in which case the strught sinus is compressed and the escape of blood obstructed from the veins of the eye. Impairment of vision is not, however, confined to these cases. It is often seen when the tumour is scated in the posterior lobes or in the cerebellum. The disturbance of sight is then attributed to compression of the vena magna Galeni; and the interference with the circulation induces at the same time a copious effusion into the lateral ven-

tricles.

Ophthalmoscopic examination of the eye almost always shows important changes which affect the retma of both eyes. We find that the disk

is swollen and blurred at the margins, with tortuosity of the central vein.

If the child live long enough the optic nerve may atrophy.

Unless chrome meningatis become developed, or there are numerous tumours in the cerebral substance of both hemispheres, intelligence is but little affected. Still the child generally shows some change in character. He is fretful and perverse, or morose in temper, and gives much trouble in the nursery and school-room.

In slowly growing tumours the development of the symptoms is very tradeal. These are the cases which are comparatively easy to recognise. We find a history of headache, of tremors, or convulsive attacks, followed at a longer or shorter interval by puralysis more or less complete, involving often special senses, and implicating the cerebral nerves as well as those

of the spane.

A good illustration of the symptoms is seen in the following case:

A little boy, aged five years and a half, who had had a slight convergent squart since the age of two years, but had otherwise enjoyed perfect both, began to suffer in the month of June from peculiar symptoms of these. A short time previously he had had a severe fall upon his head. The scalent shook him for a time, but its effects appeared to pass off completely. Furly in June, however, the boy began to complain of headache, which came on in severe paroxysms, so that he cried out with the pain. Almost at the same time his limbs began to get weak. His arms trembled when he took anything up in his hands, and he tottered as he walked. Very soon afterwards his sight began to fail, and he used to voint, especially at night; but his other senses seemed perfect, and his intelligence was unimpured. After a time the severity of the headache duminahed, but the other symptoms were intensified, so that by November, when he was admitted into the East London Children's Hospital, he was almost but I and hed quite lost the power of walking.

On a imission (November 16th) the muscles were well nourished and seemed firm, but any voluntary movement excited a kind of spasm, during back both arms were drawn up, seemed to get rigid, and were agitated or a positive trembing which lasted for one or two minutes. The legs appeared very weak. When placed upon his feet he could not stand attout support, and when he tried to do so a tremor was noticed in the egs like that which affected the arms. There was no paralysis of the face, and the tongue was protruded in the middle line. He had only partial entrol over his sphineters, for when he felt the desire to evacuate the backs or the bladder, he usually passed his water or motions in the bed before there was time for any one to come to his assistance. He was quite band, and an ophthalmoscopic examination showed the presence of optic meurits. His other senses were perfect, and his intelligence was quite equal to that of other children of his age. His temperature at 9 a.m. was

102 ; pulse, 138.

For some days after admission the boy continued in much the same state. The temperature remained between 100° and 101°, rather higher at hight than in the morning. The tremors persisted, and the weakness became more and more marke I. In about ten days, however, some rigi lity of the left arm was noted. The elbow became slightly stiff, and he kept has beful tightly checked over the inverted thumb. He used only the right hand voluntarily, although if made to hold anything in the left he could do so.

On November 28th control over the sphineters was quite lost, and he passed his water in the bed. The bowels were usually costive. There was

rigidity and tremor of both arms, the head was retracted, and the back was kept rigidly extended. Still, intelligence remained unincpaired. Sometimes the boy answered questions in a sleepy tone, but he perfectly understood all that was said to him. He made no complaints. Temperature at 9 a.m., 104.67; pulse, 144. At 6 p.m., temperature, 104.47; pulse, 148.

On November 29th he became very drowsy and would answer no questions Both arms were rigid and flexed, with the thumbs twisted inwards. The legs also had become stiff and the toes extended. The back was rigid with inclination to opisthotonus. He could swallow, but apparently with difficulty. The respiration was jerking, and appeared to be chiefly disphragmatic. The abdomen was rather retracted. The eveballs twitched, The child was alternately flushed and pale, with profuse perspiration. He had several convulsive attacks during which the left corner of his mouth was drawn up. Temperature at 9 A.M., 1082. The boy had no more fits after 2 p.m., but lay unconscious with his eyes fixed and turned to the right. There was oscillation of the eyeballs, and the pupils were diluted and immovable. He winked when the right eye was touched, but the left conjunctiva was insensible. The joints were rigid and flexed. The belly was retracted. The pulse was excessively rapid and very irregular in force and rhythm. Respiration 36, with occasional deep sighs. The child died the same night in convulsions. The temperature shortly before death was 108.8 .

On examination of the body the brain weighed fifty onness. volutions were flattened, especially over the right hemisphere. On removing a thin layer of brain-substance at the posterior part of this hemisphere a large cavity was found of between two and three inches in diameter. This was empty and was lined by a species of false membrane. The brain-substance composing its roof seemed rather firmer than natural and was from one-sixth to one fourth of an inch in thickness. The floor of the cavity was formed by a firm lobulated tumour as large as a good-sized orange. reached to the base of the skull, where it was firmly attached to the duramater. It lay external to the pons, occupying the posterior part of the middle lobe and the adjacent part of the posterior lobe. Its boundaries were not distinctly defined, for it passed insensibly into the cerebral substance around. On section the mass showed a uniform surface of a vellowish-white colour. It was generally very firm to the touch, but spots were found here and there where the substance was softer, as if from fatty degeneration. Some of these softened spots had become hollowed out into cavities of about the size of a marble, with irregular walls. On microscopycal examination the tumour was found to consist of small round cells, with many spindle-shaped cells and a fibrous matrix. There were also many fat globules. The lateral ventricles contained about eight nunces of fluid. The crura cerebri were softened, flattened, and rather twisted. The corpora quadrigemina also softened. Optic nerves small and soft. There was no appearance of recent meningitis.

This case illustrates fairly well the course of the disease. The severe paroxysms of headache with which the illness began, the vomiting, the affection of sight, the gradually increasing paralysis, and the muscular contractions and spasms which succeeded, together with the chronic progress of the case, all pointed to compression of the cerebral substance. It is probable that the effusion into the ventricles was a late symptom, only occurring when the retruction of the head and dorsal rigidity became marked. The accumulation of fluid compressed the cerebral substance, and was a cause of the drowsiness and stupor which marked the last hours of the

boy's illness. The complete clearness of mind which continued until a late period in the course of the disease is worthy of note in the case of so large a growth. A curious point in the case is the continuous elevation of temperature; for pyrexia is not a usual symptom in gliomatous tumours of the brain until quite the close of the illness, unless the growth be complicated with meningitis, and in this case no recent signs of inflammation could be discovered. On account of this pyrexia the tumour was thought to be a tubercular one, although no evidence of tubercle could be obtained laring life by examination of the other organs of the body.

In the case of children it is exceptional to find any other variety of tunour than the tubercular form. This, in the majority of cases, becomes some or later complicated with tubercular meningitis, the symptoms of which will then mix with and obscure the more special phenomena connected with the cerebral growth. Anomalous cases of tubercular meningities are often, as Dr. Hennis Green pointed out in his admirable paper,

instances of this combination.

A little garl, twelve months old, was noticed towards the beginning of Mark to sepaint outwards with the left eye, and shortly afterwards the carl of that side began to droop. Much about the same time she sufficient sickness, and was restless and agitated, often screaming out as the pain. The face used to flush, often on one side only. She took her bottle well. The bowels were confined. At the beginning of April the restlessness from which she had suffered increased, and she cried greatly, that gher head from side to side on the pillow. She then had a fit in the sh both arms and legs were rigid and convulsed; her head was retracted and her back arched. After this she did not completely recover the roundings, and, either from dulness of intelligence or from impured to un, censed to recognise her mother. She still, however, took her bottle well when the teat was put into her mouth.

When seen, on April 23d, the child lay in her cot apparently unconscious. The head was retracted and the back rigid; the arms were stiff and semiflexed, with the thumbs inverted; the big toes on each side were right and extended; but while the left lower limb lay stiff and straight the right was slightly flexed, and the leg from the knee downwards was in constant movement, alternately flexed and extended. There was ptosis of the left eye, but no squint. The pupils were unequal and insensible to bight, the left the more diluted. The breathing was irregular, with sighs and pauses. Temperature at 6 g.m., 99. The child took her bottle well, but lay as if unconscious, although the pupils contracted when the conjunctive were touched. After this the rigidity continued with occasional tempsions, and an external squint became again developed in the left eye.

The temperature varied between 99' and 100,5°.

At the beginning of May the patient began to cough, and a preumonic consolidation was discovered in the right lung. After this she became rapidly worse; the coma became deeper; the temperature rose to 103°;

and she died on May 11th.

On examination of the body there was found a consolidation breaking down in the right lung with many gray granulations. The convolutions of the brain were flattened and congested. Its substance was excessively soft, that the brain did not preserve its shape when removed. The lateral ventrules contained eight ounces of clear fluid. Attached to the under surface of the left crus cerebri was a nodulated tumour of the size of a valuat, feeling soft to the touch like a bag of pus. It was irregular on the surface, and was attached to the crus by a slender stalk of soft, yellow

cheesy matter, and covered with pia mater. No gray granulations could be detected about the membranes, but the dura mater was reddened and thickened.

In this case the occurrence of signs of paralysis of the left third nervo (ptosis an l external strabismus), accompanied by headache and vointing, pointed to localised pressure, such as that of a growth, and as this nerve and no other was affected at the first, the position of the growth in or upon the left crus cerebri (which is pierced by the oculo-motor nerse) could be positively indicated. The other symptoms-convulsions, rigidity. and stupor -which followed after an interval are such as are common in cases of cerebral tubercle, and almost invariably attend the close of the illness. In fact, such symptoms, preceded during several months by headache, vomiting, and paralysis of a cerebral nerve on one side, are very characteristic of tubercle of the brain. The disease might, indeed, be often divided into two stages-an early chronic stage, in which headache, vomiting, optic neuritis, tremors and convulsive movements, and more or less marked muscular weakness succeed one another irregularly and at various intervals of time, and into an acute second stage, in which convulsions, paralysis, rigidity of limbs, retraction of head, and stuper usher in the cul of the illness. We must not, however, always expect to meet with a division of the disease into two well-defined stages. Sometimes the earlier course of the malady is accompanied by few symptoms, and these, on account of the tender age of the child and the character of the synatoms themselves, may have little importance attached to them.

Thus a little garl, aged six months, had vomited more or less since birth, and was said to mean frequently and "fret" as if in pain. She had wasted considerably but had never had convulsions. The family history

was a healthy one.

In so young a child vomiting, pain, and restlessness, combined with loss of flesh, are familiar symptoms, and do not point in any way to intracranial disease. But on examining the baby carefully it was noticed that when the child cried the mouth was drawn up to the left side, and that the left eyebrow contracted better than the right. When the face was at rest the right eye was more open than the left, and the masal line skirting the angle of the mouth was less deep on the right side of the face. The

pupils were equal and there was no aquint.

In a few days other symptoms began to be observed. The head become retracted, there were tremulous movements in the right arm, the child seemed heavy and stupid, and often appeared to be quite unconscious. Rigidity of the limbs then came on, the drowsiness deepened into coma, and the child died. After death patches of meningitis were found at the base of the brain. A small cheesy mass, the size of a therry-stone, was imbedded in the substance of the pons -the left posterior half—and a second, pedunculated, growth of the size of a marble was attached to the upper part of the medulla oblongsta and lay underneath the right crus cerebri. There was a considerable amount of fluid in the ventricles, and a moss of caseous glands in various stages of softening lay about the roots of the lungs.

Sometimes the disease begins with extensive paralysis. This was the case with a little girl, aged four years, in whom the first symptoms noticed were left hemiplegia and vomiting four or five months before her death. In other cases the onset of the illness may be indicated by a muscular tremor or a convulsive attack. In the impority of instances, however, severe

headache precedes the other symptoms.

On account of the frequency with which tubercle occupies the corebellum a challen it is important to be aware of the phenomena which usually company a growth situated in this region of the brain. The characteristic roup of symptoms consists of vomiting, occipital headache, amaurosis,

get a staggering gait.

The counting is especially obstinate. It is a frequent accompaniment da', cerebral tumours, but when combined with occipital pain is very suggeome of a cerebellar growth. The headache is the consequence of presare upon and stretching of the tentorium. It affects the occuput especially, and may radiate to the back of the neck. If, as sometimes happens, it is accompanied by rigidity of the museles of the nucha, we find a curious rebecause to cervical caries which may be a source of perplexity. Amauhas from optic neuritis is a common symptom of this as well as of all other long of intracranial tumours, but growths in the cerebellum are especially and to press upon the venous channels in the neighbourhood and impede blood from the retina. Staggering gait is the most characbanks symptom of cerebellar tumour, and when combined with the precedwe sufficient to establish a diagnosis. Dr. Bastian compares the walk distant patients to that of one who pages the deck in a rough sea. In the cased a child it looks as if the patient were only now learning to walk, and decombined, as it often is, with a certain stiff way of carrying the head, the effect in the elder children is very curious. After a time the weakness explis to the hmbs, which then become unable to support the trunk. I ac contractions, too, may affect the muscles of the back and limbs as " those of the nucha, and are sometimes very severe. Tonic rigidity is any homore common than clonic convulsions when the tumour affects this person of the brain. Dr. Stephen Mackenzie lava it down as a general rule test 'tome contraction is a product of cerebellar, clonic of cerebral dis-These contractions, like the paresis, affect the muscles of the trunk bick those of the limbs.

The pone and medulla oblongata are also frequently visited by tubercase formations. In the former situation the growth may produce neural-calcasthesia, or paralysis of the fifth nerve, difficulty of deglutition, calchemored the function of the bladder. If the growth occupy the arenor lateral half, the third and fourth nerves may be paralysed. If it is the posterior lateral half, there may be paralysis of the tifth and facial areas and in either case there may be hemsplegia of the opposite half of

the body.

In the medulla oblongata the growth may produce wide-spread mischef Extensive paralysis is common; there may be difficulty of deglutities and articulation and incontinence or retention of urine from paralysis

of the bladder. Convulsions are common in these cases.

Taberculous tumours, when they occur in infants, are almost invariably test of a general formation of tubercle in the body. They are very apt to be complicated with catairrhal pneumonia excited by the presence of the gray granulation in the lungs, and in a large proportion of these cases, the been said, the illness closes with all the signs of the third stage of the central meningitis. In older children the formation of tubercle may be general. Still, we often find evidence of scrofulous consolidation of lang, or caseous bronchial glands, and in such cases the cerebral mass last, perhaps, be more strictly described as scrofulous cheesy matter than true tubercle. In exceptional cases no other sign of disease is to be bend in any part of the body.

bagnesis - The existence of a tumour of the brain can only be ascer-

tained by careful attention to the course of the illness and the characteristic grouping of symptoms to which it gives rise. If the combination of headache, vomiting, and double optic neuritis be discovered, it is lightly probable that a ccrebral growth is present; but in infants, although the existence of headache and romiting is easy to ascertain, an ophthalmoscopic examination of the eyes is often a far from easy matter, and even the question of impairment of sight may be a difficult one to decale. It is probable that many instances of supposed dulness of mind at this early age are really instances not of imbecility, but of blindness. The child ceases to recognise familiar faces because he has ceased to see them. In such cases the test of a bright light passed before the eves is a very valuable one; for if the eves follow the light the infant is evidently not unconscious, and the retins is usually still capable of appreciating a luminous jet, although its sensitiveness to ordinary objects is impaired. If then, in an infant who is subject to headache and vomiting, we can accertain in addition that the sight has failed, we have gone far to establish the existence of tumour. If now a local paralysis arise, or tremors or convulsive spasms are noted in special muscles, we may feel satisfied that our dagnosis is a correct one.

If a young child is seen first towards the close of the disease when the symptoms have become complicated with those of basilar meningitis, we must inquire carefully as to the previous course of the illness and the progression of the symptoms. If we find a lastory of chronic disease in which headache, sickness, and local paralysis, such as squinting, ptosis, or distortion of the face, have occurred some months previously; if any loss of power observed has been persistent; and especially if we can discover that the child is the subject of optic neuritis, or that his aight has been failing, we may give a positive opinion that a tumour is present in the brain. Even the anomalous course of a tubercular meningitis is suspicious of a cerebral growth, and the sudden appearance of symptoms characteristic of the third stage of this disease (convulsions, stupor, squinting, unequal pupils, paralysis, or rigidity of joints), preceded by signs of chronic nervous disturbance, are very suggestive of tubercle of the brain.

In older children the combination of headache, vonciting, and optic neuritis is very significant if Bright's disease can be excluded. Severe headache alone is of no value, for migrame is a not uncommon complaint in young persons. The disease does not, however, always begin with pain in the head. When this symptom is absent, tremors or muscular spasms occurring repeatedly in the same limb or the same region of the body are suspicious. If after a time they become more severe and general, and are complicated with other signs of nervous disturbance, such as paralysis, especially of a cerebral nerve, and impairment of sight, the disease is in

all probability tumour of the brain.

The actual position of the new formation can seldom be more than suspected. In the case of a cerebellar growth, the symptoms to which this gives rise have been already described. When the tumour occupies the base of the brain, paralysis of some special cerebral nerves may reveal the sent of pressure. In other parts of the brain the symptoms are so often contradictory, and are so hable to be altered and confused by disturbing causes, that the situation of the tumour can seldom be predicted with anything approaching to certainty.

If epileptiform attacks form part of the symptoms, these are distriguished from genuine epilepsy by remarking that between the attacks the patient is not well, but still continues to exhibit signs of cerebral irritation. With regard to the nature of the growth: A tumour of the brain is in additional so generally tubercular that we may conclude it to be so unless there be signs to make us suspect the contrary. If, however, the child be well accurated and of sturdy build, if there be no history of phthis is in the family, and if the other organs appear to be healthy, we should hesitate to class the growth as a tubercular one. Children with tubercle of the brain are not necessarily wasted, nor have they always a tubercular or pursued history; but they are usually pale and flabby, and generally show in the physical conformation signs of diathetic influence. No argument can be founded upon the age of the child, for although the disease is said the rare under the age of two years, I cannot agree with this statement, be look in the preceding pages I have referred to two cases—one a little put of twelve months and another aged six months, both patients of my rain the East London Children's Hospital in each of whom tubercular masses were found after death connected with the brain.

Proposes.—The disease is so fatal a one that when we are satisfied of the costonee of a tumour of the brain, we can have little expectation of the child's recovery. In very rare cases shrinking and calculation of a taberulous tumour have been known to occur; but if the growth has problems symptoms of pressure and irritation, little hope can be entertured of a favourable ending to the illness. Even in cases where the arritants, although distinct, are of a mild character, we must not allow over rest to anticipate necessarily a lengthened course to the disease, for lower chronic may have been the earlier symptoms, the disease may at

and time take on a more acute course and run moidly to a close.

Frestment. In the treatment of these cases we must attend to the constratond con lition of the child and correct any derangement which may le point to interfere with the nutritive processes. We must remedy an brestive disturbance and regulate the bowels. By improving the geard Lealth of the patient we may perhaps help to arrest the extension of the mass, and may possibly promote the calcification of the tumour. Terth.ld should live, if possible, in a dry bracing air; should be warmly cetted judiciously fed, properly exercised, and be treated generally acceeding to the rules had down for the management of the scrofulous diathese Cod liver oil and iodide of iron are useful aids to this treatment. It as history of syphilis can be obtained, mercurial treatment must be al ped without loss of time, and a long course of perchloride of mercury and the entered upon. Distressing symptoms must be treated as they Yomiting can be often allayed by keeping the child perfectly quiet it a recumbent position, and by applying an ice-bag to the head. Cold applications will also relieve the headache when this becomes severe, and specient of calomel and jalap is useful. If necessary, morphia can he guen with the same object.

CHAPTER XII.

CHRONIC HYDROCEPHALUS.

Hydrocephalus is a name given to serous effusions into the cavity of the skull, wherever situated. The effusion may be acute or chronic. Acute hydrocephalus is generally the consequence of tubercular inflammation of the meninges of the brain, and the name is practically synonymous with tubercular meningitis—a disease which is discussed in a separate chapter. It is not, however, very uncommon in cases of death from severe and protracted convulsions, occurring without discoverable organic lesson of the nervous centres, to find collections of serosity in the cerebral ventricles and at the base of the brain. This effusion is accompanied by turgescence of the veins of the pia mater—itself probably a consequence of the convulsive seizures—and may be looked upon as a result of the venous congestion. This may be considered an instance of the non-tubercular form of acute hydrocephalus. Such a case is narrated in the chapter on "Convulsions."

Chronic hydrocephalus is called either internal or external, according to the situation of the fluid. In the internal form the fluid is contained in the cerebral ventricles; in the external variety it collects in the arachnoid cavity. The disease may be congenital, or may be developed at some period after birth. Hence there are two cluef divisions of chronic hydrocephalus into the congenital and acquired variety. The congenital form is usually an internal hydrocephalus, for the fluid is for the most part in the ventricles. In the acquired variety it may be either internal or ex-

ternal, or the fluid may collect in both situations.

Consation.—It is difficult to say what may be the causes of congenital hydrocephalus, although these are probably more than merely temporary agencies; for a woman who has once given birth to a hydrocephalic infant may do so again in future pregnancies. The tendency appears to be often here htary, and it has been attributed with a doubtful amount of probability to drunkenness and other constitutional vices on the part of the parents. According to Dr. B. Rennert, of Frankfort, the children of workers in lead who have themselves suffered from chronic lead-poisoning are very apt to develope chronic hydrocephalus. Sometimes it is associated with malformation of the brain, for if there is congenital atrophy of any part of the organ fluid is thrown out to fill up the resulting space. This has been called "hydrocephalus a vacuo." Rokitansky attributes the large majority of cases of the congenital form of the malady to inflammation of the arachnoid hining of the ventricles occurring during foetal life or attacking the infant shortly after birth.

Acquired hydrocephalus usually occurs before the end of the third year. It may be induced by any cause which interferes with the cerebral circulation, such as tumours pressing upon the venie Calem or straight sinus, and so impeding the escape of blood from the ventricles. Serious pressure upon the veins of the neck by enlarged glands may produce the same result. So also the intracramal effusion may be a part of general

dropsy dependent upon disease of the heart.

Another group of causes are those which modify the quality of the Thus it may occur as a consequence of anamia, rickets, and other diseases which are accompanied by impoverishment of the blood, and as a sequel of exhausting acute illness. In Bright's disease hydrocephalus may be a part of the general dropsy induced by the state of the kidney. The fluid in acquired hydrocephalus is usually in the ventricles. In the rare cases where it is found external to the brain it is someturnes a consequence of meningeal humorrhage. In the chapter on this subject it was stated that an arachnoid clot becomes after a time, if the child survive, converted into a cyst by the adhesion of the edges of the layer of fibrine-left after absorption of the colouring matter of the blood -to the serous membrane. This false membrane, according to Legendre, ErHiet, and others, is formed, as above described, directly out of the bloodclot. Virehow, on the contrary, is of opinion that it results from an intiammation of the internal surface of the dura mater, and that the exuded I vanish arising from this process becomes vascularised and forms a pseudoserous membrane which is the wall of the cyst.

The cyst may be simple or loculated, and its contents consist of redclish serum with small clots and floculent matters. Often the cyst is clouble, each half corresponding to one of the hemispheres of the brain. Its walls become thin and transparent, and have a serous appearance. Usually arborescent vessels may be seen to ramify on the surface. The fluid contents become increased in quantity after a time, and may vary

from a few spoonfuls to half a pint or more.

Marbid Anatomy. - When the hydrocephalus is congenital and the fluid accumulates in the ventricles of the brain, it tends to press outwards the walls of those chambers. As a consequence the brain-substance is thinned; the convolutions are fluttened, and, as the pressure is equal in all directions, the corpora striata and optic thalami are flattened, separated, and pressed aside, the septum lucidum is softened, stretched, and often torn; the ventricles communicate freely through the dilated foramen of Monro, and the corpora quadrigemina, the cerebellum, and the pons are flattened and compressed. The membrane lining the ventricles is often found timekened and softened, and may be roughened or even distinctly granu-In some cases the foramen of Majendie is closed. If the effusion is large the walls of the skull also feel the effects of pressure. The head becomes distended; the frontal bone is pushed forwards; the roofs of the orbits are depressed so as to flatten the sockets of the eyeballs, and the occipital bone and the squamous portion of the temporal bone are made almost horizontal. The sutures are widened and the enlarged fontanelles communicate by the sagittal suture. The shape of the head is often not quite symmetrical, neither is it globular. The curve is much greater at the aides, and the skull is rather flattened at the vertex. Ossification in the cranial bones is delayed, and is said to be often aided by the conjunction of small islets of bone formed in the membranous interspaces. At a later stage the bones become very thick and the skull is remarkably spherical in shape.

If no great quantity of fluid is present the size of the head is not increased, but this is comparatively seldom the case; usually the skull is distended as described. The fluid is clear or slightly turbid, and varies in quantity from a few ounces to several pounds. It is of higher specific

gravity than the cerebro spinal fluid; is alkaline in reaction, and contains a very feeble proportion of albumen, besides chlorile of sodium and urea.

Various abnormalities of the cerebrum may be present from arrests of development, and sometimes traces of old disease can be discovered, such as patches of sclerosis resulting from past harmorrhage or inflammation. The cerebral substance generally may be of normal consistence, or ans mic, or edematous. Congenital hydroecphalus is often combined with other arrests of development, such as cardiac malformations, spins bifids, harelip, etc.

In acquired hydrocephalus the changes above described stop short of the extreme degree often reached when the disease is congenital. The ventrules are still dilated, but to a less extent. They contain several ounces of fluid (six, eight, ten, or twelve), usually limpid and clear. The ependyma of the ventricles is thickened and often dotted over with fine modules, especially upon the optic thalami, the fornix, and the stria cornea. The choroid plexus is congested, and the brain-substance may be denser or tougher than natural.

If the fluid is in the arachnoid space it is spread more or less over the surface of the brain. The brain is often ordenatous, and its consistence is reduced. In extreme cases it may be converted into a white pulp (hydrocephalic softening).

Symptoms.—Many cases of congenital hydrocephalus which reach the full period of gestation die during delivery or shortly afterwards. Others survive for a variable period, but they die in the majority of cases before the end of the second year. In raper instances the patient may live for five or ten years, or longer, and it is said may even reach extreme old age.

At birth the size of the head is not always remarkable. The appearance of the new-born infant may be natural, and no cramal enlargement may be observed until after the lapse of some weeks. Most cases of hydrocephalus present both physical and mental peculiarities. The head of the child becomes very burge, but his general development is strakingly backward. The increase in size of the skull is gradual and progressive, and in some cases the volume of the head becomes enormous. The peculiar shape of the skull and the strange contrast between the dimensions of the cranium and the little pinched and pointed face beneath it is very striking and characteristic. In a well-marked case the large globular head, greatly expanded at the sides and flattened at the crown, combined with the small face, if represented merely in outline upon paper, would give the impression of a large oriental turban placed upon the head of a child of ordinary size. The skin over the cranium is thin and seems stretched; the veins are full; the hair is scattered and meagre. On placing the hand upon the head the large fontanelles, the widely opened sutures, and the thin, yielding bones convey almost the impression of a tense bag of fluid. Often fluctuation can be detected, and the soft parts may have a slight pulsation, rhythmical with the breathing, falling in during inspiration and dilating again as the breath is expired. The face is thin, the cheeks are often hollow, and the chin is small and pointed. The eyeballs are forced forwards by the flattening of the roofs of their sockets, and at the same time the evebrows and eyelids are drawn upwards by the tension of the skin. Consequently the eves look prominent. They appear also to be directed downwards, for there is a rim of white above the corner from uncovering of the sclerotic, while the lower half of the pupil is covered by the lower eyelid. This large head is necessarily a heavy one, so that the child has a difficulty in supporting it. As the general nutrition

imperfect, and the muscular development of the patient far below a part standard, the difficulty is often great. The child may endeavour to part the head with his hand, but often he has to abandon the attempt teep himself upright, and is forced to rest his head on a pillow or on a mather's kip. The weight of the head is one reason why these children see slow in learning to walk. Another cause is the imperfect state of estation of the body generally. Although the child as a rule takes food readly and appears to digest it, he does not thrive. His head gets bigger ad by ger, but the muscles of the trunk and limbs remain feeble, flabby,

bitan and seem to derive no benefit from his copious meals.

The intelligence of hydrocephalic patients varies greatly in different set. Sometimes it appears to be unaffected, and mental development catalogs in normal progression. As a rule, however, the child is backwill. He is slow to take notice, apathetic, and dull at an age when other infants can be easily amused. The time for walking arrives, but he makes to effect to "feel his feet," and if held upon the ground allows his limbs to double up helplessly underneath his body. When at last he learns to walk his gait is tottering and uncertain. This backwardness in locomology uppears to be partially due in many cases to want of intelligence, but he heard muscular weakness and the weight of the head contribute, no

lost greatly to the deficiency

It is very difficult to ascertain the degree of keenness of the senses in the sense hydrocephalic babies are often thought to be deaf, but this is retably due in many cases to want of attention. The sight is often important of an in many other cerebral diseases of infants—the child may set take notice of faces and objects because he sees them indistinctly. Or Childrel Alibrith believes is chemia papillie to be the enricest change, but states that soon the disks and retinas become wholly disorganised and be often nerve is atrophied from pressure. The ophthalmoscope shows the lists strophied, their outlines blurred or lost, the vessels distorted or lost, and the return inaculated with patches and streaks of a brownish colour from old his morrhages, exudations, and fatty degeneratives. Nystagmus is a common symptom in these cases, and there is the a convergent squipt.

Nerrous symptoms are seldom absent. The patient may be distressed attacks of laryngismus stridulus, and Dr. West has observed spasmodic repeat. Convulsions are not rare, and sometimes recur at short intervals, abo partial paralyses, contractions, and automatic movements may be abroad the disease. There may be also diminished sensibility of the lar, and occasion dly the opposite condition—hyperasthesia—has been outed. These children appear to suffer from frequent cephalalgia. The result of the head into the pillow and the frequent rolling of the head as a le to side as the infant lies in his cot are almost invariably symptom of uneroiness within the skull, and these are seldom absent in hydro-

This cases. Sometimes the head is retracted.

As an example of an ordinary case of chronic hydrocephalus I may inthe a little girl, aged two years and a half, who was admitted under my
the the Fast London Children's Hospital. The child was of small
the partial transfer of three months, and had
the constantly growing larger. The patient had been subject to convultions ever since birth. She could not stand or support her head. The
tell it the level of the bosses of the temporal bones measured twenty-two
sches in circumference. The fontanelles were very large and tense, and

the sutures were widely open. There was slight retraction of the ball with some rigility of the muscles at the back of the neck. The west ratellows of both upper extremities were kept constantly flexed, and ike thumbs were inverted. There were no actual convulsions, but the cast often twitched all over. She was very dull and stupid, but could be not to look round by calling to her. She was not blind; but there was the tagmus, and squant was often noticed. Her temperature was normal.

The duration of the disease varies. Many patients die during the 18st year of life, and comparatively few survive to the second. Stal death denot always take place so early. Sometimes a sudden arrest occurs in the disease. The head then ceases to enlarge, ossification goes on slowly, and general matrition improves. In these cases it is often long before long union is completed in the skull. In the case of Cardinal, recorded by Dr. Bright, who lived with an enormous skull to the long of thatly year ossification was not completed until two years before the patient duri

In acquired hydrocephalus the symptoms are much the same as these described in the congenital form, so long as the effusion occurs below consolidation of the skull is completed. If, however, it takes place after the fontanelle is closed, the symptoms are obscure, for there are no external signs of distention. The child generally becomes dull and bear. There is headache, vertigo, and often an apparent difficulty in supported the head, so that the patient lies about and seems to dislike measurest if made to walk, he totters and steps cautiously. Twitching or converse movements may come on, the pupils get sluggish and dilated, and at pulse slow. Then the stupor deepens into come and the child dies.

In rare cases the symptoms may be relieved by spontaneous execution of the fluid. Mr. L. W. Sedgwick has recorded such a case. A late. boy, two years of age, two of whose brothers had died of the disease, and who had always himself had a large head, began to be listless and dal He often complained of headache and wanted to he down. He say badly at night and often woke up with a scream. After a time by its. was noticed to be growing larger; the fontanelle became very water the pupils were dilated and sluggish, and there was some insensibility to external impressions. The respirations, too, became slower and the breating was oppressed. While in this state, the case appearing every day to be more hopcless, a sudden change was noticed for the better. The patient became brighter; his drowsiness cleared off; his pupils began again to respond to light; and he ceased to complain of his head. This improvement coincided with a copious flow of watery fluid from the nose; and after a large quantity of fluid had thus escaped all the unfavourable synques disappeared. Twelve months afterwards they returned, and increased to a degree that seemed to render the child's recovery out of the questic. but again they were relieved in a precisely similar manner. A case of the same kind is recorded by Mr. Barron in which a large quantity of water fluid mived with blood was discharged from the nose and mouth. In tas instance the patient died, and on examination of the skull, a narrow passage was found conducting from the cranium to the nose through the mord bone.

Although the disease may become arrested, and in children who surver the accumulation of fluid always becomes stationary after a time, the usual termination is in death. Such children, with their weakly frames and feels resisting power, fall easy victims to any intercurrent disease; and, as a runsuccumb to an attack of bronclutas, pneumonia, or severe intestinal catarity even if they do not die from actual interference with cerebral function.

Phagnoses.—Mere enlargement of the head is no proof in itself of the existence of hydrocephalus unless other symptoms of fined are present. In nekets the head is often large, and sometimes this increase in size is due to actual hypertrophy of the brain. In syphilis it may be also large from extreme timekening of the cranial bones. In both of these cases, however, a certain excess of fined may be effused, although the quantity can be insufficient to produce any ill effects from pressure. Still, unless actual intra-cranial dropsy be present, we never see the peculiar globular stage of the skull which is met with in chronic hydrocephalus. The caracteristic features of this condition have already been sufficiently described.

in cases of acquired hydrocephalus, when the collection of fluid takes the after closure of the fontanelle, diagnosis is very difficult. The condition is usually dependent upon a tumour of the brain compressing the case of them. It may be suspected when symptoms of gradually increasing pressure upon the brain are noticed, and absence of the more special phenomena peculiar to the inflammatory forms of cerebral disease throws as back upon this as the most likely cause of the symptoms. The seat of the had effusion is often difficult to ascertain with any precision, but it must be remembered that internal or ventricular hydrocephalus is more cannon than the external variety. Mr Prescott Hewitt states that the latternal of the orbital plates, which forces forwards the eyeballs, occurs only in the internal form. If, then, in any case the eyeballs are prominent, at we see the lower half of the pupil covered by the lower eyebal, while a run of white is seen above the cornea, we may conclude that the dropsy is rentricular.

Proposis—So few children, comparatively, survive the second year that the prognosis in intracranial dropsy is always very serious. Congenital cases mostly die, and in no instance can we give a favourable opinion takes evidences of arrest of the disease have become numistakable. Certainly in no case can we venture to hope for so favourable a termination as a spontaneous evacuation of the fluid. Even if the disease become arrested, the patient remains in most cases with a large unsughtly head and a more or less blunted intelligence. Convulsions, twitchings, retraction of the head, and other signs of cerebral irritation are unfavourable symptoms. So, also, are continued wasting and looseness of the bowels. If the patient

is weak, any intercurrent disease generally proves fital.

Treatment.—Cases of chrome hydrocephalus are the despair of the physican. He can do little more than attend to the general health of the child, regulate his bowels, and evercise a judicious supervision over his dictary. As regards arresting the disease, or causing absorption of fluid already accumulated, treatment appears to be of slight value. I have thought that the persevering employment of perchloride of mercury has been of service, for I have found arrest of the disease to occur in one or two instances This the drug was being given, but the same treatment has failed in so many other cases that the more favourable result was in all probability a were coincidence. I have never seen special benefit derived from diuretics or tomes, blisters, strapping or artificial evacuation of the fluid. I have everal times punctured the fontanelle half an inch to one side of the and an line, and after withdrawing a quantity of fluid have strapped up the head tightly with carefully applied strips of adhesive plaster. But although the patient appeared uninjured by the operation the fluid always quekly re accumulated. If the skull is enlarging rapidly, I behave the strapping treatment to be decidedly injurious.

CHAPTER XIII.

OTITIS AND ITS CONSEQUENCES.

(Purulent Meningitia; Thrombosis of the Cerebral Sinuses, Knoephallis,

OTITIS in the child is a common disease, and may lead to very serious orsequences on account of the facility with which inflammation can creat from the tympanic cavity to the interior of the shull. During the firster years of life the mastoid process is in a rudimentary state. In the your child, therefore, the mustoid cells are limited to the horizontal perba which lies behind the tympanic cavity, and above and slightly postenor a the auditory mentus. It is only at a later period that they extend done wards and backwards to form the hollow of the masterd process. The cells communicate with the tympanum, and share in any catarrhal prove of which that cavity may be the seat. The tympsnum itself is seperated from the interior of the skull by a thin layer of bone, which is often a men transluce at shell. This, according to Toynboe, may even be deficient a places, so that the mucous lining of the tympanum is sometimes here. there in actual contact with the dura mater covering the temporal box It is then easy to understand how, without any disorganisation of the bey layer itself, inflammation may extend from the tympanic cavity to the w terior of the cramium, and give rise to serious disease of the brain and its membranes.

The inflammation may spread from the ear to the skull-cavity through either the roof of the tympanum or that of the mastord cells. It may also pass through the upper wall of the external auditory canal, or be converd inwards by means of the internal auditory meatus, which is limitly a prolongation of the brain membranes. The petrous bone may or may be participate in the disease. Sometimes it becomes carious. In other case serious disease of the brain and its membranes may be set up, although the bony layer separating the ear cavities from the interior of the crains.

seems in no way affected by the inflammation around it.

Causation.—In childhood there appears to be a special tendency to catarrh of the mucous membrane lining the middle car. Von Treach has commented upon the frequency with which in young persons this caudition is discovered after death, without any symptom of the derangement having been observed during the life of the patient. The tendency is heightened by the scrolulous diathesis, and in the subjects of this constitutional state the catarrh has a special proneness to become a serious appuration. Diseases which have an influence in provoking the mandetations of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration of the scrolulous cachesia are very apt to be followed by suppuration. Thus inflammation may spread to the middle car in the cachesia are very apt to be followed by suppurations.

the external auditory meature or from the pluryux. Dr. Knapp, of New York, states that in the majority of cases the occurrence of suppurative extern of the middle car is due to cold, which affects first the maso-pluryugeal cavity, and then apreads up the Eustacham tube. In 8.78 per cent of his cases he attributes the immediate cause of the otitis to sea lathing: in 7.74 per cent, to scarlating. The extension of the inflammation further inwards to the skull-cavity may be determined by any agency apable of setting up acute inflammation in the ear. Cold is a frequent cause of this disaster, and blows upon the head may produce the same result. It is an occasional complication of dentition (see page 560).

Merical Acatomy.—When the mucous membrane lining the tympanum becomes acutely inflamed, it is of a deep red colour, and its vessels are full and distended. In the chronic stage the mucous membrane becomes thekened and pours out a copious purulent secretion which usually perboutes the tympanic membrane and issues from the external meatus as a whorst-white discharge. A chronic otitis may continue for months, or eas years, without producing much inconvenience. But sometimes the manimum oversulas to the bony wall, which becomes carious and softend, or the inflammation suddenly assumes an acute character. In either case volent symptoms may be all at once noticed from implication of the bran and its membranes. The consequences of spreading of the inflammation to the skull cavity are the occurrence of purulent meningitis, and

of encephalitis with abscess of the brain.

le purelent meningitis there may be inflammation and thickening of the dura mater (pachymeningitis), and this membrane may be separated from the petrous bone. Often suppuration takes place between it and the bue the membrane is perforated, and pus is effused into the cavity of the archnoid. If disease of the petrous bone is one of the consequences of the otitis, thrombosis of the cerebral sinuses may occur, and pyremia any be produced. In all cases where the dura mater is inflame I, phlebihe and thromboose of the cramal sumses are frequent consequences. The cognitation of the blood and arrest of the circulation in the venous chanacls is due to narrowing of the calibre of the sinus either by pressure upon it of inflammatory products or by thickening of its walls owing to adummatory infiltrations and abscesses. As a rule the lining membrane of the sinus is smooth, but it sometimes becomes roughened and dullboking The clot which forms the thrombus is fibrinous, and contains but few red blood corpuscles. It is therefore whitish-yellow in colour, or slightly gelatmous-looking, from the number of white corpuscles. It may be free in the sinus or form loose adhesions to the walls. These decolourised clots are sometimes very extensive, and may reach from the Interal sinus downwards to the vens cava. If the child live long enough, the thrombus may soften in the centre, and the disintegrated fibrine may present a puslike appearance to the eve.

The pia mater is almost always affected. Its vessels become dilated and filled with blood, small patches of ecclymosis are scattered about; and a yellowish or greenish exudation is poured into the subarachnoid tissue. This exudation may be solid like an ordinary false membrane, but is often distinctly purulent. It varies greatly in amount. The cortex of the brain, as might be expected from the intimate connection which exists between its vessels and those of the investing pia mater, usually shares in

the inflammatory condition, and becomes injected and softened.

Encephaltis usually occurs in patches. The vessels are dilated and congested; there is effusion into the tissue around them which becomes

swollen, red, and soft (acute red softening), and can be washed awaylers stream of water. Surrounding the milamed patch the cerebral tases a congested and addenatous, and of a yellowish colour. As the processors on the colour of the diseased spot changes from red to greened it substance gets softer and softer, and the central part breaks down as yellow or green purulent matter. The wall of the abscess thus fearly consists of bram-substance more or less softened. The seat of the abscess thus fearly consists of order or less softened. The seat of the abscess in cases of otitis is in the adjacent part of the middle or posterior; but the cerebrum, or in the cerebellum. As a consequence of the abscess inflammation of the brain-substance at the spot, there is enlarge and the affected part of the brain, its convolutions are flattened, and disease partly obliterated.

To produce these secondary results in the skull cavity it is not necessary that caries of the petrous bone should occur. In many cases the bre itself is found intact, the dura mater even may have the appearant of health, and a layer of healthy-looking cerebral substance may separately

abscess from the surface of the brain.

Symptoms.—Acute outils may be present without any symptoms adcating the existence of the inflammation. Usually, however, as the prelent secretion accumulates in the cavity of the tympanum, especialis les tympanic membrane shares in the inflammation, there is severe put it is ear and side of the head, and pressure on or around the ear mere east. suffering. In babies earache is a common affliction, and may eve be cause of convulsions. The child cries incessantly with a propositional scream, and refuses to be comforted. He burrows his head in the party of or rests it against his mother's shoulder, often lifts his hand to his beand refuses the bottle or the breast. If the pain cease or subace to time, he falls asleep, but usually wakes up again after a short more screaming loudly, and continues to cry again incessantly as before. Also some hours of this agony the tympanic membrane gives way, a discusof pus issues from the meatus, and the cry at once ceases. Examinable of the car in these cases seldom affords much information, nithough te passage sometimes looks red and inflamed.

When a chronic otitis exists, there is a more or less copious paralicidischarge from the ear, the tympanic membrane is destroyed, and to sense of hearing is blunted. So long as no more put is formed that expass readily away, no other ill effects are observed, and the absolute of tympanic membrane usually allows of free escape of the matter could Sometimes, however, an accumulation of put takes place in the new decells, and ill consequences follow. The chief danger in these cases a facells, and ill consequences follow. The chief danger in these cases a facells, and ill consequences follow. The otorrhora then ceases at the there is an intense pain in the ear and side of the head, and often neargitis with all its serious consequences ensues. It must be remembered however, that as offits may exist without giving rise to symptoms, neargitis occurring as a result of inflammation of the tympanium is not always preceded by otorrhora. Sometimes the symptoms of meninguing preceded

the otorrhea, and sometimes the outis is latent throughout,

In an ordinary case of extension of the inflammation to the memors the sequence of symptoms is as follows: A little child of a few year at has a discharge of purulent matter from the ear. This may have followed an attack of severe earache, or may have begun without pain and continued without discomfort, although the hearing on that side has been network be dull. The otorrhoen continues for several months. Occasionally the child is feverish and complains of scute pain in the affected ear and side

of the head. At the same time the discharge from the meetus ceases to low. After some hours, however, the pain subsides and the running reappears. At length the patient is seized with high fever, and has an attack of molent convulsions. After several repetitions of the fits, in the intervals of which he seems drowey and stupul, he sinks into a state of come and des within the week. This is called the convulsive form-long standing starbea; then, suddenly, fever, convulsions, come, death. It is the ships the disease takes in babies and children under two years of age.

The fever is high. The temperature rises to between 104 and 105°, and undergoes at first little remission in the mornings. The pulse almost dears intermits more or less completely, and very often falls in frequency, sisking to 75 or 80. This, however, is a very variable symptom, and sixtures the pulse remains quick throughout. Pain in the affected side of the head is seldom absent. The voungest children, in the intervals of convulsions, may be noticed to monn and put their hands to their heads. Reportions are quickened and may be perfectly regular, although somewas we notice sighing respirations, and the breathing towards the end my assume the Cheyne-Stokes type. The pupils are generally contracted at host and become dilated later. They are often unequal in size. There may be squinting of one or both eyes, and sometimes we note a paralysis of the face on the affected side.

The convulsions are violent, and, for the most part, bilateral. In the intervals consciousness is not completely restored, the child is heavy and superied, taking little notice of persons and things around, although his strention can be usually attracted by calling him loudly by name. He is ver restless and often keeps one or more of his limbs in constant movement Regulity of the joints may be present, and if there is any accompuring spinal meningitis, the head is firmly retracted on the shoulders mia ngidity of the muscles of the nucles. The abdomen is seldom avially retracted as in tubercular meningitis, and the characteristic durant feel of the abdominal wall is also usually absent. The child rehas a his bottle, and often can scarcely be made to swallow liquid from a apon. The disease runs its course rapidly. After a day or two the con-Wis me become less frequent. The child lies plunged in a deep stupor, and after remaining commatose for a variable time, dues without any return of consciousness. Sometimes convulsions immediately precede death.

In certain cases the disease may run an even shorter course, and death

take place with startling rapidity.

A little boy, aged twelve months, strong-looking and well nourished, was seized with vomiting at 1 a.m. on February 16th, and continued to munit at intervals for twelve hours. He then had several fits, and at 3 r.m. was brought to the East London Children's Hospital. He was seen by Mr. Scott Buttams, the house surgeon, who noted that all the limbs were conrulsed and the pupils were dilated. When the fits ceased the child still continued insensible; there was nystagmus; the pupils were equal and dilated, and acted well with light; the conjunctive were insensitive; there was no spaint; the cerebral flush was fairly marked; the limbs were flacerd.

At S P M. the child was still insensible. He had had no more fits; pulse, 150, with occasional intermissions; respirations, 40; temperature,

103; pupils equal, and still acted with light.

All through the night the child remained insensible. There was no rounting and the convulsions were not repeated. No twitching was noticed and the head was not retracted. He died at 8 a.m. Before death the temperature was 104'.

On examination of the brain, the whole convexity was found couted with yellow lymph which had extended to the under surface of the frontal lobes, and had glued the anterior and middle lobes to one another. There was no flattening of the convolutions; no excess of fluid in the ventricles; no exudation in the optic space; and no inflammation of the membranes at the base of the brain. No gray granulations could be seen; the brain was firm, and seemed perfectly healthy; the cerebral sinuses contained semifluid dark blood.

In this case there was slight discharge from the ears, but without offensive smell. It is doubtful if this had any part in producing the meningitis, for the dura mater covering the petrous bones had a healthy appearance. Nothing in the history of the child could be discovered to account
for the illness, for although he had had a cough for a fortnight, and had
whooped during the last two days, this could not be looked upon as
a determining cause of the inflammation. It may be remarked that
the symptoms above described resemble exactly those often present in
cases of meningeal hamorrhage in the young child, with the exception that in this case the temperature was elevated. A raised temperature, present in meninguis and absent in hamorrhage, appears to be
the single important symptom by which the two diseases may be dis-

tinguished.

Above the age of two years it is usual for the meningitis to assume a different shape. Convulsions are a less prominent symptom; instead we find a more or less violent delirium. Hence Ruhet-to whose labours all descriptions of meningitis in the child are so much indebted-has called it the "phrenitic" form. It is of longer duration than the convulsive variety, and resembles more meningitis as that disease occurs in the adult. The child complains of severe headache, is agitated and restless, and very rapidly becomes delirious. The debrium is noisy. The child raves at out the pain in his head. His eyes are red and wild-looking, his pupils contracted and often unequal in size. The pulse is quick and irregular, and may be completely intermittent. His temperature is high, marking 104° or 105', as in the preceding variety; and his breathing is rapid, although usually regular. After some days the delirium becomes less violent. The child has intervals of quiet in which he appears to be unconscious. He lies with his eyelids half open and his eyes turned upwards, moaning occasionally; the muscles of his face twitch; there is trismus or granding of teeth; and his head is often retracted upon his shoulders. As the disease progresses the coma becomes more constant, but at first a touch may excite violent delirious struggles, for there seems to be general hypercesthesia making the slightest pressure painful. The pupils dilate, and are insensible to light; there is often oscillation of the globe of the eye and equinting. The pulse becomes very frequent, and the respirations are of the Cheyne-Stokes type. There may be rigidity of the joints. The coma continues profound, and the patient gradually sinks and dies. Usually there is profuse sweating before death, although the temperature continues high; and the disease may terminate in a fit of convulsions.

Sometimes the temperature falls considerably before death. At other times it rises rapidly to 108°, or even higher. The duration of the phrenitic form of the disease varies; its course may be rapid like that of the convulsive variety, but sometimes it is prolonged to three, four, or more weeks. In these slower cases the illness often assumes a subscute type, with only slight elevations of temperature; but at any time the heat of the body may

undergo a sudden and apparently causeless increase.

In many cases inflammation of the dura mater is accompanied by rombosis of the cerebral sinuses. The symptoms, however, of this conson are masked by those of the accompanying meningitis; and its exerce, therefore, can seldom be more than suspected. According to triangle, we may sometimes detect on the affected side comparative optimes of the jugular vein, which is no longer filled with blood from constructed sinus, but this is a symptom the existence of which it ast be difficult to ascertain. In ordinary cases the occurrence of shiveral, or great variations in the temperature, with signs of metastatic quality in the lungs (sudden dyspines, cough, and perhaps scattered zones trapitation about the chest or back) would point to the probable occurrence of cerebral philebrits.

When meningitis occurs as a consequence of other causes than otitis, becamptoms are as described, with the addition, in most cases, of a premary stage in which the child complains, if old enough of headache, radually increasing in intensity. He is feverish, vomits, is very restless, if his ideas are confused. The course of the disease is therefore rather

bager than in the form described above.

Inflammation of the brain (encephalitis) is more frequently than the sceling a consequence of outis. Indeed, it has been estimated that fully all of the cases of alseess of the brain are due to inflammation originating a the middle or internal ear. The inflammation is limited to certain the brain, a usually confined to the cerebrum in the immediate neighborhood of the petrous bone. Sometimes, however, it is found in children, at a commonly in the adult, in the cerebellum.

The symptoms are often obscured by meningitis, which may exist at became time; and there may be thrombosis of the cranial situses.

The disease begins with pain in the head, which is indicated in the being child by repeated screaming and frequent movement of the hand to to head. The chibl seems drowsy, and behaves as if only half awake. He ates food unwillingly or refuses it altogether. The bowels are generally of hed, and there is usually vomiting. The temperature seldom rises to 102. The pulse is generally slow (70 to 80), and the pupils are satracted. The drowsiness soon deepens into stupor, and there is rigidsy of the joints, usually limited to one side, with perhaps paresis or muves of the limbs. Much depends upon the sent of the abscess, and It ther it affects the centres of special sense or interferes with the conouten of motor influences. Thus there may be incomplete hemiplegia compression of the fibres of the internal capsule; paralysis of the and nerve from pressure on the cerebral peduncle; or paralysis of the heal acree. The loss of power is almost invariably limited to one side of lady. Convulsions may occur; there are frequent twitchings of the but muscles, and the child grands his teeth and makes movements with he mouth as if chewing. The stupor is not constant. At first the child the roused by being spoken to loudly; and occasionally the mind be-The child will often begin again to answer The respirations are quickmed and very irregular; the pulse, after the first few days, increases in regular, and often becomes intermittent. In acute cases the stuper soon because more profound, and deepens into a come in which the child dies, toulsons, if previously present, may cease when the patient becomes belief readed throughout, or falls notably before the fatal termination, or to a high level during the last few hours of hie.

A rickety little boy, aged two years, was admitted into the East Leadon Children's Hospital with the symptoms of severe pulmonary cates. For some months the child had been subject to otorrhous, but there as no history of carache. He went on well at first; the cough improve the his chest seemed greatly relieved, when, on December 7th, his temperature rose to 102, and there was a copious discharge of pus from the letter. The discharge continued through the week, but the child seemed to effect little inconvenience from the state of his cur. He was lively, to kill food with appetite, and his temperature, which for a few days had been

high, again sank to 99°,

On December 13th a change was noticed. The child scremely quently and seemed indifferent to his food. His temperature that every was only 99. On the morning of the 14th the temperature was still but the pulse, which had been always considerably over 100, was for all have fallen to 80. The child was drowsy and could not be thorse, by roused. He lay on his right side with a puffy-looking flushed face, and ing his teeth and making other movements with his paws. The paper were equal, slightly contracted, and sluggish; occasionally there was slight squint. Some rigidity was noticed of the right knee and else joints. The child took no notice of questions and refused food. At 6 is the temperature was 100; pulse, 96; respirations, 34; and in the event the stupor deepened into come.

For the next forty-eight hours the child's state continued much the same. He was completely insensible, and squinted outwards with the right eye. During this time his temperature was 101-101.4°; puls 130; respiration, 21-48, and very irregular. The abdomen was slot 4.

retracted; the bowels were confined, and he vomited once

On December 16th the bowels had been moved by aperients, and the was some approach to consciousness. The child resisted the feeding wand in the evening seemed to recognise the nurse. He was heard to "no" repeatedly when offered drink. He could move both his legs. The

temperature was 100"-101".

On December 17th the stupor was even less, although the patients, mained very drowsy; he turned his head when called loudly by name, a answered when asked to drink. There was no flushing of the face to a redness when pressure was made on the skin. Temperature, 100 -101 m pulse, 156; respirations, 38. On the 15th the child had two fits. The were followed by no rigidity of the joints; but the patient lay in a semi-contess condition, although it was still possible to rouse him by load call. From that time he gradually sank, and died on the afternoon of the filting day. The temperature shortly before death was 101°. On course tion of the body, the petrous part of the temporal bane was found a nuded of dura mater at one spot, and the membrane around was much flamed. An abscess was discovered in the adjacent cerebellum tilled will offensive pus, and there was excess of fluid in the lateral ventricles.

The course of encephalitis is usually rapid. It may last only five of days, or may be prolonged to two or three weeks. Sometimes after a the acute symptoms disappear, consciousness is recovered, and the chief health may appear to be restored. It is even said that such children as grow up to adult age, the abscess having become encysted and ceasing

be a source of irritation.

Diagnosis.—Otitis should be suspected in all cases where a young chicries incessantly without any symptoms being detected—such as drawn up of the legs, tension of the abdominal wall, unbealthy evacuations, etc.— draw attention to the belly. Abdominal pain is intermittent, and the best cease when the uneasiness subsides. Earache is constant, and until that is obtained by the discharge of pus from the meatus the child cries

nth a persistence which is very characteristic.

When purulent meningitis occurs, the onset of violent convulsions, with interest fever, following upon sudden cessation of discharge from the ear, are ensuspicious; and when we remark that in the intervals of the fits the dail remains drowsy and stupid, refuses food, and takes no notice of access mel faces; that he is restless, contracts his brows, and constantly mass his learned to his head, we can speak with some confidence us to the sature of the case. In reflex convulsions the mind is clear between the flares. Drowsiness or support with recurring convulsive movements is any characteristic of a cerebral origin. An alteration in the pulse adds a new and important feature to the case. A pulse of 80 in a young child be also pulse. If the child be feverish, the contrast between the bodily bettend the comparative infrequency of the arterial pulsations is still more triang. Therefore if to the preceding symptoms we add a slow and percent intermitting pulse, our suspicions are sufficiently contirmed.

Forces or inflammatory diseases in the young child may begin with the cashination of pyrexia and convulsions. In the case of the exanthemata about 1 ind some of the early symptoms of the eruptive fever; and its convulsive movements themselves are few and not violent. There is the restlessness, and between the attacks the child takes notice and acceptages his friends. In the case of malignant scarlatina, beginning with a realizable and dehrium, there is little headache, and the cruption appears

The twenty-four hours of the first symptoms of the fever.

Pheumonia in the child not unfrequently begins with convulsions, and there is high pyrema; but the absence of stupor and of headache, the activate of the nares, the greater rapidity of the breathing, and the perverted plactespiration rates would serve to exclude meningitis although a physical arms attorn of the chest might reveal no signs of disease. In the some larger and high fever, the nature of the disease may be often detected task by an examination of the chest. Sometimes, however, physical signs to appear, and in such a case we must wait before pronouncing a panion. Usually the head symptoms of cerebral pneumonia are not but, but assume more the characters of tubercular meningitis than of the incompanion of the disease. The distinction between these two varies of meningitis will be considered elsewhere (see Tubercular Meningitis). From urasing an 1 the various forms of cranial disease unaccompanied

by process, the high temperature which is one of the characteristic features as the meningers will form a sufficient distinguishing mark.

In the case of encephalitis, drowsmess with consulsions or rigidity of buts or both, followed by come and hemplegue—the symptoms occurring weblid the subject of chronic otorrhea, or following upon an attack of the paraticular — sufficiently reveal the nature of the discase. When there is paraticular it is difficult, perhaps impossible, to distinguish inflammator the substance of the brain from inflammation merely of its membrass, and a certain amount of meningitis usually accompanies the encephalitis.

Thrumbosis of the cerebral sinuses can seldom be more than suspected. If the lurn mater be unlamed, it is reasonable to suppose that the sinuses the seat of disease are also implicated. If in a case where the cerebral Taptoms have endeady followed upon a long standing otorrhea we can

detect deficient filling of the jugular vein on the affected side, or can discern signs of pya-min-rigors, or rapid variations of temperature, with evidence of metastatic deposits in the lungs or other organs -we may conclude that thrombosis in the sinuses has probably occurred.

Prognosis.—Ontis can usually be cured by suitable treatment, and if, while the discharge continues, proper measures be taken to prevent the collection of purulent matter in the tympanic cavity or masteid cells, there

is no reason to apprehend any ill results from the state of the ear.

If extension of the inflammation take place to the skull cavity, the worst consequences may be anticipated. The patient does not, indeed, always die, but the proportion of recoveries is very small. In encephalitis it is common for the stupor to clear away more or less completely for a time, and therefore false hopes should not be raised by the patient's appaired amendment; and the friends should be warned that such signs of im-

provement are seldom to be trusted.

Treatment.—When offits occurs, it is important to remove pus early from the interior of the tympanum. This is done by inflating the Eastachian tube by means of Politzer's bag. The operation is easily performed upon children, as it is not necessary that they should swallow. All that is required is to send a forcible blast of air through their closed nostrals. If the purulent contents are not removed by this means the tympanum must be punctured. When a discharge appears from the meatus, the passage should be syringed several times daily with warm water. If any uneasures appears to be felt in the ear, counter-irritation with tincture of iodine may

be employed behind the pinna,

A chronic oforrhea should be stopped as quickly as possible. Any mild astringent injection may be employed; but care should be taken thoroughly to cleanse out the passage with warm water before using the astringent lotion. In obstinate cases the use, several times daily, of an application composed of sulphate of zinc and borax, ten grains of each, and one drachin of glycerine, to the ounce of water, will often arrest the discharge very quickly. Glycerine of tannin diluted in the proportion of one drachin to the ounce of water, used frequently, is often of service. Sometimes the injection, once daily, of a solution of nitrate of silver (gr. x. to the oz.) will histen the cure. In cases of long-standing oforrhion, when the membrane of the tympanum is destroyed, the child should wear small pledglets of cotton wool in the car, except in very warm weather, as a fresh externi

is easily excited by cold and damp. When meningitis occurs, the room should be kept in a half light : free ventilation and perfect quiet should be insisted upon, and the thermometer must be watched that the temperature of the room does rot rise allove 60°, The feet must be kept warm and the head cool. It is advoid le to remove the hair, and keep the shaven scalp constantly covered with an ice-bag. The bowels must be opened freely by aperients, such as caloniel and jalap. Opinions differ as to the value of morphia in these cases. Morphia, even if it produces no impression upon the inflammation itself, can scarcely be injurious. Its use has at any rate this advantage, that when the child is kept under its influence the more violent symptoms are moderated, and much pain is saved to the friends by the apparent rehef thus extended to the patient's sufferings. Counter-pritation, although often advocated, is of little value; and the old plan of leeching behind the ears has never seemed. to me to be followed by any improvement. Our great trust should be placed in the constant application of cold to the head, in perfect quest, and in free purgation. Encephalitis is to be treated on similar principles.

CHAPTER XIV.

TUBERCULAR MENINGITIS.

here meningitis induced by tuberculosis of the pia mater is undenitive the commonest form of intra-cranial disease to be met with in the 111. The symptoms to which this variety of meningitis gives rise are allowed characteristic to merit a separate description; for the seat of the inflammation, the insidous beginning of the illness, and its well-decode course are very different from what we find in simple inflammation of the meninges, and make the affection for all practical purposes a differ-

It but an I children of all ages are subject to tubercular meningitis, it but hess common in infants than it is in older children; but in the linear the disease invariably occurs in the course of an attack of general broadens. It is then called "secondary," for its symptoms, being precial by others arising from inflammatory affections of various organs also descalent upon the distinctic state, are completely masked in their earlier said only reveal themselves as the more violent phenomena which set the closing period of the illness. After the age of infancy the dissecusally assumes the primary form, for although other organs may be set of tubercle, the symptoms first noticed are those arising from the leap, and these retain their prominence throughout the course of the littless.

therefor.—As a form of acute tuberculosis, tubercular meningitis is topen lent upon the same predisposing causes as those which give rise to be lattetic condition. It is wortny of remark that in families in which the inhereular disthesis exists, not only the tendency to tubercular formatical handed down, but often also, a proneness to the particular shape to have is to assume. This is especially the case with regard to the tendency of the malady. It is not uncommon to hear of several time of the same family being carried off by tubercular meningitis; and in doubtful cases the fact that a previous child has fallen a victim to the intra-cranial inflammation becomes an important aid in arriving at a decision.

Although children who become the subjects of this disease are often maly and delicate-looking, with a marked tubercular family history, this was always the case. It is not uncommon to see the disease break out mailiren who are stout and vigorous, and who certainly differ widely a spect from the delicately formed and frail-looking type which is contrad characteristic of the tubercular diathesis. It is possible that infection of the system by softening cheesy matter may induce the disorder in a self-free from any constitutional tendency to this form of illness; but have eases, however unlikely a subject the child may appear to be, carelingury will discover evidences of "consumptive" tendency in collateral matters of the family, if not in the direct line from which the child has

descended. The disease is common in all ranks of life: but as p (which too often implies reckless indifference to insumary again, helpless submission to them, even more, perhaps, than actual point food) may help to determine the outbreak, the affection is especially

mon amongst the poor.

Of the exciting causes, possibly any injury or shock to the heat as blows or exposure, may help to induce the illness. Over-excitation mind, whether from study or amusement, may not improbable the same effect. It has been denied that pressing sensitive children wards in their learning can act injuriously in this direction. I are ever, strongly of opinion that such heedless expedition is very har the child, and has often determined the occurrence of the manner.

inflammation in subjects predisposed to tubercle.

Morbid Anatomy. The starting-point of the disease is the devel on the pia mater of numerous gray granulations as a result of the tutional state. These gray nodules are found especially on that the membrane which covers the base of the cerebrum. On the pid of the cerebellum and convexity of the brain they are much less nu and indeed appear often to be quite absent from these situation careful inspection the gray or yellow nodules may be noticed follow course of the vessels, especially of their smaller branches. They congregate in and about the Sylvian fissure, and may be often seen the chiasma of the optic nerve. If very numerous, they may be sprinkled about like a fine glistening dust in these regions and alsides of the hemispheres. The larger granules may be as big as head or even a hempseed. By the nucroscope the small nodular are observed to lie upon the vessels within the perivascular carals, adhere closely to their coats. On the larger branches they form tions on one side of the artery. On the smaller, they may con embrace the vessel. In either case - and this is an essential part they project inwards as well as outwards, so as to narrow the cha the tube; and they may even perforate the delicate coats and p into the interior of the vessel. The granulations are formed by proliferation of nuclei from the epithehal lining of the perivascular and the obstruction to the vascular channels which results from cossive accumulation causes thrombosis within the small reself impediment to the circulation, severe congestion, and extensive co fluxions.

As the meningeal tuberculosis is usually merely a part of a gentribution of "tubercle" over the body, the gray granulation is four in other organs and serous membranes, and has been noticed by Co ou the vascular tunic of the retina.

The vessels of the pia mater are engaged, and the membrane is and often adheres closely to the surface of the brain, so that who away it brings with it small particles of the cerebral substance. Hess copious yellowish or greenish jelly-like exudation is found meshes of the subarachnoid tussue, often running in streaks all course of the vessels. It is usually confined to the base of the brain.

An almost invariable feature in these cases is the ventricular of This is so constant a phenomenon that it used to be looked upon a stituting the essence of the disease (hence the name of "scute had alus" by which the affection was formerly distinguished). The distinguished is often very considerable. It may distend the ventricles, flatten to volutions, and even cause rupture of the septum lucidum. In apply

is clear or turbid with suspended flocculent particles, or tinged with coal. The cerebral substance around the ventricles is softened. The feeing is attributed by some writers to the effects of mere imbilition and caption. Others ascribe it to inflammation. Dr. Bastian is inclined to opinion that it is often the result of degenerative changes set up by a accertous condition of the central brain tissue; and that both the intricular effusion and the softening result from the pressure of the blood the overlanded veins and capillaries, and in some cases, perhaps, from the pressure of the blood the overlanded veins and capillaries, and in some cases, perhaps, from the action basis in the veins of Galen.

liendes this softening of the central parts of the brain, the cortical abstance is inflamed as well as the pia mater which invests it, and some-ness spots of softening with capillary homorrhages have been seen in the vistance of the corpora striata and the optic thalami. As a rule the brain abstance is pade and bloodless, and the greater the centricular effusion the

aser and softer the cerebral tissue becomes,

The above morbid appearances are singularly constant in cases of placeular meningitis. The granulations, the exuded lymph, the vascular a regement, the superficial encephalitis, the ventricular effusion, and the hate oftening of the ventricular walls are almost invariably to be disoveral when death has occurred from this disease. In addition, signs of bere or less general tuberculosis are also present. These in infants are well marked, and almost all the other organs and serous membranes pay is sprinkled over with the gray granulation. In older children, howfor the memogitis occurs before nutrition has been appreciably impaired, but to perhaps itself the earliest indication of the doublesis. In such cases be ther organs may be healthy, and the granulations scattered over the mater may be the only morbid formation to be discovered in the body. Isday, however, signs of the cachexia are perceptible in other organs, at sometimes the granulations are so equally and generally distributed that we cannot but wonder at the little interference the constitutional and local states had exercised upon the general health of the patient.

Symptoms.—The onset of the illness is almost always preceded by a proternal period of variable duration. This is to be expected in every mainly then disease of special organs is dependent upon a general diathetic state. It ill forms of tubercular disease it is a rule which is rarely infringed that had symptoms are preceded by phenomena indicating the general disorder

Materition induced by the constitutional cachexia.

The premonitory symptoms vary in severity, partly according to the send the child, partly according to the previous state of his health, and putly according to the intensity of the disthetic influence to which he is support. In young babies, in whom the disease invariably occurs at the rid of an attack of general tuberculosis, the head symptoms are preceded by others indicative of the disease from which he has been suffering. In what children, especially in those in whom the disthetic tendency is community feeble, the prodromal period may be short and the symptoms which, Therefore in different cases we may find marked variety in the transa and severity of the symptoms which immediately precede the outlinesk of the disease.

Two forms of tubercular meningitis, a primary and a secondary form,

In primary tubercular meninguts the prodromal period is often short, of its symptoms, on account of their indefinite character, may excite little tention. The child is thought not to look well, but he makes no combact for he suffers no pain. He generally becomes thinner and paler,

and his appetite is capricious. The loss of flesh is, however, seldon siderable, and may be only recognised by the use of the weight, so for no dimmution in bulk may be visible to the eye. He is usually and unwilling to exert himself; sits and lies about instead of pair the sports of his companions, and if urged to take part in their gard jects that he is fired. He is often drowsy, and may be noticed to a the middle of some childish employment and fall askep on the floor room. A change in character is frequently noticed; and this is a sur so common that it should be always inquired for. The change is u indicated by an increase in his emotional sensibility. If reproce shows exaggerated distress; his endearments exhibit an unscrust warmth; he readily takes offence, and cries without apparent neso sits moody and allent in a corner of the room. A certain sluggislar mind is also apparent. An ordinarily bright child becomes stupad his lessons; he seems drowsy and incapable of fixing his mind upon task. There may be headache, and he may say that the room seems ing round. Sometimes there is confusion of sight. The bowels m irregular and costive. The temperature during this period is alightly elevated, and the child looks flushed at might and has he hands. In one case which came under my own notice the evening perature for the five nights immediately preceding the outbreak 100.4", 98.4°, 98, 99.6°, and 97.6.

The special symptoms of the disease are usually divided into stages; and when the affection is a primary one this arrangement is field by clinical observation. There is a stage of invasion, in which definite symptoms of the prodromal period are suddenly broken in by the first indications of local mischief, a stage of irritation, in which is explicit nervous activity; and, finally, a third stage, which is mark diminution of nervous power and abolition of the functions of life.

The first symptoms of the stage of invasion are in the large me of cases vomiting and headache, and the bowels which were before become obstinately constipated. The vomiting is often repeated distressing, and occurs without any reference to taking food. It deed, characteristic of a cerebral origin that retching and vomiting in the intervals of the meals-towards the end of digestion when the ach is nearly empty. The heaving is often excited by raising the ch into a sitting position. The matters ejected consist of food and or watery fluid. The headache is generally severe. It is referred front or top of the head, and seems to occur in paroxysms so the patient screams out with pain. The cephalalgia is increased by move or by a bright light, and is accompanied by dizziness so that the staggers in his walk. The expression is distressed, and may be in or spiteful. The tongue may be clean, but is often thickly furred thirst is often great, and appetite is completely lost. The child early to his bed, from which he never again rises. The abdomen is mal fulness to the eye, but its parietes have a peculiar, soft, lough which is very characteristic, and are easily compressible. Often the marked loss of elasticity of the skin. The pulse is generally rapid regular at this time, but may be slow, and sometimes a fall in the reof the pulse is the earliest symptom noticed. Thus, in the child case has been referred to, a fall in the pulse from 100 to 74 occurs the evening preceding the actual outbreak. The temperature is ately elevated (100° to 101'). The breathing is generally irrigals may be unequal and sighing from the first. This is a symptom of by the respiratory movements cease, and during some seconds the chest with mass. The patient then heaves a deep sigh and pauses again, or buryling returns for a few minutes to the natural rhythm. Signs of a trutability of the nervous system are rare at this early period of the heaves, although in exceptional cases the disease may be ushered in by a multive science. Still, there are sufficient indications of nervous agitation full to the eyes; the child is distressed by loud noises; and hyperschool of the skin may be present so that a touch is painful. During he age the urine is scanty and may contain excess of phosphates.

Of these symptoms the most important are the combination of headthe comiting, and confined bowels, with irregular breathing. Even if the ever be absent, the occurrence of vomiting and obstinate constitution to be absent in a child who for some weeks has shown signs of failing

our tor, is always to be regarded with anxiety.

It the second stage—the stage of irritation—the symptoms become a cagginate it. The headache increases in severity, and the child often expressed by the case of the second making chewing movements with a pass or granting his teeth loudly. Sometimes he screams out as if in the child usually opens his eyes, but he answers questions mailingly or stares at the speaker angrily and makes no attempt to reply. We therefrom headache or irritability, the cyclrows often have a second at a gaves a peculiarly forbidding expression to the face of the patient.

To palse generally falls in frequency at this stage and becomes interwat. It varies in rapility from 60 to 80, and the finger pressing the rey fasts the rhythm of the pulsations interrupted at irregular intervals of the complete omession of one beat. It is important in examining the pile in these cases to seize an opportunity when the child is lying quietly Like not recently made a movement; for a pulse which is slow and irat his during repose may become quick and regular for a time upon the the about drange of position. The temperature is generally lower by a de-The tian in the first stage, and may rise no higher than 90°. The respihtens continue pregular as before, and often at this time assume the Come Stokes type. The pupils now become dilated and are often slug-Sometimes there is a slight squint, but this is seldom more than a Pesar deviation Examination by the ophthalmoscope, if it can be manked, lower a congested state of the retinal vessels and disk, and some-Was an all boshes like gray granulations can be seen projecting from the sof the anall retinal arteries. Towards the end of this stage the enting usually ceases, but the constipation continues, and the child 4. 34 no lesire even for liquids. There is often retention of urine, and the as are passed in the bed after an aperient. The pulse generally 42 bus again, and the temperature rises. The abdomen usually becomes Tork Ly retracted, but still remains soft, doughy, and compressible. Be-His a singular tendency to flushing of the skin is noticed. The cheeks willerly become red, then the flush dies away leaving them apparently than before. Slight pressure on the skin, especially of the face, become and front of the thighs, produces a bright redness—the "cerethe district of Trousseau, which remains visible for a considerable time.

The principal symptoms of this stage are the full in the pulse and temperature, the apathy and drowsness of the child, the violent headache, the mailirity of breathing, the excavation of the abdomen, the dilutation of

the pupils, and the passing strabismus. The cerebral flush, unless very vivid, is an uncertain symptom, for it is often well marked in cases where there is no reason to suspect tubercular inflammation of the cerebral meninges.

In the third stage the temperature gradually rises again, and towards the and may attain a high elevation. The pulse also mercuses in rapidity and becomes regular, but the irregularity of breathing continues. The most prominent symptoms of this stage are the increasing coma and the occurrence of convulsions and paralysis. The child, who before could be roused by loud calling, now makes no sign of response, or if for a moment he raises the lids, he closes his eyes again almost immediately. The aspect of the child at this period is often very characteristic; for if, often happens, the disease have been preceded by few signs of ill-health. and the patient have retained his plumpness, he presents to the uneducated eye the appearance of a healthy child in quiet slumber. His checks are brightly flushed, his countenance perfectly placid, his features rounded as in health, but it will be noticed that the evolus close imperfectly, and that the respirations are very irregular and disturbed by deep sighs and long pauses. On raising the eyelids with the finger the pupils are seen to be widely dilated, they act sluggishly or not at all, and are often unequal in size. There may be nystagmus or a distinct squint.

When the come becomes complete, the flush usually subsides and the face becomes very pale. The insensibility is not, however, always profound. Often it varies in degree, and the child may seem to wake up for a time and look round with some intelligence in his glance. Still, it is difficult to say whether at these times he is always conscious. In some cases the stupor clears off completely for some hours, and the child may sit up, apparently infinitely improved, and again show some interest in his toys. These cases are very distressing in their effect upon the relatives, who had given up the child as hopeless, but now conclude that all danger has passed. Unfortunately, if the eyes be examined, it will be found that the pupils continue sluggish, dilated, and unequal in size; the squint, if it had been present, still persists, and little hope can be entertained that the improvement will be lasting. After a short interval, to the infinite grief of the friends, the come returns as profoundly as before, and then con-

tinues until the close.

Increase in the come is usually associated with effusion into the ventricles. If ossification of the cranial bones is still incomplete, the fontanelle, when the effusion occurs, generally becomes elevated and tense. Still, it is important to be aware that a large effusion in the ventricles is quite computable with a level or even a depressed fontanelle.

Convulsive movements generally come on early in this stage. They are often partial, and may be confined to twitchings on one side of the face or in one arm. Often, however, they are general and more severs. Between the seizures the joints are often stiff, and paralysis is more or less distinctly marked. Squinting of one or both eyes is seldom absent, and there is frequently ptosis, but general paralysis of the face is rarely seen.

Loss of power in the limbs usually assumes the form of hemplegia. The arm is sometimes affected alone, but the paralysis is said never to be confined to one leg. At the end of this stage, when the come is complete, the head often becomes retracted upon the shoulders, and the tonio rigidity may affect the whole spine; the joints are stiff; there is more or less complete paralysis of one side; the pupils are dilated and unequal; there is squint of one or both eyes; the eyeballs often oscillate; and tramors and twitchings may be noticed in the muscles of the face and limbs.

Before death the pulse usually becomes very rapid; the constipation is replaced by districes; aphths appear upon the mouth; the retracted ablance swells out again with gaseous distention; ophthalmia may occur, and the corner often ulcerates; there is generally profuse sweating, and crute telema occurs in the lungs. On the last day the temperature may falte a subnormal level or may rise very high, and sometimes it reaches surprising elevation. Thus, in a little girl, five years of age, the temperature on the morning before her death was 97.6°; but from that point sees progressively through the day and night, until at 7.45°, w. on the basing morning, the time at which she died, it was 110°, and two hours sherher death level only sunk to 107°.

The average duration of the illness, counting from the first day of venting, is twelve days. It may, however, run a shorter course, and we tend comes to an end on the sixth or seventh day. In other cases it becover a longer period, but is seldom prolonged beyond the end of the

than week.

The sequence of the phenomena, as given in the preceding description, s ont or linarily met with in cases of the primary form of the disease, but there are occasional variations in the symptoms which it is importast to be aware of. Thus, in exceptional cases the illness begins with durbes, and I have known the looseness to persist, with occasion d interassess, throughout the course of the attack, although no ulceration was Vounting, also, may be a far from prominent present in the howels. suptom. Sometimes it is quite absent; at other times the child vomits once or twice, and not afterwards. Again, the pulse may be slow from the beginning, or, on the contrary, may be rapid at the onset and never offerences fall in frequency. Still, as a general rule, repeated observawas will usually detect a slow pulse at some period of the illness, even if and but a few hours. It is always important in ascertaining the state of t - pulse to do so at a time when the child is perfectly motionless. The bachele, too, varies greatly in severity. It may be excessively severe or Departively slight. The intolerance of light is also a variable symptom. Sometimes it is extreme. In other cases the child can bear the light with-out apparent dissound ut. Lastly, the temperature is not always high. It my be little raised above the normal level, and in most cases the pyrexia less, at the beginning of the second stage. Indeed, at this period the relation in the fever, together with the diminished fretfulness of the patest is he becomes more stupid and drowsy, may excite in the minds of to fromts false hopes of improvement. It is generally the case that the her a higher in the third stage than at an earlier period. If it rise to a lassimitary tubeccular mean pits the earlier symptoms of the special

la secondary tubeccular mean pits the earlier symptoms of the special less are maked by the more general phenomena indicative of the sufferms of the winde system from the tubercular cacheria. This form of the diseases the shape the affection invariably takes in infants, and it is not measured with. The child is thin, weakly, and miscrable-looking. He is some or less feverish, although, unless catarrhal pneumonia be present, the imperature rarely exceeds 101; has no appetite; often vomits; and measure to be gradually wasting away. Suddenly he is seized with a fit of carelorns. This is followed by partial paralysis which involves some the corollary nerves, notably the occulo-motor; dilated, singgish, and also unequal pupils; rigidity of joints, and stupor. In this state he linger few days; the convulsions are repeated; the pulse is small and rapid;

the breathing is irregular; the abdomen is retracted, and the child dies without any return of consciousness. After death the gray granulation is discovered widely distributed throughout the internal organs, and the lungs as well as the cerebral meninges are usually the seat of inflammation.

The convulsions are often very partial in those cases, and may consist merely of tonic spasms affecting one or more limbs, with squart or conjugated deviation of the eyes. Sometimes, also, there are slight clonic spasms or faint tremors, undateral or limited to one limb. The outbreak of the head symptoms is often preceded by sighing or arregular breathing, thattened abdominal parietes, and slight twitches in the limbs; but the slow intermittent pulse, which is such a valuable sign in the diagnosis of the primary form, is usually absent. Often, before the actual onset nothing at all is noticed to give rise to suspicious of intracramal muschief, although our knowledge that in every case of scute general tuberculosis affecting a very young child such symptoms are likely to occur should lead us to watch for

them very narrowly.

In infants the affection, when secondary, almost invariably assumes this form, and death usually follows within a few days of the occurrence of the head symptoms. In older children the course of the secondary form is somewhat longer, and, indeed, the symptoms in some cases may approach nearly to the type observed when the disease is primary. Still, there are in most cases many differences. Delirium alternating with stupor, without convulsions, squinting, or other form of paralysis, may be the only sign that the meninges are affected. Sometimes there is repeated vomiting, with some wan lering of mind and intellectual sluggishness, so that the child seems not to understand questions addressed to him, and when told to put out his tongue makes no effort to obey. The disease may even reach its termination without any more positive signs of intracranial lesion being noticed. Indeed, in these cases the variations in the symptoms are infinite; but if the existence of general tuberculosis has been ascertained. we shall be at no loss to explain the meaning of any new symptoms which may arise from the head at this late period of the illness,

Many anomalous cases of secondary tubercular meningitis occur in children suffering from cerebral tubercle. This is a chronic disease which continues often for months, and is accompanied by more or less severe symptoms pointing to the brain. Fever is usually present, and siekness and headache, which are characteristic symptoms at the onset of the meningitis, are also common in the brain tumour. Consequently the recurrence of these familiar phenomena is often attributed to the growth, and is seldom interpreted as indicating a new phase of the illness. In such cases the early period of the meningitis passes unnoticed, and the complication is seldom recognised before the more violent symptoms which are charac-

teristic of its third stage are actually present.

Diagnosis.—It is not always easy at the beginning of an attack of tubercular meningitis to speak positively as to the nature of the illness. The first symptoms are often mild and apparently trifling, and if, misapprehending their importance, we make light of what eventually proves to be a fatal disease, the mistake is one which will be certainly remembered to our disadvantage. Vomiting and constipation, especially if conjoined with

It is well in all cases, even of apparently trifling fabrils derangement occurring in children of known tubercular tendences to warn the parents that although the case appears to be at present one of trifling importance, even such casual lister-baness are found occasionally to arouse the dormant tendency to mischief and to be corlowed by very serious consequences.

which, form a very suspicious combination, and if these occur in a deliate child or succeed to a period, however short, of general failure of
with, we should view them with serious apprehension. If our suspicious
a well founded, symptoms soon appear to give them confirmation. The
pure becomes slow and intermittent, the breathing is irregular, the child
get suppid and drowsy, the pupils dilate and are sluggish, and there may
be a high squint. When this stage of the disease is reached, there is
late from for he-station. It is principally in cases where the illness varies
but the normal type that the beginning of the disease gives rise to uncerlately. Vomiting may be absent. Instead of constitution there may be
lateless of the bowels. But still, if the child is feverish, complains of
response he looks really ill, we should never speak slightingly of his
too become.

Tubercular moningitis almost invariably begins insidiously, and the suptoms have a regular progression. It is seldom ushered in by a conrubive fit, and if such a seizure occur at the beginning, it is rarely reported. Slighter signs of nervous disturbance may, however, he generdiv descovered by careful observation and inquiry. The child will be keind to have lately changed in character. From an even-tempered placable toy, he has become suddenly irratable and spiteful; if naturally headthere and independent, he turns strangely timid and affectionate, and is to tears by a kind word. Often he grows curiously silent and unmi word the light. He flushes frequently, sighs deeply, and complains of bulable and guiddiness. All these small details assume great value if parased with feverishness, vointing, and a look of care. Drowsiness is wrives inprom, and when succeeding to the above is very suspicious. at the same time the breathing generally becomes unequal, with long passes and deep sighs, and this, itself an important symptom, becomes of ble value when associated with others pointing in the same direction. It was the pulse falls in frequency and is intermittent, without improvebest in other symptoms, the evidence it supplies may be considered con-Bitanite.

The early period of tubercular meningitis may be mistaken for any of the ther leavens or derangements which are accompanied by loss of flesh,

wasting, headache, and signs of nervous excitement,

The condition called spurious livdrocephalus, which sometimes occurs remarked infants as a result of anomia of the brain, with sluggish coreand circulation, and is sometimes a sign of thrombosis of the crausal server is usually readily distinguished by the history of severe vomiting or darrhypa, the evident exhaustion of the child, the depressed fontanelle, 101 Use normal or even subnormal temperature. This condition is seldom after the first year of life, and therefore is more likely to be mistaken by a general tuberculous with secondary meningitis than for the primary han of the discuse. Sometimes older children after an attack of serious The hasse may be left in a state of profound malautrition, in which all bal stortes counting, and the stomach seems incapable of retaining or desting even the simplest articles of diet. The child is restless and fret-R. and complains of headache. His skin ceases entirely to act, is dry and and the hardened epithelial scales can be brushed off as a fine dust. de peare dry and cracked, his bowels confined, and his urine scanty and and coloure l. After a time the child becomes drowsy and sinks into a topar in which he dies. In these cases the brain and the internal organs generally are bloodless and wasted. A distinction from menn, is the usually be made by the low temperature, which even in the return often no higher than 97°; the history of the case, the absence of remetion of the belly, and the course of the illness, which has not the remotion

progression peculiar to the tubercular disease.

An acute catarrhal condition of the stomach in a scrofulous child some times presents symptoms—feverishness, vomiting, headache, and considerion—which may be mistaken for the onset of tabercular menicials menicials repecially as, when convalence begins, the pulse often gets was an intermittent. But in all derangements, as distinguished from grave meases, there is an important distinguishing mark, viz., that the paint has not look seriously ill. If he be not profoundly depressed by the scrape of the symptoms, or harassed with pain, his face is placed and shower signs of distress. Moreover, his breathing is regular, and his ablence mormal in appearance and not retracted. If, later, the pulse becomes should intermittent, the elackening coincides with an improvement in asymptoms and not with an unfavourable change in the condition of the patient.

Still, even a child suffering from tubercular meningitis has not always a haggard, careworn look. Some time ago I saw, with Dr. Miller, of Bl. bheath, a little boy, four years old, who had been noticed to be getting that and pale for six weeks. He was often found askep on the floor in the miller of his play. He flushed up at times and was very fretful, cross

without cause.

On November 18th he began to vomit, and the sickness controls all through the week. It occurred usually about an hour after final relationships generally to be induced by movement. The bowels were control but acted readily after aperients. The temperature at night was also

100°.

When I saw the child, on November 25th, he was lying in bed, with a slight flush on his cheeks. His pulse was at first 100, and regular, abovered 80, and slightly intermittent; respirations, 26, and somewhat the lar, for the child occasionally heaved a deep sigh, although his breakast was never quite arrested. Temperature (at 3 p.m.) 98.4; eyes bright, so squint; pupils normal, and acted perfectly; no photophobia; no creak flush; consciousness perfect, and the boy answered questions readily. He said that his head sometimes ached at the back. Tongue furred, white motions, after aperients, of normal appearance and contained no much stonger. The belly was deeply hollowed, and the partietes were stonger, and compressible; the liver and spleen were of normal are, and the physical signs of his heart and lungs were healthy. There was no debumen in his urine.

In this case which was seen on the seventh day of the disease, the general mildness of the symptoms, especially the slightness of the headse and the complete clearness of mind of the child at so long a period after the beginning of his illness, seemed to tell against tubercular menu and but the history of the case, the pulse, the sighing breathing, the day's excavated abdomen, the absence of sufficient signs of digestive designent to account for his state, and the want of elevation in the temperature which excluded a continued fever—all these symptoms taken together pointed very strongly in favour of the tubercular disease; indeed in a law days the child became comatose, and he died shortly afterwards

"Cerebral pneumonia" may be accompanied by symptoms when the semble tubercular meningitis; and as the physical signs of the chest and

cormal on the first examination, it is often difficult at once to distinguish the real nature of the disease. There is often debrium and stuper; cruze may be a prominent symptom; and the pulse, although rapid, is introduced. In such a case the history, the absence of prodromata, the permittent. In such a case the history, the absence of prodromata, the permittent pulse-respiration ratio, the greater elevation of temperature, and the advocurrence of the head symptoms are not in favour of tubercular magnitis; but until signs of consolidation are discovered we cannot ven-

on positively to exclude meningeal tubercle.

In special cerebral disease the course is usually very different from his of tubercular meningitis, as the illness almost invariably begins with a laterous symptoms. The phrenitic form of simple meningitis of the course approaches most nearly to tubercular basic meningitis in its attract pheromena; but here the early symptoms are far more severe for man ordinary case of the tubercular variety. The disease breaks out within with violent headache, almost immediately followed by loud, the farious delirium; the temperature is very high from the first; stupor outly supervenes, and the whole course of the disease is rapid.

In the secon lary form of the tubercular disease the earliest sign of the rearrence of the cerebral complication is usually vomiting, and this symptom is able to be disregarded. Often, however, the intro-crainal influencian may first reveal itself by a fit of convulsions or a squart. In a ctill who, after a period of wasting and general illness, has an attack of citarbal pneumonia in which he is suddenly taken with a convulsive seizure has presence of a secondary tubercular meningitis may be more than

Burperteri.

A basic meningitis is sometimes seen in infants as a consequence of inbraced syphilis. The symptoms are identical with those of the tubercular brace but the nature of the illness may be sometimes inferred from the up wince of the child and the presence of other signs of the congenital

Ma viv

Lises are sometimes seen in which a child dies with all the signs of a table of meningitis, although after death no appearance of intracranial late, mation or exudation can be discovered, nor can the closest examination detect any gray granulations either in the skull cavity or at any other part of the body. Such cases occur now and then in most children's hospitals. I have seen one or two; and as far as I know the form of tubercular meningians thus simulated is always the secondary form; i.e., the cerebral contents do not true saidenly in an apparently healthy child, but come to the close of a more or less prolonged febrile attack.

Percosis — Tubercular inflammation of the cerebral meninges is so rail a discuse that when the nature of the case is established beyond a dock a fatal termination is inevitable. The disease is said to have been mechanism arrests i before the second stage had been reached. In such a case it is reasonable to doubt the accuracy of the diagnosis. Probably many of the cases in which recovery from a basic manights has been mortal have been instances of the syphilitic form of the intracranial

lister an attorn, which is much more amenable to treatment.

The disease is so fatal when once established that special programs should be taken in every case where we have ascertained the tusture of the tubercular distless to prevent the development of the Science and ward off-all influences tending to promote irritation and constitution of the brain. For the general means to be adopted to strengthen the constitution and weaken the district tendency the reader is referred to the chapter on tuberculosis. With regard to special measures, we

should be careful to forbid the more exciting amusements and too bodies out games. The mind of the child should not be overtaxed with perturbate study, and care should be taken that his intervals of relaxation are frequent

and regular.

When the disease is actually established, we can have little how the any treatment we can adopt will succeed in checking the cours of the allness. The violent measures which it was at one time thought necessar to employ in cases of tubercular meningitis have been found to be on only useless but actually huriful. Few judicious practitioners would rethink of applying leeches, of blistering the skin, of running a seton and the neck, or of rubbing tartar emetic continent into the shaven scalp if the case be seen early, perfect quiet in a room carefully shaded from the light should be enforced; ice-bags should be applied to the head, and the feet should be kept warm. The bowels must be relieved by a dose of mineral and judapine, or compound scammons powder, and in the hope that disease may have a syphilitie origin, the perchloride of mercury, in dose of tifteen to thirty drops, can be given two or three times a day. The could should be supplied with liquid food in sufficient quantities; and if it refuse to swallow, he must be fed through an elastic catheter passed don the gullet. Stimulants must be given as seems necessary.

CHAPTER XV.

PARALYSIS OF THE PORTIO DURA.

Freeze, p ralvsis from affection of the portio dura of the seventh nerve may be a mind or severe complaint according to the cause on which the paralless depends. It is common enough in children, and in them is fre-

quently a sign of severe and perhaps incurable disease.

It will be remembered that the facial nerve rises in the floor of the fourth ventricle from a nucleus common to it and the sixth nerve. Thence it passes outwards with the auditory nerve, enters the internal auditory meatus, and is conveyed by the Fallopian aqueduct to its foramen of exit from the skull. It is important to bear in mind the principal branches given off by the nerve in the Fallopian canal, as the seat of the leaon is determined by the extent and distribution of the paralysis. Shortly after entering the aqueduct, the facial nerve is joined by the large superficial petrocal branch of the Vidian nerve. It is by this channel that it conveys nervous influence to the velum; for the Vidian nerve united with Mecklis gaughon, from which branches descend to supply the muscles of the lavilla and soft pulite. Soon afterwards it is joined by the small superficial petrosal branch from the tympanic nerve; and a little farther on it gaves off the chords tympani, which joins the gustatory branch of the fifth nerve, and is distributed to the tongue.

Consulton.—The function of the facial nerve may be interfered with by a lesson at any part of its course, from its origin in the floor of the fourth verifice to its periphery. The cause of the paralysis may therefore he insule the skull cavity, in the Fallopian aqueduct, or outside the temporal

POLICE

Inside the skull the nerve may be injured by extravasation of blood or be compressed by tumours, inflammatory thickenings of the dura mater, are I by exudations. In the Fallopian canal the nerve may be damaged by fracture at the base of the skull, or be destroyed by carries of the petrons beam. After leaving the temporal bone the nerve may be injured by the turceps during delivery; or by blows upon the face; or by inflammation set up in its sheath by extension from neighbouring parts, as in parotidities; or by an inspression of cold, causing rheumatic inflammation of the sheath of the nerve.

The two chief causes which give rise to this condition in children are, to doubt, carious disease of the petrous bone, and exposure of the face to a current of cold air. Of these the first is a very serious disease, the second a comparatively trifling one.

^{&#}x27;According to some anatomists the cheeds tympani is derived from the nerve of Weiglers, and not from the factal. It is intermetely connected with the linear branch of the 17th, at I the sense of faste in the auterior two threes of the tractic is dependent entirely upon the chords tympani, the linear presiding over general sensitility only.

Caries of the petrous part of the temporal bone is a common consequence of neglected offits in the child. According to Von Trillschaft for from uncommon to find the masteid cells, with the tympanic carry and the Eustachian tube the seat of suppurative catarrh in a challed had lived and died without the disease having been suspected. The cadition may exist without external discharge, without pain, or any sympt a by which its presence may be revealed (see Offits).

In children under three years of age facial paralysis is not rate. It this time of life it is due almost invariably to offits and carries of box. Whe suppuration in the sheath of the nerve. Older children may suffer to paralysis arising from the same cause, but in them there is increasing to be

ability that the loss of power is the consequence of a chill.

Symptoms.—The first symptom usually noticed by the mother is that the child's mouth is drawn to one aide when he laughs, or cries. On curful inspection it will be found that the absence of movement involve the whole side of the face. While the features are at rest, the eve on the dfected side is incompletely closed; the nostril is flattened; the checkest hang a little, although this is not easy to detect in babies; and the size of the mouth is slightly lowered. It is when the child cries that the grid difference between the two sides is seen. Then, on the Lealthy side at eyebrow contracts; the forehead wrinkles; the eye closes; the ala 4 to nose and the mouth are drawn upwards; and the middle in e of the appr pulled far out of the centre of the face. On the affected side, on the neetrary, the muscles are motionless; the eye is open; and the skin remains smooth. If the nerve is affected in the Fallopian canal, the paraisse of fects the soft palate. On looking into the throat, it will be seen that a the side of the lesion the arch of the pulate is flattened, and that the und is curved to the sound side; for the motor fibres which pass through the large superficial petrosal nerve and the Vidian nerve to Mickels gan, la from which the palatine branches proceed, contract the azygos uvula [13] on the sound side. For the same reason children may complain that the month is dry and their taste impaired—the chords tympan, which the the papillic of the tongue and promotes secretion of solver, no longer of veying the nervous influence. Sensibility is not affected, but babies and seem to have a difficulty in swallowing their food; and if there would is loss of power on one side of the soft palate, some of the walk may be to casionally returned through the nose. An older child complains of reinconvenience from food collecting between the gums and the class through the action of the buccinator being paralysed. He can no load whistle, and even his speech may be impaired. The half-open eye is a to become inflamed from exposure; and there may be a flow of tears of the check as a consequence, according to Duchenne, of paralysis of 'be tensor tarsi muscle, which no longer retains the puncta in its normal pel tion

The symptoms which are produced by a lesion affecting the facial per-

in the Fallopian aqueduct are well seen in the following case:

A little girl, aged sixteen months, was admitted into the East Lorder Children's Hospital on March 24th. The mother stated that the tird had been always healthy until two weeks previously, when she had been to be feverish and to be writable and thirsty. For the same time at had been losing tlesh and had had some cough. The day before, while sitting by her mother's arms, the child had suddenly fallen backwards in a factor condition, and had seemed to lose consciousness. It was then noticed that her face was drawn to the right. On admission there was found compare

paralisis of the left side of the face, and the left eye closed incompletely, the rule was small and showed no distortion. A discharge escaped from the left ear, but the mother could not say how long this had been going at the left ear, but the mother could not say how long this had been going at the could not say how long this had been going at each apex and the breathing was high-pitched and bronchial, with a large but any rhonchus. Over both sides of the chest dry and moist rides were lead. During the first fortinght of the child's residence in the hospital her superature varied between 99° and 100°. She took her food fairly well, but send to swallow with difficulty, and occasionally fluids returned through the use. The paralysis of the face continued, and the left eye became reland congested. The otorrhee improved; but the child's temperature beame higher, and rose to 104.5 in the evening. Then the left cornea atagned, and the patient died suddenly on April 19th.

After death both lungs were found studded over with small cheesy masses. On examination of the left ear the tympanic membrane was destroyd; the o sucles were carnous and broken down; the tympanum and mastord cells were filled with pus; the wall of the tympanum was carious, and a probe could be passed though it in the direction of the Fallopian cand. There was no inflammation of the brain or its membranes. The

count sinuses were not examined.

The occurrence of the paralysis is not always attended with symptoms of shock, as in the above instance. Usually it is only discovered accidentally by noticing a deviation in the child's face when it cries. The sleaghing of the cornea in the case narrated was due to implication of the

secony branch of the tifth nerve.

In the parts supplied by the paralysed facial nerve the loss of power a scally complete, and if the lesion affect the nerve after its passage through the internal auditory meatus—that is to say, if the facial nerve aid to other be implicated, the motion of the tongue is ununpaired, the massles of importantion act well, and there is no loss of power in the levator palpetine or the muscles of the cychall. In all but the mildest forms the paralysed muscles soon lose their irritability, and cease to respond to the electric current.

When the paralysis is due to caries of the petrous bone there is usually discharge from the meatus of a very offensive hand, and more or less imparment of hearing. When the cause of the loss of power is inside the stuli cavity, we get signs indicating the involvement of other nerves. There is squarting, or deafness, or amesthesia, and homplegia may be preseat Occasionally it happens that paralysis of the sensory branch of the ith nerve accompanies the facial paralysis. If this nerve be affected at a 1944 interior to the Gasserian ganglion, where it lies on the petrous part of the temporal bone, there result loss of sensibility of that side of the as, of the conjunctiva, and of the anterior portion of the tongue, also, "Memmation of the conjunctive, and ulceration of the corner. If the nerve be affected at a point posterior to the Gasserian ganghon, inflammation and alceration of the cornea do not follow, although the sensibility of the face is still affected. If the portia dura be diseased at its origin in the has some to it and the sixth nerve, internal strabismus from paralysis of the external rectus muscle of the eyeball will accompany the facial palsy.

Dagnosis and Proposis —If the paralysis is noticed directly after birth in a child who has been delivered with instruments, the cause of the infirmity is evident and the prognosis most favourable. In older babies and Joung children it is very important to discover the sent of the lesion. If it is due to caries of bone, and the nerve is consequently affected in the Fal-

lopian canal, there is an offensive discharge from the auditory meater, wi the sense of hearing is more or less blunted. Perhaps, also we car over a certain degree of flattening of the palatal arch on the affected sale was little twisting of the uvula, but this sign in children whose uvula is man is often absent. The existence of impairment or perversion of the size of taste is also impossible to ascertain in young children. In the old standing otorrhoes, or even a recent offensive discharge from the tests. combined with facial paralysis, affords suspicion of the strongest him. the facial nerve is affected in the Fallopian aqueduct. The progress a these cases is very unfavourable. In fact, death usually occurs some of later from extension of the inflammation to the dura mater and the ira-The form of facial palsy which is found in children under the age of the years is commonly due to this cause. In an older child, if the parties has not been preceded by any impairment of the sense of hearn and otorrheea; if his sense of taste is natural, his mouth perfectly most as his uvula straight, we may conclude that the nerve is affected in the topart of its course. If, as usually happens in such cases, there is to c of exposure to cold or of some slight injury to the face, the program a favourable although recovery may take some time.

Treatment.—Facial palsy from pressure of the forceps during device soon disappears, and little treatment is required beyond frequent forces to the face. Paralysis from cold should be treated by steady frictions was stimulating liniments, and the affected side of the face should be weight up in cotton wool. Electricity is useful. Dr. Duchenne's plan was respectively first the constant current with frequent intermissions, and as tog-ritability of the muscles returned, to make the intermissions less frequent and the sittings shorter. He never used faradism until several were said clapsed after the beginning of the paralysis, although at the later star allowed its value. Under the use of these measures the tomcity of the muscles returns, and the face regains its symmetry some weeks below

voluntary power is restored.

Besides electricity and passive exercise, Dr. W. A. Hammond more mends the early employment of strychnia in sufficient closes to bring the patient under the full influence of the drug. He also insists upon the portance of supporting the affected side of the face by means of a later hook placed in the angle of the mouth and fastened to the ear. But a chanical supports of this kind, which depend for their usefulness upon the intelligent co-operation of the patient, are not well suited to young characteristics.

In cases where the pulsy is due to disease of bone, little can be use in the way of treatment. Our efforts must be then directed cutrely to

the cure of the outis.

CHAPTER XVL

ACUTE INFANTILE SPINAL PARALYSIS.

Acre infantile spinal paralysis, or acute anterior polio-myelitis, is not, as was formerly supposed, a disease peculiar to childhood. It is now known to occur also in adults, although in them much more rarely than in younger farsons. This lesion constitutes the ordinary form of paralytic affection to which children are liable. It nearly always begins in babyhood—during the time of the first dentition—but often lasts long after the first teeth have been completed, and indeed may render the child a cripple for life.

The disease is never a fatal one in itself, but if death occur from other causes in a child so paralyse I, no naked-eye changes in the spinal cord can be discovered. Consequently the nature of the lesion was long doubtand has only recently been clucidated. Now, however, owing to the researches of MM Charcot, Joffroy, Roger, Damaschino, and others, the loss of power has been shown to be due primarily to an inflammation affeeting the gray matter of the anterior cornus of the spinal cord, causing atrophy and disappearance of the large multipolar gauglion cells in that entuation. The reader may be reminded that these large ganglion cells are believed to be centres of reflex action and transmitters of impulses received through the spinal tracts. They therefore influence the movements of muscle. Besides this, they are probably trophic centres and regulate the nutrition of tissues. Consequently the disappearance of these cells is followed by impairment or even abolition of reflex and voluntary action in the parts with which they are in communication, and also by impaired nutrition in muscles, tendons, bones, and jointa,

Causation.—As the disease is mainly limited to the period of the first dentition, cutting of the teeth has been supposed to be a cause of the myelitis; but if this be the case it is probably so only indirectly. An infant feverish from teething is in a high state of nervous irritability. His digestion is mapaired, and his pyrexia renders him exceptionally sensitive to chill and other causes of inflammatory and catarrhal disorder. For this reason pulmonary and intestinal derangements are common at this period of life. But these ailments cannot be said strictly to be caused by dentition, except in the sense that the process of teething, by making the child feverish, heightens his susceptibility to ordinary injurious influences. So, also, in the case of this disease, an infant, when feverish, is more likely to be affected by causes which produce the myelitis than he would be at another time when his temperature is normal, his digestion good, and his nervous system undisturbed. What these causes may be is doubtful. The inflammation is often attributed to chills, and there is no doubt that the season of the year has a distinct influence in inducing the attacks. Wharton Sinkler, of Philadelphia, and Barlow, of Manchester, have made inquiries into this matter. Out of one hundred and forty-nine cases collected by the former physician no less then seventy-seven occurred in the months of July and August. In Dr. Barlow's one hundred and eleven cases fortyeight occurred during the same months. Now July and August, although the hottest months in the year, are also those in which alternations of temperature are most rapid and unexpected, and in which, therefore, sudders chills are very likely to be incurred. If the child at the time of the change is depressed and exhausted by previous intense heat—as he is apt to be irally a tropical chimate—the sudden lowering of the temperature is the more likely to produce an injurious effect. The disease sometimes occurs after typhoid fever: Dr. Buzzard has known it to come on after measles; and the paralytic attack appeared in a patient of my own—a little garl of two and a half years old—during convalescence from an obstinate chronic diarrhesa. Both sexes appear to be subject to it in an equal degree; and, apparently, robust health is no protection from its attacks, for it as often affects a constitutionally healthy child as a cachectic and weakly one.

Morbid Anatomy.—The lesion is limited to the spinal cord, the brain being unaffected. An inflammatory process attacks the auterior cornulated produces certain changes in the gray matter itself, in the roots of the nerves which take their origin in this situation, and in the muscles, tendons.

bones, and joints to which they are distributed.

In the gray matter the changes are not appreciable by the naked eye, except that in old standing cases a certain diminution in bulk, with increase the consistence of the affected parts, can be sometimes detected. By careful microscopic examination, however, the changes can be distinctly recognised.

The inflammatory process is diffused through the gray matter forming the anterior horns; but is more intense at certain points, notably the cervical and lumbar enlargements. As a consequence, areas of softening can be seen, more or less sharply defined, seated towards the front of one or both cornua. In these areas the tissue is soft and friable, the bloodvessels are fuller than natural, and numerous granulation cells are seen with an increase in the amount of connective tissue. The most striking change consists, however, in the fact that the large gauglion cells have almost. completely disappeared, and the few which are left are greatly strophied. and degenerated. The nerve fibres and axis cylinders are also destroyed. and the anterior roots are degenerated and wasted. As a consequence of these changes the anterior horns look small and shrunken at the spots where these diseased foci are situated. Although the diseased process is thus concentrated in certain patches, the gray substance generally is not completely healthy. Throughout the whole dorsal portion of the cord the gray matter is often more or less affected. Granulation cells may be seen to be scattered through the tissue; the nuclei are multiplied; the bloodvessels are dilated and ganglion cells here and there have disappeared.

The above changes constitute the first stage—that of active inflammation. As the acute process subsides improvement takes place in parts where the gray matter has not undergone entire destruction. But in other regions, where the disintegrating process has been complete, further changes ensue. These consist in a more extreme wasting and shrinking of the anterior horns, so that the diminution in bulk becomes visible to the naked eye. The disease is most marked in the cervical and lumbar enlargements. In the affected areas there is complete destruction of all nerve fibres and gaughou cells. Even if a few are left, they are degenerated and shrivelled. The area becomes filled with a fine fibroid connective tissue, rich in nuclei, and the blood-vessels are hypertrophied. Even the anterior white columns become more or less degenerated. Their neuroglia is thickened, their nerve fibres are atrophied, and the development of the columns is retarded, so that they look small and narrow. This is, however, probably a secondary affection, and is not necessary for

the complete development of the symptoms. Stated briefly, the lesion with constitutes infantile paralysis may be said to be an acute mychine of the anterior gray cornus, leading to circumscribed patches of sclerosis and complete destruction of the large ganglion cells and other nervoluments.

The changes which have been described supply an explanation of the pechar phenomena observed in the disease. The striking limitation of the paralysis to certain muscles, or groups of muscles, and the complete mannity of others, is due to the concentration of the lesion into certain muscles areas; while the early resolution of the inflammation in the larger portion of the tissue attacked accounts for the disappearance of the instructions, and the restitution of power in many of the muscles

premarily affected.

The paralysed muscles also undergo atrophy and degeneration. They become at that paler and softer, then grayish or reddish yellow, with bands of connective tissue, and vellow lines or streaks of fatty tissue. The microcope shows at different stages the fibres wasted, and their striction indistrant hyperplasia of the cells of the succelemma; then the fibres cody with numerous fat molecules; finally, almost complete absence of excitantibre. The normal structure is often replaced by an increased becomes a more throughout tissue, so that what was once a muscle becomes a more throughout the in other cases we find substitution of the normal mannar substance by adopose tissue, and by this means the original prime of the muscle may be actually increased.

fatty degeneration is not an invariable consequence of the muscular polynamic liven when it occurs, it is often not universal, and proceeds

much faster in some bundles of fibres than in others.

The bones as well as the muscles become wasted. Their development

and mowth are retarded, and their density dimunshed.

Symptoms.—The attack is sudden, and the paralysis reaches its height at once, both in distribution and degree. In many cases the child exhibits no suprems of illness. He goes to bed to all appearance perfectly well. In the morning one or more of his himbs is found to hang loosely and to be motionless, otherwise he shows no sign of all health. In quite young bous, who cannot walk, the loss of power may remain unnoticed for several days. In a second class of cases the symptoms are a little more maked. A child who has been put to bed in his usual health is seried in the night with fever. He cries and is very restless. In the morning more of loss extensive paralysis is discovered. In a third class of cases the child a ferrish and poorly for several days before the paralysis occurs, sometimes he is delirious, or he may have an attack of convulsions followed by alujor. In all cases, probably even in those where the symptoms are the less accentuated, there is some preliminary fever, but this may last only a few bours, and is often unnoticed by the attendants.

The paralysis is complete. It may be widely distributed, or may be unded to one muscle or a group of muscles. It may affect all four limbs; It may attack only the lower extremities; it may assume the hemplegue form and fix upon the arm and leg of one side; or, again, it may settle upon me unbonly—in such a case the right foot is said to be the part most irrepently selected. In this form of paralysis the face and parts sup-

With regard to the absence of paralysis of the face it is right to say that Dr. Burmiles recorded a case which appears to be one of undoubted infantile paralysis in about facial paralysis was noted. Its Buzzard attributes this exceptional phenomenon was axionation upwards of the inflammatory process into the medulia obiongsta. He

plied by cerebral nerves are never affected, the intelligence, after the first onset, is never impaired, and control over the rectum and bladder, at any rate after the first few days, is never lost. Sensibility in the paralysed parts remains in every way normal; there is no pain anywhere; no rash upon the skin; no tendency to the formation of sores or sloughs upon parts exposed to pressure; no rigidity of the joints. The affected limb is perfectly flaceid and painless, but also perfectly motionless. In some rare cases the onset of the disease has been said to be attended by pains in the back and limbs, and by hyperesthesia of the skin; but these phenomens are not directly the consequence of the spinal lesion, and form no necessary part of the group of symptoms which are held to be characteristic of

infantile paralysis.

The flacedity of the paralysed muscles is accompanied by a loss of reflex phenomena and a diminution or complete disappearance of the normal contractility. This takes place early in certain muscles, so that in the course of a few days they may be found to respond faintly or not at all to faradic stimulation. While, however, the muscles have ceased to react to the strong faradic current, they will still respond to slow interruptions of the constant current. When contractions are obtained by this means in a muscle which has lost all familic contractility the phenomenon is called "reaction of degeneration." It implies that the muscle for the time is physiologically cut off from the influence of the spinal cord. Besides this, early sugns are noticed that the nutrition of the limb is no longer efficiently maintained. The part is cold and often looks purple; the pulse is smaller; the fat becomes absorbed; the muscles waste; the liguments of the joints are relaxed and there is even a slackening of growth in the bone. These trophic changes are usually marked and generally continue after apparent restoration of power in the affected limb

The paralysis is at first complete and much more extensive than it afterwards becomes. After some weeks, or perhaps months, a partial recovery takes place in the muscles whose familie contractility had not been entirely destroyed. Sometimes this restitution of motor power is perfect, and, except for the impaired nutrition in the affected limb, the child may seem to be well. More usually, however, certain muscles, or groups of muscles, still continue disabled; and when the paralysis has thus limited itself, the parts which remain crippled are in most cases permanently use-

less.

When the paralysis is at first extensive, there appears to be no definite rule as to the parts which are afterwards to recover their power. If an arm and a leg are both affected, the one limb does not necessarily recover sooner or more completely than the other. The only indication is the persistence of contractility in the palsied muscles. Each muscle should be carefully tested by the faradic current, and in those whose contractility is not destroyed we may hope for eventual recovery. Cases have been recorded—notably by Dr. Kennedy—in which the limbs recovered early and completely without the disease leaving any trace of its passage; but it has been doubted if in such instances the lesion is the same as in those where recovery is slow and more or less imperfect.

believes that facial paralysis occurs so seldom because the acute affection invading the bulb is not likely to spare the nuclei of nerves essential to life, for if it attacked the nuclei of the vagus sudden death would be the consequence. He suggests that cases of sudden or rapid death in young children may be sometimes due to the disease striking the modulia oblongate with the same suddenness with which it usually attacks the anterior gray matter of the spinal cord.

In course of time changes take place in the muscles which remain permuently paralysed after the general restoration of power. This stage of the disease is called the period of atrophy; for the affected muscles waste, and at the same time the sluckening of growth in the bone becomes a noticeable feature in the case. This arrest of development in the affected limb has been already referred to. It is a variable phenomenon and is not alway present. When it occurs, it does not appear to be proportioned to too severity of the disease as to muscular wasting and paralysis; but may be present in a mild case, and absent, or nearly so, in a severe one. According to Volkmann, it has been seen in cases of the most transient infancies paralysis where the muscles quickly recovered their power, and atrophy of secret muscles was not noticed. As the growth and development of the muffected limbs proceed in the normal manner, the difference between the two sides is often very evident.

The wasting of the muscles permanently paralysed sometimes begins early, and, according to Duchenne, may be evident at the end of a month. It is rule the permanent paralysis is not widely diffused. It is not comfortune may occur. Usually it is a group of muscles, or even a single that this disabled; and in practice certain parts more than others are found to undergo the atrophic change. In the leg the common extension of the toes, the peronei longus and brevis, the tibulis anticus, and metimes the gastroenemius may become atrophical; in the thigh, parts of the triceps extensor; of the muscles attached to the upper extra mity, the deltard, the servatus magnus, and some of the muscles of the forearm.

One of the most important and characteristic results of the disease consists in the paralytic contractions which almost invariably occur when muswhen are permanently disabled, and constitute various kinds of deformity. They are especially common in the feet, and are the principal cause of the chifferent forms of clubfoot which develope in the child after birth. The contractions occur not in the paralysed inuscles, as a rule, but in those which still retain their contractile power. They begin early, and tend to increase as time goes on. This contraction of unaffected muscles, or of muscles only partially affected, was attributed formerly to the influence of the so called "muscular tonus." It was supposed that a constant stimulus proceeded from the spinal cord, and kept all healthy muscles in a state of persistent slight contraction. In the normal condition, it was said, opposite muscles neutralise each other; but if the muscles become paralysed on one ade, so that the contracting power on that side is abolished, the limb is drawn to the affected side by the action of the "tonus" in the unaffected This theory was combated by Werner, who maintained that the contraction could be explained without recourse to the imaginary tonus. He asserted that when one set of muscles is paralysed, there is no deformitr until the opposite set of muscles is put into action. The limb is then drawn to that sole and cannot be replaced by the paralysed antagonistic muscles. It therefore remains in its new position until replaced, or until it falls back again by its own weight. Consequently, it must happen that the limb is often and long in one position, for the muscles once contracted remain so because the antagonistic muscles can no longer act. After a time they lose the power to relax, and a permanent contraction becomes gradu dly established.

But even this theory does not account for the whole of the facts, for, as was pointed out by C. Huter, it is not always the muscles anatomically opposed to the paralysed groups which undergo contraction; and indeed the deviation sometimes occurs in the direction of the paralysed side. The real cause of the deformities of the foot appears from the researches of Huter, Volkmann, and others, to be only partially the unopposed action of healthy muscles and inability to antagonise their contractions. Farmore important agents are the weight of the affected part itself and the greater pressure thrown upon it when in use. For instance, the commonest deformity of the foot is the talipes equino-varus; but this is exactly the position in which the foot will fall when the ankle-joint is not acted. upon by its muscles. If a child be made to sit upon the edge of a table, with his legs hanging down, the foot instantly fulls into the equino-varusa position. In paralysis of the limb, if the child has not walked, this is the form the deformity invariably takes. The foot assumes this position, and the shortened muscles in time become permanently contricted. The arrest of growth in the hone, which is generally present, promotes the formation of this deformity, for the affected leg being shorter than the other, the child has to point the toes in order to reach the floor. If the paralysis. occur in a child who has already learned to walk, the flat foot (talines valgus) is the usual form of distortion, and is, according to Volkmann, irrespective of the actual muscles paralysed. When the patient brings his weight to bear through the leg upon the sole placed flat on the ground, the foot, being no longer braced up by the paralysed muscles, curves outwards until checked by the hgaments. By repetition of this action the ligaments stretch, and the bones on the compressed side are interfered with in their growth. The talipes valgus thus formed is less perfect than the same deformity produced by over-exercise and fatigue in a child with unparalysed muscles, for during rest the foot is brought again by gravitation into the equino-varus position. The shortened muscles are therefore again drawn out, and their contraction is less complete, so that the joint is comparatively loose.

When the muscles of the thigh are permanently weakened, there is no contraction about the knee unless the child attempt to aid hunself by the use of crutches. Children in whom there is partial paralysis of the quadriceps femoris walk, says Volkmann, exactly like a person who wears an artificial leg. To get such a leg to support the weight of the body without bending the knee, the weight must be thrown in front of and not behind the joint. Every time that the body rests upon the weakened limb, the weight is thrown forwards, so that the knee is in a state of complete extension, and the posterior ligamentance put upon the stretch. These after a time relax, and the knee is over-extended so as to produce a genu recurvatum.

In the arm, the elbow-joint is little affected. It remains quite free, and no contractions occur unless the arm is kept permanently in the bent position, as when worn constantly in a sling. When the paralysis is so marked that the hand is useless, the power of supination of the arm is soon lost, for the child, having no occasion for the movement, soon ceases to employ it. The wrist becomes slightly flexed, and the fingers, completely clenched upon the palm, undergo contraction in that position. This is the position the fingers assume when left to themselves; and if the flexors are not used, or are not passively stretched, they become contracted. The shoulder is flattened, and if the muscles proceeding from the thorax to the arm are extremely weakened, the capsule is pulled upon by the dead weight of the arm and becomes permanently stretched, so that a distinct interval is felt between the head of the bone and the socket. In this case the affected arm, by measurement from the acromion, may seem longer than the sound one.

From what has gone before it will be noticed that cases of infantile spinal paralysis fall naturally into two classes: those in which complete recovery takes place in all the muscles affected, after the lapse of weeks or months; and those in which power is completely restored in some muscles, while others remain permanently useless, and the disease ends in atrophy and deformity. In the muscles in which the paralysis is likely to be lasting, faradic contractility disappears at a very early date—usually before the end of the first week, or in the course of the second. According to the elder Duchenne, muscles which retain some degree of faradic contractility on the seventh or eighth day may be expected to recover their power, and this the more rapidly the less their faradic irritability has been weakened.

Diagnosis.—In a case which is seen at an early period of the disease the symptoms are so characteristic that it is difficult to mistake this form of tilness for any other lesion of the nervous system. But every case of paralysis with atrophy is not a case of infantile spanal paralysis. To identify the disease with accuracy we must require all the essential phenomena of the affection, viz., complete motor paralysis without alteration of sensibility or pain in the back or elsewhere; rapid loss of faradic excitability; a normal temperature; absence of paralysis of the face or of the sphineters; complete the orbits of the limb, without stiffness or contraction of the joints; marked coldness of the affected parts, and no tendency to the formation of sores upon the skin.

In acute generalised mychtis, where the whole of the gray matter is involved and a large part of the white columns, there is lessened cutaneous sensibility; there is paralysis of the sphincters, so that the child can no longer control the bladder or the bowel; there is an increase of reflex excitability; sores form readily on the parts exposed to pressure; the urine askaline, purulent, and offensive, and, as a rule, atrophy in the affected

muscles does not occur.

Hismorrhage into the cord produces a sudden paralysis, which is followed by strophy of the affected muscles and loss of reflex excitability; but here also there is diminution of cutaneous sensibility, the sphine-

ters are paralysed, and bed-sores form early.

Pamilysis of cerebral origin may be distinguished by the affection of the cerebral nerves, such as squinting, facial paralysis, etc; by the palsy being accompanied by tension of the muscles and spasmodic contractures; by the preservation of electrical irritability; by the stiffness and extension of the joints; by increased excitability of tendons, and by the absence of atrophy.

In spasmodic spinal paralysis the loss of power is incomplete, and occurs alowly and insidiously; muscular tension and contractions are present; there is increased irritability of the tendons, and the affected muscles do

not atrophy.

The course of infantile paralysis is also very characteristic. The rapid restoration of power in the larger number of muscles affected and the complete paralysis of others is very peculiar; also the arrest of growth, which embraces the whole of the region first affected, is a very striking phenomenon. At a later period, when contractions occur in the lumb, the resulting deformity may be distinguished from congenital distortion by the very partial atrophy of muscles, the striking looseness of the ligaments of the joint, and the permanent coldness of the part.

Prognosts.—As infantile paralysis is not a fatal form of illness, our chief anxiety must be to estimate the chances of complete recovery in the paralysed muscles. For our own comfort and that of the friends we may re-

member that complete recovery, or at any rate vast improvement is the rule and not the exception. Careful tosting with the faradic current all give us very accurate means of determining in which muscles speed retoration of power may be anticipated, and in which of them persent paralysis is to be feared. The muscles which have lost all physically connection with the spinal cord no longer respond to the induced carea, while they react to slow interruptions of the constant current (respected degeneration). This change takes place very rapidly. Faradic interior is enfeebled as early as the third or fifth day, and is lost by the sevent of eighth.

In testing the irritability of the muscles at this period a weak correshould be used—one just sufficient to cause contraction in healthy ascless. Every muscle which does not react to the faradic current after the lapse of a fortnight from the beginning of the illness is likely to be permanently disabled. Still, according to G. Sigerson, muscles which is long ceased to contract may sometimes regain their faradic contract by and recover their power more or less completely. On the other hand the muscles which retain some amount of faradic irritability, however faintly they may react to the current, return of power may be confidently predicted. Even when recovery from the paralysis is complete, the child is still hable to some arrest of growth in the affected hind; and it is not to warn the friends of the patient of this possible consequence of had

Treatment.—If we have the opportunity of seeing the child immediately after the occurrence of the paralysis, we should keep him perfectly que in bed, clear out his bowels with a brisk aperient, and employ contents irritation to the region of the spine. By the repeated application of and tard poultices, first to one part, then to another, of the spine, a derivant action may be kept up as long as the skin will bear it. During the early days of the disease it is well to insist upon a prone position, varied assonably by laying the patient on his side. The dorsal position, which favours congestion of the vessels within the spinal canal, should, if possble, be avoided. The child should be put upon a diet of malk and lock, and care should be taken that his bowels act regularly once a day. Well there is any fever Dr. Althaus recommends a daily subcutaneous injection of a solution of Bonjean's ergotine -a quarter of a grain for a clastic twelve months. At first no local treatment is admissible to the partied muscles; and the faradic current should be used only for diagnostic party poses and not as a therapeutic agent. But immediately any recover of power begins to be noticed, we should employ the familie current dails, so as to aid the restoration of the affected muscles. If there is at first no se sponse to the induced current, the continuous current, with slow interruptions may be employed. It is advisable to use a current of sufficient strength to cause a visible contraction of the muscles. This, however & often impossible with children. Even a weak application may cause such agitation and alarm that its employment has to be discontinued. We should not in any case use a strong current at first. Probably a well current, in its influence upon the nutrition of the muscle, is preferal to none at all. Dr. Gowers recommends that in the beginning such a star A should be employed as the child will bear without much emotional distant ance, and if care be taken not to alarm the child at the first, a current of con siderable strength can be perhaps made use of afterwards.

Besides electricity other means should be used. The paralysed had must be kept warm with cotton wadding. This is a matter the important

per of which has been very properly insisted upon by Dr. R. J. Lee. If affected parts are very cold, they may be rubbed several times a day more the fire, and hot applications of any kind—bags of hot salt, bran, by thunel, etc., may be kept in contact with the limb to maintain its temperature. Great assistance will also be derived from vigorous shampooing. It a already to order stimulating liminents for this purpose, as frictions in aways employed with more energy if something is given "to be maked into the skin." The child should be also encouraged to use the valeed limb as much as possible; and Volkmann insists strongly upon he worse than uselessness in these cases of crutches or other forms of commeal support.

It is usual to give strychnia to these patients, either internally or by abutaneous injection. The remedy has probably little inducate in relating power to the disabled muscles, but as a general tonic its use may set without value during the stage of recovery. It may be combined

will mon and quinme.

b. most cases of infantile paralysis, when recovery does not take place at in the first two months, the course of the disease is long and tedious, at improvement goes on but slowly. Still, our efforts are eventually returned by a striking return of power even in cases which at first had appeared almost hopeless.

fue cure of the deformities resulting from atrophy and contraction of

was come under the department of the surgeon.

CHAPTER XVII.

SPASMODIC SPINAL PARALYSIS.

Seasone spinal paralysis, sometimes called spastic paraplegia, appears from the researches of Charcot and of Erb to be due to a sclerosis of the literal columns of the cord. The disease, which consists in a gradually advancing weakness or paralysis of the limbs—generally the legs—is sometimes seen in children and even in young babies; indeed in many cases it appears to be congenital. Like infantile spinal paralysis the lesion is accompanied by no disturbance of the cerebral functions, no affection of sensation, and no loss of control over the bladder and rectum; but, unlike infantile paralysis, the affected muscles seldom waste, there is excessive regulary of the joints, and the tendinous reflexes, instead of being abolished, are increased in activity.

Causation.—The lesion may develop itself in the earliest childhood. Its causes are unknown. Schigmueller has recorded an instance in which four children of the same family suffered from a form of the attection.

Morbid Anatomy.—No cases of death from this disease have been noticed in children; but in adults the symptoms have been connected by Charcot with degeneration of the lateral columns of the cord. On section of the cord the gray degeneration is seen to be symmetrical and to occupy the lateral columns on each side of the cord. The diseased region, as seen on the surface of the section, is triangular in shape, and reaches inwards to the anterior gray cornua, outwards to the parameter; in front it passes gradually into the healthy substance of the columns. The degeneration is not in patches, but appears to be diffused over the greater portion of the length of the cord, and may reach up to the medulla or even beyond it. In some spots the process is more intense than it is in others. On microscopical examination of the degenerated portions, the neuroglia is found to be thickened, the nerve fibres to be degenerated and wasted, and the ganglion cells to be cloudy and swollen, or atrophied, pigmented, and finally almost destroyed.

Symptoms.—Whatever may be the age of the child when he first comes under observation, we shall generally find that the symptoms date back to the period of infancy, and that they were first noticed only a few weeks or months after birth. On questioning the mother we commonly hear that when quite a baby the child's legs were stiff, and that on this account washing and dressing him was a troublesome matter; that although able to move his legs when lying down, he could never stand, and that any attempt to do so increased the stiffness. If he did succeed in walking at an age long after that at which a healthy child can run alone, he was never firm on his legs, and soon became weaker and tumbled about. Then the power deserted him altogether, and when placed on his feet his legs became stiff and crossed, the toes touching the ground but the heels being raised. As there is no fever, pain, or evident impairment of nutrition, and

as in many cases the mental development is satisfactory, the weakness is looked upon as a personal peculiarity which the child will "grow out of," and he seldom comes under observation until the disease is fully developed.

In a child so afflicted two phenomena are at once noticed: there is weakness of the lower limbs, and the joints are stiff, and become stiffer

when handled.

On examination we find that the legs are moved awkwardly and with difficulty. As the child lies in his cot the himbs are extended and only slightly flexed, and the patient may have some power of bending his joints, although some are moved with greater faithty than others. The muscles feel rigid to the touch, and when the joints are foreibly flexed, which can be done without inflicting pain upon the child—they straighten again abscriptly, as if moved by a spring. Handling the limbs increases the rigidity of the joints, and often the mere approach of the physician appears to have the same effect. Movement, whether active or passive, produces no tremors in the affected limbs. It only increases the rigidity of the muscles.

When the child is held under the arms, so as to feel the ground with his feet, directly he attempts to walk the thighs are closely pressed together, the knees are a ightly hent, the feet are inverted, and the ankles extended so that only the points of the toes touch the floor; the legs become rigid and soon cross one over the other. In bad cases the heels are not brought into contact with the ground at all. Sometimes the child, although he cannot walk, is able to stand, supporting himself against some object. The tighties appear to contribute to his helplessness as much as the motor teckness, and sometimes the attempt at voluntary movement, conflicting

with the stiffness of the muscles, results in a sort of choren.

The back is often very weak, and the muscles of the abdomen may become hard when the skin is irritated. Control over the spinneters is not interfered with; there is no paralysis of the face, nor any tendency to the formation of sores or sloughs upon the parts exposed to pressure. The signer of intelligence varies in different cases. Often the child seems us quick as others of his age, but sometimes he is dull and stupid. Articulation may be affected, but, as a rule, the patients speak readily and clearly.

Occasionally the arms are affected. In a case reported by Dr. Gee—a little girl, eight years old, in whom the paralysis had existed certainly from the age of twelve months, perhaps from an earlier period—the arms as well as the legs became stiff when the girl was noticed. The arms were rotated outwards; the elbows were strongly extended and the wrists promated; the hands were also extended strongly and thrown back at the wrist; the fingers were flexed. The child could move the opposing noiscles, but with difficulty, and after movement the arms soon returned into the position described. The left arm was more affected than the right. Dr. Greches described eight cases of this interesting nedady, of which the first was observed before the publications of Erb and Charcot had attracted general attention to the disease.

The constant rigidity of the muscles affected is not accompanied, as a rule, by any wasting, although in exceptional cases, when the disease is of long standing, one or more (not all) of the implicated muscles may show some signs of atrophy. The rigidity is a permanent phenomenon, persisting during sleep, and only disappearing temporarily when the child is placed under the complete influence of chloroform. The tendinous reflexes are more active than in the normal state, and the response to faradism is rapid

and energetic. Sensation is ununpared.

In many cases the actual amount of weakening of the muscles upon to be slight. The impediment to walking seems to be more the party rigidaties and contractions of muscles, which prevent the foot and had had being placed in a fitting position to support the weight of the body at frustrate the voluntary impulse, rather than of any actual paralysis. From observations made upon the adult sufferer, contractions are found to come as a later phenomenon, the muscles being merely rigid at first without a shortening in their length. When the contractions come on the pure becomes more noticeable. Eventually it may amount to complete and voluntary motor power. This is, however, generally of unequal intesty in different regions, being well developed in certain groups of mosess apperfect in others. Usually the disease is more advanced in one of the limbs than it is in its fellow.

If a child, the subject of this disease, be able to walk, his gait is very peculiar. The patient behaves as if giddy, and sways from side to size his limbs are widely separated, and he moves each leg awkwardly forward often sliding it along the ground. The tendency appears to be together foot so that the heel is not in full contact with the floor Consequently the toes are apt to catch at any unevenness of the ground, and the

child would fall on his face if not supported.

As the disease advances all the symptoms become intensified. The rigidities, the contractions, the paresis, and the reflex irritability of the come increased. The lesion does not appear to be fatal to life. Of its later stages little is known, for after a certain degree of intensity is revied, and the patient has been rendered quite helpless, the disease excess to

undergo no further change.

Paralysis of the lower extremities, without wasting, but accompared paralysis of the lower extremities, without wasting, but accompared excessive spasmodic rigidity of muscle and increased activity of the termous reflexes. The disease is therefore readily distinguished from rimitile spinal paralysis, in which wasting and arrest of growth in the affected limb are the rule; the joints, far from being rigid, are excessively related and the tendinous reflexes are abolished.

General scute myelitis resembles the spastic disease in its increase of reflex excitability and absence of atrophy, but differs from it by processes paralysis of the sphincters, diminishing the cutaneous sensibility, saippointing the formation of bed-sores. Besides, there is a well-defined note zontal limit beyond which the disease does not pass, and there is no specific proach to the muscular rigidity which is such a characteristic feature of

spasmodic spinal paralysis.

In paralysis of cerebral origin the loss of power is accompanied by the sion of muscle and spasmodic contractions, the joints are stiff and detended, the muscles do not atrophy and continue to respond to faraise, and the reflex irritability of tendons is preserved. But in such a case there is paralysis of cerebral nerves, the loss of power is hemipiene in detribution, the rigidities and contractions are very late to occur, and sention as well as motion is affected.

Prognosis.—The life of the patient appears to be in no danger from the illness, but at the same time his chances of recovery are small. Little a known as to the course of the disease in the child, but none of Dr. then

cases were influenced by treatment in the slightest degree.

Treatment.—Erb recommends the galvanic current applied principal to the spine, but also to the affected limbs, and the application of adcompresses. Drugs appear to have but slight influence on the disease.

ae of recovery reported by Von der Velden—in a man aged twenty—bromide of potassium, belladonna, and morphia had no beneficial ce; indeed, the latter seemed to increase the number and intensity attacks. Chloral, however, was useful in moderating the spasmodic; when they were at their worst, and improvement began to be manwhile the patient was taking the double salt of gold and sodium. Gee's cases hemlock, belladonna, Calabar bean, and strychnia—the st hypodermically—were used in turn, but without the slightest

CHAPTER XVIII.

PSEUDO-HYPERTROPHIC PARALYSIS.

This singular form of paralysis, in which extreme feebleness of the muscles is combined with an appearance of extraordinary development and vigour, was first studied and described by Duchenne, of Boulogne. Almost at the same time, however, Dr. Edward Meryon, in England, had published some interesting particulars of four boys in the same family who were all affected with what appears to have been hypertrophic paralysis, although the nutbor at the time was of opinion that the disease was identical with progressive muscular atrophy. Many cases have since been placed upon record, and there must be few children's hospitals which have not at one time or another had an example of the disease within their walls.

Causation Of the etiology of the infirmity nothing is known. It is in the large majority of cases confined to the male sex. In Dr Mervon's first series of cases, above referred to, all the boys (four) of the family suffered from it, while the eight girls escaped. This fact also illustrates another tendency of the disease, viz., its proneness to attack several members of a family. Two, four, and more children of the same parents have been known to be affected, and Dr. Meryon has referred to a striking instance in which eight brothers all died of the disease. This tendency seems to point to a herechtary element in the ctiology of the infirmity. In investigating this question it is not enough, as Dr. Gowers has pointed out, to ascertain merely the health of the parents. Females are rarely affected by it, and males, the subjects of the disease, usually die at or soon after Therefore the tendency must be searched for amongst the collateral branches of the family. Such evidence is generally found on the side of the mother, and instances of the disease in some members of her family can be discovered sufficiently often to determine positively the frequent existence of this one-sided inheritance.

The disease appears to be limited to childhood, and, indeed, is often congenital, the first symptoms manifesting themselves during infancy or

shortly after that period. It seldom begins after the sixth year.

Morbal Anatomy.—No morbid changes have as yet been discovered in any part of the nervous system to account for the disease, but the changes in the affected nuscles themselves are sufficient to explain the phenomena of the affliction, and especially the apparent inconsistency between the unusual size of the muscles and their remarkable want of power.

In the muscles the morbid process consists in an overgrowth of the interstitial connective tissue between the fibres. The nucleated fibrous tissue and the fat cells gradually increase in quantity and compress the muscular fibres. These under the pressure become narrower, and their strue farther apart, although still distinct; afterwards the structures become indistinct, and the fibres dwindle and eventually disappear, leaving the

empti sarcolemma sheath running by the side of the fibrous bundles and

proof rated fat cells.

If the fat is greatly increased in quantity, the muscles on section may have the appearance of a fatty tumour in which no sign of muscular reduces is visible to the naked eye. Under the microscope the fibres are seen to be separated by fat cells, but it is not common to find fatty degeneration of the muscular fibres themselves.

Supplies. The earlier symptoms are very apt to escape notice as they have no distinctive character. They consist merely in weakness of certain among usually those of the lower hubs, and sometimes of the back. If the lose see begins in early infancy, before the time for walking has arrived, tar child is noticed to be heavy to lift, and to want the responsive "string" which is so marked a feature in the healthy infant. In such a case it is late before he acquires the power of walking. If he has been and to walk before the disease begins, he very quickly gets tired, and brave by a slight push, and when on the ground rises again with difficalty. When the weakness of the muscles has reached a certain degree. the child is forced to assume a characteristic attitude. In standing he securities his legs widely, and throws his shoulders backwards so as to eviderate the antero-posterior curve of the lumbar spine. Consequently has belly as protraded, and, in a marked case, a vertical line dropped from the back of the neck falls clear of the buttocks. This attitude is the conso since of weakness of the extensors and flexors of the hip and the extensors of the knee -the muscles which maintain the body upright in standmy The child, feeling these to be insecure, tries by separating his feet to charge his base, and as, owing to the weakness of the extensors of the hip, the pelvis is inclined unnaturally forwards, he throws his shoulders backwill so as to keep the centre of gravity in the normal position. As he walks he still continues to separate his feet widely, and he sways his boly from side to side so as to keep the centre of gravity over the foot upon which the weight of the body is resting.

After a certain number of months, or, according to Duchenne, a year has changes can be noticed in the muscles, and the weakness becomes more marked. The culves of the legs become enlarged, so as to give the apparance of unusual vigour, and generally a similar hypertrophy affects other muscles as well. The gluteal muscles, the muscles of the thighs, the posterior muscles of the spine, the deltoids, and sometimes almost all the muscles of the trunk and limbs may share in this enlargement. If the muscles do not become hypertropined, they usually waste, and this diament in in size of some muscles renders more striking the extraordinary hypertrophy which affects other muscles in their neighbourhood.

As the weakness of the muscles goes on progressively increasing, the characteristic attitude and guit become more and more marked. At the same time any slight extra strain put upon the muscles in the performance of certain acts increases the difficulty to such a degree that the child is reduced to some very curious expedients in order to accomplish them successfully. Thus, in rising from a chair, he endeavours to assist the extension of the knee-joint by placing a hand on each femur just above the knee. By this means, especially if at the same time he bend forwards, he transfers a large part of the weight from the extremity (the hip) of a laver whose fulcrum is at the knee to a part of the lever close to the fulcrum or, even, if the body is bent forwards sufficiently to throw the centre of gravity in front of the knees, actually uses the weight to be

moved as a motor power to effect the straightening of the knee-joint. Again, in extending the hip-joints the patient begins by placing his hands, as in the former case, just above the knee, and then moves the hands alternately higher and higher until the straight position is arrived at.

For some time the muscles retain sufficient power to carry the patient at a moderate pace along a level surface; but he cannot jump, and in mounting the stairs he is forced to do so on his hands and knees. to get up from the ground, the child can only obey by going through a series of claborate manusures, all calculated to relieve or assist the weakened muscles. As Dr. Gowers describes the process, the patient, being on all fours, keeps his hands on the ground, and stretches the legs out behind him far apart. Then, still keeping the body supported chiefly by the hands, he manages by shuffling backwards on the toes to get the knees extended. The body is thus supported by the hands and feet all placed as widely apart as possible. Next, the hands are alternately moved backwards along the ground so as to bring the larger portion of the weight of the trunk over the legs. Then, one hand is placed on the knee, and a push with this, and with the other still on the ground, is sufficient to enable the extensors of the hip to bring the trunk into the upright position. In many cases the child cannot rise at all unless near to some piece of furniture, by means of which he can gradually hoist his trunk upwards with his hands.

As the paralysis extends the patient gets more and more helpless; and when the upper limbs become affected, as usually happens after a few

years have elapsed, his condition is very distressing.

The affected muscles do not always increase in size. Sometimes they waste, and the hypertrophy and atrophy are irregularly distributed. Usually many more muscles are wasted than are enlarged. The hypertrophy is apt to affect by preference certain muscles. The muscles of the calf, the visit of the thigh, the glutsei, the infra spinati, and the deltoids are often enlarged. On the contrary, the muscles on the front of the leg are more usually wasted, and wasting is also more common in the latissimus dorsi and the sterno-costal portion of the great pectoral muscle. In the arm the biceps and traceps may be enlarged, but the muscles of the forearm are rarely affected. Sometimes the temporals and mussisters are hypertrophied. In some rare cases the muscles, before they begin to enlarge, have been noticed to be smaller than natural.

This form of paralysis is not accompanied by any general fever, but Dr. Ord has noticed a higher temperature in the leg where the muscles are hypertrophied than in the corresponding thigh. This, however, is not a constant phenomenon. At first the muscles respond normally, or nearly so, to the galvanie current, both interrupted and continuous; but when greatly wasted, the muscular response is weak, or even absent. The knee reflex is usually notably diminished. Sensition, however, is unimpaired,

and there is perfect control over the bladder and sphineter.

Towards the end of the disease contraction and shortening may occur in certain muscles—usually in those the opponents of which are excessively enfectled. This is a phenomenon which is seen in other forms of paralysis, and its mechanism is discussed elsewhere (see page 375). There is, however, one form of contraction which has been said by Duchenne to be a constant symptom of pseudo-hypertrophic paralysis. This is seldom noticed before the end of the sixth year. It takes place at an earlier period than the ordinary paralytic contractions, and occurs as a consequence of shortening in the length of the diseased gastroenemic. These

muscles draw up the heel so that the patient cannot press this part of his lost to the ground, and as the contraction increases a talipes equals is developed. The deformity is usually symmetrical. When combined with the muscular weakness it makes walking very difficult. Consequently there is nothing to oppose further contraction, and the extension of the male soon becomes extreme.

The disease may be associated with idiocy and mental feebleness, as appears from some cases published by Dr. Langdon Down, and with epispey and other forms of cerebral deliciency and disturbance. But these disease appear to be an essential part of the disease; indeed, in most re-

oriel cases the cerebral functions have been unimpaired.

The course of the disease is fairly constant, and the age at which the these reaches its fatal termination varies, as a rule, according to the age when the symptoms first appeared. Thus, if the symptoms have occurred to these, the power of standing is lost about the tenth or twelfth, and death ensures between the fourteenth and eighteenth years. If the early supptoms have been delayed until the sixth or eighth year, the patient is less measuremental by the time puberty is reached, and may live to the age of mattern or twenty, or even longer. Still, sometimes the disease runs a storter course, and it may happen that although late to appear the symptoms levelope rapidly, and the patient quickly loses all power of supportant the language of the hypertrophic disease. When the muscles of the chest because attacked, the inspiratory power is greatly enfeebled, and any accidital lung completation soon assumes alarming proportions. In fact, it is usually to bronchitis or pneumonia that the fatal termination is to be due thy attributed.

Despines. Inordinate size and firmness of muscle combined with extense weakness and unstradiness, developing slowly, and becoming graduals more and more marked, without cerebral symptoms, impairment of a rection, or weakness of the bladder or rectum, are the most characteristic features of the disease. The peculiarities of attitude and gait are also to be noted. The position of the child, as he stands with his feet widely apart, his adding protruded and his shoulders thrown back, his rolling gait in wating, and his method of helping to straighten the knees by pressing will his hands upon the femur just above the joint, must not be overlooked.

hispertrophy of the muscles is not always present. Largeness and hispass of the calves are very characteristic, but scarcely any less characteristic are their contraction and wasting with drawing up of the heels. Dr. Gowers attaches great importance in diagnosis to the increased size of the infra-spinatus muscle, with wasting of the latissimus dors and lower

part of the pectoralis major.

To read lattle deficulty in distinguishing the disease from infantile the paralysis, which comes on quite suddenly, in which the paralysis, at first general, quickly limits itself to certain muscles, faradic contractility such analysis, in which spasm is a marked feature, with great rigidity of the paralysis, in which spasm is a marked feature, with great rigidity of the analysis, in which spasm is a marked feature, with great rigidity of the analysis, in which spasm is a marked feature, with great rigidity of the analysis and exaggration of the tendinous reflexes. It is more difficult to the like two in this affection in its early stage and cerebellar tumour, or the tendinous beginning of intracranial disease in well-neurished children where sometimes all that can be detected is that the child is giddy and fails about. Still, in pseudo-hypertrophic paralysis the attitude is untracakable, and the way in which the child rises from the ground can arrest the insunterpreted. Progressive muscular atrophy is so excessively

rare in childhood that it may be left out of consideration. It differs markedly from the disease we are considering by being never attended by muscular pseudo-hypertrophy, and by invariably beginning in the upper part of the body. In a child seen by Duchenne it began in the face.

Prognoss.—When the disease is confirmed we can scarcely lose to any reincidal measures to stop the progress of the muscular charge. If the patient be seen at an early period of the attack, before any enlargenest of the muscles has been noticed, treatment is said to afford more here success. In estimating the chances of a lengthened course we must at into consideration the period at which the first symptoms were rotated the rate at which the affection is advancing, and the age and sex of the patient. According to Dr. Gowers, the progress of the disease appears be often related to the process of growth; therefore the less the muscus change has advanced at a period when the growth of the body is explicitly the greater the likelihood that the disease will become statistically as a rule, when it appears late it advances slowly. Therefore in the now favourable cases the affection has appeared late, and has advanced by this at the time of full growth of the body. As these conditions are more of found united in girls than in boys, the female sex is in itself a favorate element in the prognosis.

element in the prognosis.

Treatment. There is little to be done in the way of treatment. Dechenne states that he has succeeded in arresting the disease in two case is means of faradism, kneading and shampooing the muscles, and the use of baths. Benedikt recommends the continuous current. Arsenic and phorus given internally have been thought to be useful by some. Support to the spine are of service when there is great weakness of the baca, and in cases of marked contraction of the calf muscles the tendo Achain is

been divided with great temporary advantage.

CHAPTER XIX.

IDIOCY.

Mexical feebleness or deficiency, either congenital or acquired, is, unfortunately, a far from uncommon defect in childhood. The subject is an important one to the physician, for although he may not be called upon to treat such cases, he is often consulted upon the chances of recovery, and every degree of feebleness of mind, but especially the milder forms of imbucility and mere backwardness, may be brought under his notice.

Cinstian. - Heredity plays a very important part in the production of mental deficiency in the child. Imbeciles, fortunately, do not often marry, but a tendency to neurotic disease, such as insanity, epilepsy, etc., in the parents has a powerful influence in inducing feebleness of mind in their offspring. Dr. Lingdon Down, from careful investigation in two thousand cases of idiocy, found that in no less than forty-five per cent. a well-marked

neurosis existed in the families of one or both the parents.

The scrofulous diathesis has been said to favour the occurrence of idiocy; and there is no doubt that a large proportion of imbeciles are the subjects of profulous exchevia. Still, mental feebleness is not a necessary part of the diathetic disease; indeed, children of very evident scrofulous constitution often display exceptional intelligence. The explanation may probably be that the scrofulous habit tends to foster the influence of a neurotic tendency, and that the latter will operate with greater force and certainty in cases where it is associated with malnutrition in any of its forms. So, also, consanguineous marriages, and intemperance on the part of the parents, are well-known agencies in giving increased energy to any hereditary neurosis or morbid taint. Therefore any instability of the nervous system which may exist in such persons is likely to develope into a new and more striking phase in their offspring.

The above influences are influences of a very general kind, and all children born of the same parents must be equally subject to them. Idiots are seldom "only" children; indeed, statistics show that they are often born of more than ordinarily prolific parents whose other children exhibit no sign of intellectual deficiency. This being so, we must look for other

and more special couses for their mental failing.

These special causes may either operate during gestation, at the time

of birth, or after the child is born.

It is a suggestive fact that out of the two thousand cases investigated by Dr. Langdon Down no less than twenty-four per cent, were primiparous children. The cause of this undue preponderance in the first-born is no doubt owing, as Dr. Down points out, not only to the exalted emotional state of the mother during her first pregnancy—a state in which all causes of disturbance would naturally operate with exceptional force, but to the tediousness of the first labour, which is apt to give rise to a condition of suspended animation in the infant. Dr. Down's statistics well illustrate the force of these influences. Twenty per cent, of the idiots were born with well-marked symptoms of suspended animation; and of reliefs born in this condition, and only resuscitated by assiduous labour, no less than forty per cent, were first-born children. Bearing upon the same matter is the fact of the preponderance of male over female idiots, for the larger head of the former would increase the difficulty of parturation, and conduce to the state of suspended animation which experience shows to be so hurtful to the cerebral functions.

Whether the mother be a primipara or not, powerful emotional shocks are injurious, and may act very unfavourably upon her offspring. In no less than thirty two per cent. of Dr. Down's cases there was a well-founded history of mental shock. Again, excessive sickness, by impairing the mother's nutrition, is also calculated to exercise an unfavourable influence upon the intellectual development of her infant. Dr. Langdon Down found in ten per cent, of his cases a history of marked and persistent

vomiting.

After the child is born other causes come into operation. The mental incapacity may develope at a constitutional crists, such as the time of the first or second dentition, or of puberty; the amount of brain-power which had been previously sufficient for the wants of the economy faming to carry it through such critical periods of development. Masturbation in these cases may be an important factor in determining the break down. Again, accidental causes may come into operation in a child who had never shown symptoms of mental failure. Thus, he may become induce as a result of repeated convulsions or epileptic attacks, of chronic hydrocephalus, of injuries or blows upon the head, of some inflammatory condition occurring as a complication of acute disease, and of majarruent of the senses interfering with the development of the intellectual faculties

One form of idnocy-cretinism-is endemic in certain parts, although it

may also occur sporadically.

Morbul Anatomy. In most cases of idiocy in all in which the mental . deficiency is congenital -the brain is small and often imperfectly developed as well. There may be great simplicity in the convolutions, approaching to the condition of the bram in the anthropoid spes; there may be atrophy of the medulla oblongata, and asymmetry of the base of the brain; absence of the corpora geniculata, the corpus callosum, or even, as was seen in a case recorded by Cruveillier, the whole cerebellum; the convolutions may be shrunken and the brain substance hardened. In other cases the child may be from birth the subject of chronic hydrocophalus. brain is sometimes abnormally large, but may present no obvious change to the naked eye. Still, from the researches of Dr. M. Jastrowitz it seems that even in these cases careful microscopic examination may detect alterations in structure in the minute tissues of the brain, especially a persistence of anatomical elements which are normal in the embryo, but which ought to have passed into another form in the growing child,

Again, there may be cranial as well as cerebral abnormalities. The sutures and fontanelles may undergo premature coalescence; and if there be no compensation by unusually slow ossification at the base, allowing of greater expansion in that region, the entire emnium is well proportioned but very small, and profound disturbance of the growth of the brain is the consequence. If, however, there be basic expansion, a special type of physiognomical and physical development, which Griesinger has described as the "Aztec" type, results. When the base of the cramium is shortened by ossification, it is indicated to the eye by malformation of the face. We

and the eyes widely separated, a prominent ridge to the nose, and high and prominent cheek-bones. There may be actual microcephalus, and the development of the pons and medulla is often affected. Usually, however, a cutain compensation is found in extension of the skull in different directions, producing many varieties in the shape of the cranium, and allow-

matef more or less expansion of the brain in the upper regions.

I process.—Many different methods of classification of idots have been proceed. There is the psychical classification of Esquirol, in which the states arranged into three classes, according to the degree of speech of stack it is capable. The first class includes those who use merely words and short phrases. The second class consists of those who can articulate monosyllables or certain cries. To the third class are referred those who are mubble of articulating neither words nor monosyllables.

Thots may be also arranged into three classes according to the development of nervous function. A first class exhibits nothing beyond the results assument known as excito-motor. In a second class the reflex acts are conscisual or sensori-motor, including those of an ideo-motor or energy and character. In a third class we see manifest volition; their ideas

produce some intellectual operations and consequent will.

Joother classification is that suggested by Dr. Langdon Down, according to their resemblance to ethnological types—the Caucasian, Ethiopian, Many, and Mongohan. Dr. Down has also proposed a good practical custication, based on etiology, into 1, Congential; 2, Developmental; 3, Ambental.

The congenital group embraces all those cases where the signs of mental deficiency date from birth, and includes as subdivisions: a, Strumers, b, Microscephalic; c, Macroscephalic; d, Hydrocephalic; c, Eclampsic;

f Epreptic; q, Paralytic; h, Chorsic.

The developmental idiot is a child who is born with a fair amount of bran power, but who breaks down at one or another of the developmental cases at the first or second dentition or at puberty. Such children lose the power of speech and their minds seem to give way at one of these evolutional stages. The group includes as subdivisions: a, Eclampsic; b, Epaptic; c. Choreic.

In seedental phocy the mental break-down is the consequence of some stock or transmatic inpury, or disease operating upon a healthy child born the from any tendency to intellectual deficiency. This group includes:

4 Trumatic, b, Inflammatory; c, Epileptic.

Semptoms.—In cases of congenital idiocy the baby begins from an early are to show that he is not the same as other infants. The development of his faculties does not run the ordinary course. He cannot support he head like another child, but lets it hang back on his nurse's arm. Then, he takes little notice. A healthy infant will often recognise his mother by the sixth week; but long after that period the idiot child shows no recognition of faces. His eyes have a vacant look, seem incapable of faces upon an object, and often oscillate from side to side (nystagmus). Arm, he does not smile or laugh as a child will do whose mental development is advancing naturally; and manifests a strange inability to greep will the hand. A healthy child's fingers curl round any object presented to them at a very early age, but the idiot infant seems to have no power of haling any use of his hands. Moreover, when danced up and down, has muscless do not contract in sympathy with the movement. He seems to tens he pleasure from the exercise, but remains a dead weight like a lawy doll.

The head is usually noticed to be peculiar in shape from an early real it is often high in the crown, and perhaps the fontanelles are closel a nearly so, at the end of six months. Again, from the investigations of it. Langdon Down it appears that a high-vaulted palate—the V-shaped pane—with a very narrow transverse diameter is a common deformity of the congenital idiot. The tongue is often corrugated with transverse furror and sometimes is not completely under command. It hangs out if the mouth, and the child dribbles in an unusual degree even for a baby. The teeth are commonly late in being cut and often appear irregularly.

At twelve months old, when the child should be able to stand or should at least crawl on the floor and try to raise himself on to his feet, to be just as he is put down, without an attempt to move himself along. When does not learn to walk until he is three or four years old. It is difficult to teach him cleanly habits, and he remains infantine to be ways at an age when other children have long been taught decears at

order.

When idiocy is congenital, growth and development are impaired a well as mental power, and the general health is far from satisfactor. Be patient is stunted in his stature and looks younger than his age. The regulation is often feeble, and the temperature a degree or two lower that that of health. The feet are cold. The heart is frequently small and was in structure, and there may be an open foramen ovale or other concerns deficiency. Often other mulformations are seen, as imperfect development of one or more fingers, a club foot, or some strunge shape of the results such children may show signs of rickets, and are not seldom of decided secrefulous constitution. As they grow up, an unpleasant smell is else noticed about the body and breath. In bad cases automatic movements are present; chorea and epileptic fits are common complications, and we senses are frequently dull.

Griesinger describes two special varieties of idiots—the anathetic and

the excited.

The apathetic class are awkward, clumsy, and dispreportioned, with repulsive, old-looking features. From their torpor and impassiveness transfer to be in a dreamy state. Their expression is either brooding and melancholy, or vacuous and indifferent.

The excited or agitated class are just as stupid as the other, but are quick in movement and protable, passing rapidly from one impresses to

another, and quite incapable of fixing anything on their mind.

Between these two principal groups there are many intermediate re-

ricties.

There is one form of idiocy, endemic in some countries, spondic as others, which merits a separate description. This is cretimism. The feebleness of intellect from which cretims suffer is combined with strain; peculiarities of bodily structure. The condition is always congruital it is not hereditary in the ordinary sense, although where the other con litters inducing the disease prevail, the child will become cretinous more certain if born of cretinous parents. The disease has been said to be depended upon the general causes of all health—bad air, bad water, imperfect emange, insufficient light and poor food, combined with the use of water loaded with calcareous salts. It may therefore prevail in any quarter of the world where these conditions are found; and certain close values in the Alps, Pyrenees, and Himalaya mountains are especially notorious in the number of cretims born in them. The value of these causes in peakering the condition has, however, been called in question. Perhaps it is less.

we say that nothing positive is known with regard to the etiology of the diswe whatever the cause may be, it appears to be also the cause of goitre,
to crumsm and gottre are frequently associated. It has been said that acting feebly the causes produce gottre, acting strongly they give rise to cretaism; but even this is hypothesis. Cretins are not invariably gottrous. Inded in sporadic cases, such as occur from time to time in London, it is not

tan that in which cretinism is prevalent.

Virehow's researches have done much to elucidate the chief feature of According to this authority, it consists in an abnormal tendency to confication and coalescence of the three bones which represent the lines of the last three cramal vertebrae, viz., the busilar process of the ocental house the post-sphenoidal, and the pre-sphenoidal bones. In the nexual condition ossification in these bones goes on slowly from behind fourly, and traces of unossified cartilege may be found as late as the thereenth year. During the whole of this time the cartilaginous parts are still growing, and allow of expansion of the base of the skull and enlugement of the cranial cavity in proportion to the wants of the growing bean In the cretin, in whom ossification in these parts takes place early, the lase of the skull cannot elongate; the distance from the crista galli to the occipital foramen remains short; the corresponding parts of the brain we a perfectly developed, and the form of the skull is modified. Moreover, he bones of the skull are in many cases greatly thickened and the foramax parrowed. The bones of the limbs frequently show the same tenwher to rapel assification, and the shafts form early union with their sponses. Consequently, the growth of the bones is imperfect. The beau un lergoes many modifications. Important parts, such as the ganga at the lasse, are often ill developed, the medulla oblongata may be and and the fissure of Sylvius shallow and ill defined.

The physical and mental characteristics of the cretin are well illustrated of a case which was under my care in the East London Children's Hospital The patient was a little girl, aged seven years, who had come of a haltsy family on both sides. She had five perfectly healthy brothers and step. The family lived in Shadwell, in the neighbourhood of the hospital The child was said to have been a fine baby at birth, but as the math passed no teeth appeared and she showed no inclination to stand otems crawl upon the floor. She generally seemed very duil and aparents are crawl upon the floor. She generally seemed very duil and aparents are seen crawl upon the floor.

tiete, but sometimes brightened up and became more lively.

thereone melies in height. She looked very broad for her height, and without the thirty-one pounds eight ounces. Head large, nineteen inches in the profession of the professi

other sign of rickets. The tibile were somewhat bowed outwards but in hunbs were massive and the flesh tirm.

The child smiled when spoken to, and could say the word "doll to appeared to apply it indifferently to all kinds of toys. She could not she but crawled about on her hands and feet, keeping her knees russ. When she reached a table or bed, she would raise herself into an upply position with her hands and stand holding by it. The child passed are and faces in the bed. Her temperature was habitually subnormal.

The soft globular lumps above the clavicles are frequent in the spends form of cretinism. In Mr. Curling's cases they were found after dead to

consist of fatty tissue.

In another case which came under my notice the patient, who had the appearance of a child, was really over seventeen years of age. His hap was half an inch under three feet, his weight, thirty-six pounds feature ounces. He had all the physical peculiarities described in the privace case, but was more intelligent and cleanly in his habits. He could asser simple questions as to his food intelligibly. He had the same help masses in the supraclavicular hollows, and no thyroid body could felt. His genitals were those of a child, and he never manifested at

sexual propensities.

The symptoms of cretinism seldom appear before the sixth or serve month. The head is usually large, for cretias never belong to the marcephalic type. The palate is often flat, and not highly arched, as in order congenital idiocy. These patients are usually quiet and good-tempered although subject to occasional fits of passion. Their senses are often its and they endure great cold and heat without apparent discomfort. It is however, one of the characteristics of idiots generally that their senses to obtuse: they can often bear pain with singular in lifterence, their testion to uncommonly impaired or perverted, and sometimes they have but faint sense of smell. Often their sight is defective from congenital above, or imperfect sensibility of the retina, or hypermetropia with duminosed accommodation; but unless they have suffered from disease of the ear, that hearing is usually of normal acuteness.

The mental condition of idiots has many varieties. In the lowest for there is complete apathy and torpor; no power of attending to or our recognising their own wants, and no capacity to speak or to understand words apoken to them. Such beings can only make unintelligible notes. They have not the slightest power of will, and seem to have little power of originating a movement, but often repeat mechanically some automate

motion of the head, the body, or a limb.

At the other end of the scale is mere feebleness of mind. Such charges and perseverance. Even in the higher class of idiots speech is usually defective, partly from malformation of the mouth; partly from want of co-ordination of the lingual muscles; but chiefly, no doubt from the poverty of their vocabulary, and the small stock of words to which they attach any definite meaning. In all the severer forms of idiocy no attempt at speech is ever made; and, as Griesinger observes, the idiot who day not speak has no internal idea of speech, and is therefore "deficient is in most essential element in the mechanism of abstraction"

Idiocy has been described as a fixed infantile condition, and the dath has been compared, as regards intelligence, with a healthy child of so want months or years of age. An idiot, however, is not merely a because child. With him volition is feeble or quite absent, and he has had

imigination or power of abstract thought. Therefore, although his actual degree of intellectual development may correspond with that of the younger child, there is a something still wanting, which if wanting in the child with whom he is compared would occasion very serious anxiety. Sometimes one faculty is developed in idiots to the exclusion of all others. In all transces on this subject instances are given showing remarkable aptitude for music drawing, and reckoning; also for various forms of mechanical construction as carpentering, model-making, etc.

thinguistics. —Idiocy must be distinguished from mere backwardness, and doo from cases where the development of the mental faculties suffers

tamenth deficiency in the sense of hearing.

Mr. backwardness, even when present in a marked degree, is far remoid from idiocy. The class of backward children presents many points of interest. The delay in development is usually physical as well as mental. They are small but not usually deformed; and there is no symptom of discuse of brain or disorder of mind. They are simply backward children to whom progress of every kind takes place very leisurely. Instead of bring early to walk, and picking up words and ideas with the quickness of a healthy child, they are slow to walk, slow to talk, slow to quit the labits and helplessness of the baby for the decency and independence of interchilds sod. Still, they do not remain stationary like the idiot; they be bearn, although slowly; and with patience can be taught in time much that forms the education of a child of ordinary capacity. Backward children, however, sometimes become idiotic. If they happen to be also epileptic or addicted to self-abuse, they may gradually become duller and dader and fall into a state of complete idiocy.

In all cases of backwardness, especially of lateness of talking, with apparent duluess of mind, the state of the hearing should be inquired into. A child who hears imperfectly is always slow in acquiring the power of articulation; and besi les, as Dr. West has pointed out, his difficulty with this defect of keeping up intercourse with other children makes the patient

dull, suspicious, an I unchildlike.

I Locy, when confirmed, is of interest chiefly to the specialist. The ordinary practitioner is most concerned with the early symptoms of mental feebleness, as this is seen in the infant. Nothing is commoner than for the family physician to be consulted because the baby "does not seem to take

In a healthy infant the senses come into play in the following order: Sight is the earliest to manifest itself. A fortnight after birth the infant's eyes should follow a light, as that of a lamp; and at the end of a month or six weeks he is often able to recognise his nurse and will smile when she approaches. During the first few weeks babies often squint, especially when looking at a near object. Later they become more expert in focusing their eyes to suit various distances.

The child sellow gives evidence of hearing sounds before the third month, although Darwin states that his infants started at sudden noises when under a fortnight old. Babies do not recognise voices until after the fourth month, and it is the eighth or ninth month before they begin to

recognise objects by name,

With regard to movements: a child of two months of age will raise his head from the pillow; and after the third month will begin to use his hinds and to toss up his head. At this time (the third month he can support his head well. It is usually the ninth month before the child feels his feet," i.e., presses his soles to the ground when held to the floor. He should walk some time between the tenth and the eighteen month.

A healthy infant should keep his tongue within his mouth from the earliest age. His fontanelle should not close before the eighteenth man, nor be completely assified before the end of the second year.

The faculty of speech is acquired much more quickly by some ctifue than by others. Most babies will begin to say words after the end 4 to

first year, and many can talk freely by the end of the second.

It is seldom before the end of the sixth month that any suspense is to that all is not right with the infant's mental development. There is usually the vacancy of his expression, the absence of any smale to greater mother's approach, some peculiarity in his way of taking food, and dead weight of the child as he lies with his head back in his nurse - are that first excites the anxiety of the parents. In such cases we notice the weakness of the muscles of the back and neck, and their mability to apport the head or keep the body erect for a moment, the nystagmax is vacant look in the eyes, which never seem to fix upon an object and evnot be made to follow it when it is moved before them, the abnormal in of saliva from the mouth, and the passiveness of the child's hand *les t finger is placed in it-so different from what occurs with the healthy be't who at once squeezes anything which touches his fingers. On maun or find either that the child is always whining, or that he is strangely and and pays no attention to sounds which please other infants of his extalso, perhaps, that he takes the broast or bottle very slowly, and often made a curious choking noise at the back of his nose. In such cases we proally find that the palate is narrow and highly arched (the V-shaped pair) that the head is small and of a curious shape—unsymmetrical, or yere in and narrow in the crown; that the fontanelle is excessively small or ... closed; that the hands and feet tend to be cold; that the muscles to flabby, and ou examination we can sometimes discover a congental less complaint, a club foot, or some other form of congenital deformits. It Langdon Down has drawn especial attention to the appearance and potion of the car. A helix or the lobule may be quite absent, and the prois often planted farther back in relation to the head and face than it healthy child. Dr. Down also directs that the position of the cyc 2 4 obliqueness, as well as degree of separation, should be noted, as then a often an approach to the ethnical variety described by this physical the Mongolian type. Also, that the integument about the eyes storils examined for semilunar folds of skin at the inner cantlus appearable folds), which are more common in feeble-minded infants than in the testily

The cretin can usually be recognised without difficulty by his started growth; his large head; his depressed nose, with widely separated eyes be dull, heavy expression; wide mouth, broad hps, and thick tongue; his defel-looking tawny skin; his heavy limbs and awkward walk. If the discisse endemic, there is probably a goitre; if sporadic, we notice the care fleshy clustic masses above the clavicles and the absence of a thyroid gain.

Prognoss.—The most hopeful cases are those in which the defect to congenital one; the worst are those of accidental origin who bear in that faces and persons little trace of their infirmity. Paralysis or epilepsy other form of nervous instability, increases the difficulty of the case is also, general feebleness of health is a bar to improvement; and professed scrofulous cachexia, or a weak heart and feeble circulation, remied department less responsive to systematic training than another whose nutricols more satisfactory.

Dr. Edward Seguin regards as favourable signs: Steadiness of the wik, which deviates little from the centre of gravity; a hand firm without suffices, and not disturbed by automatic movements—one which can take all leave hold at command; an unimpaired state of the senses, especially allok which is easily called into action; a command of the words, however approper or few, which the child may possess, so that they have a connected meaning and come out opportunely; activity without restlessness; willingness to obey; sensibility to praise, and capability of returning as well as of receiving caresses.

A contrary state of things must be looked upon as unfavourable. Moreer, if some feelings of affection have been developed by kind parents, and are not followed by corresponding intellectual progress; or if the above is complicated by extensive paralysis, or worse, by epilepsy, the

prognosia is very bad.

Treatment. - In the treatment of idiocy our first care should be to attend to the general health of the patient, so that he may be put physically into a good a condition as he is capable of reaching, and afterwards to inculcate volition and co-ordinated voluntary movement by careful physical traing; to attend to his moral education, and do what can be done to

develop his intellect.

It is very important that the idiot should be removed from the society of healthy children, whose games he cannot share, and whose companionship he cannot enjoy, to association with beings afflicted like himself, in the presence of whom he is not oppressed by a painful sense of inferiority. It is indispensable to the due progress of the feeble in mind that they should be received into asylums and establishments especially devoted to me treatment of such cases. In these every means can be adopted to counteract the scrofulous tendencies of which a large proportion of the patients are the subjects. The building can be creeted at a suitable elevation on a porous soil of sand or gravel. The rooms and passages can be large, well ventilated, and suitably warmed. Moreover, a proper system of bathing and shampooning can be established to promote the healthy action of the skin and invigorate the feeble muscles.

The dictary should be liberal, and presented in a form to suit the peculiarities of the patient, for many idiots cannot chew their food. Some, indeed, can only swallow it when it is placed far back on the tongue, so

that it may come within the grasp of the pharyngeal muscles.

Residence at a special training school, it is generally held, should begin when the patient is about seven years of age, unless the existence of constitutional disease, epileptic fits, or other complication requiring constant medical supervision necessitate earlier admission. The system of training can be divided into three branches: physical, moral, and intellectual.

The physical training consists in careful education of the muscles by agular co-ordinated movements which bring the will into exercise, and substitute purposive acts for the aimless automatic motions which are so characteristic of the vacant mind. The excresses are graduated, and pass from the simplest movements to others more complex in character, so that, as Dr. Langdon Down observes, "the idiot builds up a series of co-ordinated voluntary movements which are applicable to the wants of daily high."

Moral education teaches the child obedience, and encourages him to endeavour to win the approval and retain the affection of his teachers by doing what he is told is right, and avoiding what he is told is wrong.

The intellectual education is based on a cultivation of the senses.

Touch and feeling are trained to appreciate differences in the form of objects, beginning with simple things and proceeding gradually to the more complex. Sight is cultivated by making the patient appreciate light and darkness, and accustoming him to match coloured counters or sing coloured beads. So on with the other senses. Everything that is target should be taught in the beginning in the simplest way, and we should make sure that the first fact has been thoroughly grasped before we put on to the second. In this way the mind is educated through the sense, and in time by patience and perseverance astonishing results may be often obtained.

Part 6.

DISEASES OF THE ORGANS OF RESPIRATION.

CHAPTER I.

FXAMINATION OF THE CHEST.

The affections of the lungs constitute a very important branch of the discusses of childhood. The study of these complaints must no doubt present Peculiar difficulties, for persons who are fairly conversant with the ordinary makedness of early life will often profess their inability to understand them. In many cases an examination of the chest in a child cannot be carried through without much tast and management; in others the utmost gentle-pess will not reconcile the patient to a procedure of which he only perceives the inconveniences; and even in the most favourable cases the observer meets with peculiarities in the physical signs which in one unaccustomed to such youthful patients may give rise to considerable perplexity.

In order to examine the chest of a child with success the patient must be raised up to a convenient height. If we stoop down to a child as he gits upon his nurse's lip, our own position is crumped and uncomfortable. Fully to appreciate minute deviations from a healthy state the attitude of the observer should be one of ease. In the case of an infant, to examine the front of the chest the child should be laid upon his back on a cushion placed upon the table. Some babies, however, cry at once when laid upon the back. In such cases the patient may be placed in a sitting position on the cushion supported by the nurse. When the back is examined the nurse should stand up and take the child on her left arm, so that his head and right arm hang over her left shoulder, and his left arm is loosely applied round her neck. In this position the muscles of both shoulders are relaxed. An older child can be seated upon a table for examination. It is needless to say that in both cases the patient should be completely stripped to the waist.

Much may be learned from mere impection of the chest. In the case of an infant the points to which attention should be directed have already been referred to used page 12). In children of four or five years old and upwards we can often ascertain by this means the existence of a constitutional predisposition. In children of consumptive tendencies the lungs are small. As a consequence the thorax is forced to adapt itself to the size of its con-

tents. The shoulders are narrow and sloping; the ribe are very oblace and the chest clongated; and the scapular project backwards has ware. The prominence of the shoulder-blades has given the name of "and of "pterygoid" to this variety of chest. In small-lunged children, and deduce with vulnerable chests, the thorax is often flattened anteriors as a to dimanish the antero posterior diameter. The flattening is due to the ing of the costal cartilages under the pressure of the atmosphere was 20 lungs are expanded in the act of inspiration. It is usually the consequence of narrowing of the air-tubes from catarrh of the nucous membras to must examine the spices very carefully for signs of disease. If new in the treatment of even the simplest pulmonary derangement is strong measures, and wait for complete crossition of the cough before pulmon are the simplest pulmonary derangement in the cases we must be careful to follow up any special medication by increasing measures, and wait for complete crossition of the cough before pulmonary decough before pulmon and the cough before pulmon are the cough before pulmon are the cough before pulmon and the cough before pulmon are the cough cough are t

mitting the child to resume the ordinary habits of health.

If we notice an infra-mammary depression on each side of the loss with some prominence of the lower part of the sternum, we infer that the patient has been subject to long-continued or frequently repeated attack of pulmonary catarrh. In these attacks the air-tubes are marrowed to a presence of catarrh, so that air penetrates insufficiently into the lings, a expansion, especially of the inferior lobes, is incomplete. As a consequent the lower ribs, corresponding to the imperfectly inflated tissue, are tracted at each descent of the diaphragm. As the lower ribs fail in the lower end of the breast-bone is forced forwards, so that a horizontal section of the chest at this point, instead of elliptical, would be transplanted in the lower lobes, and the deformity becomes a permanent one. The prominence of the sternum from this cause constitutes one of the varieties of "pigeon-breast." The rickety chest is also pigeon-breasted is explained elsewhere (see page 139).

The central cup-shaped depression of the lower end of the sternus and corresponding cartilages, sometimes met with, has been referred to a 2

previous chapter (see page 12).

The movements of the chest in inspiration must be carefully noted. Sometimes we find a general exaggeration of movement combined with a perfect expansion of the chest-wall. This abnormality indicates a possitive want of air from some impediment to the efficient expansion of the interval with bilateral, it is seen in cases of catarrhal pneumonis, in advantabilities, and in double pleurisy and hydrothorax. When unlateration may be produced by one-sided pleurisy, pneumothorax (a very rare constitution in the child), extensive fibroid induration, or condensation of the

from a former pleurisy with firm pleural adhesions.

In early life the thoracic walls yield readily to the pressure of the sternal air, and this plancy is especially noticeable in infants and nekely children. Consequently in them dysphoes is often indicated by new less retraction of the chest wall in inspiration. This retraction is next in the infra-mammary region, and in pronounced cases may preclaim deep horizontal furrow across the base of the chest at the level of the siferim cartilage. If the retraction is limited to this part, it indicates most cases a catarrh of the inferior lobes of the lungs, which are unadicated with air; but if the ribs are very soft from makets, the interest pression may be noticed in ordinary respiration although the large in sound. Sometimes the soft parts of the chest also sink in. The interest tall spaces are hollowed; the suprasternal notch and supraciavious spars

Traif of the sternum with its attached cartilages is depressed into a deep pit rate eich inspiratory movement. When the retraction is thus pronounced, there is usually an impediment at the upper part of the trachea. Retraction to this degree is seen in membranous and stridulous laryngitis, in marrowing of the glotus from any cause, and in cases of lodgement of a foreign substance in the upper part of the windpipe. Still, even in some causes of pleurisy with effusion, marked retraction is seen on both sides of the chest although the impediment to full inspiration only affects one

Enlargement of one side of the chest can sometimes be detected by the ve; but it is more accurately estimated by the cyrtometer.' A tracing rande from this instrument upon paper shows immediately if one side of the chest be larger than the other. A characteristic sign of pleuritic effu-

sion is dilutation and squareness of outline of the affected side.

Undateral shrinking, from fibroid induration, or old pleurisy with firm

calhesions, may be also readily estimated by the same means,

Deficiency of movement of the chest is sometimes better appreciated by the hand than by the eye. The hand also detects ribration of the chestwall, if this be present. In children, however, there is seldom a normal fremitus when the child speaks or cries; for in the high-pitched notes which alone escape from the childish larvax the vibrations succeed one another too rapidly to be readily perceptible by the hand. Consequently, undateral absence of this sign, which in the adult is an important means of distinguishing between consolidation of the lung and liquid effusion in the pleura, fails us in the case of young patients. Even when detected, vocal fremitus furnishes no certain indication. If present on the sound side, it may be felt strongly over a liquid effusion, for the vibration is readily conducted by the thoracic wall from one side of the chest to the other. I have known it to be felt strongly on the affected side in a case of recent absorption of pleuritic fluid, although almost absent on the sound half of the chest; and again, in a case of apparently exactly similar kind it has been completely absent over the seat of disease, although present elsewhere.

A rhonchal or friction fremitus is much more common than a vocal vibration in the young subject, but the sign is of little value. Fluctuation can sometimes be discovered in the interspaces in cases of pleuritic effusion and is a valuable sign of the presence of fluid. To detect it, a finger of each hand should be placed at the two extremities of the same interspace. The impulse of a gentle tap is then often conducted distinctly through the

fluid from one finger to the other.

The exact site of the apex-heat of the heart should be always ascertained, as this may be greatly influenced by disease in the chest cavity. In young children and infants the normal position of the heart's apex is nearer to the left nipple than is the case in the adult. This is partly due to the position of the nipple, which is placed relatively lower than it is in later life. In many children, instead of lying over the fourth rib it is in the fourth interspace or on the upper border of the fifth rib. But in addition to the lower position of the nipple, the heart itself is relatively smaller or seems to be higher in children, especially during the period of infancy.

A perfectly efficient extremeter may be made by taking two pieces of soft metal, inthost result to such as composition gas-tulities, drawn out to one-eighth of an inch, and uniting them by a piece of caoutchoic tubing.

Often the apex will be found to beat in the fourth interspace, exactly

the site of the nipple.

Diseases of the heart-walls of course influence considerably the position of the apex-beat; but when the organ is healthy, the position of its apex may be altered by morbid conditions in neighbouring parts. Effusion into the chest cavity causes displacement of the heart's apex. According to the side affected the heart may be pushed considerably to the right or to the left. In cases of left pleurisy with copious effusion it is not uncommon to find the aper-heat of the heart in the opigastrum, and sometimes the impulse can be felt to the right of the sternum. Cardiac displacement does not, however, always result from effusion into the pleura; and therefore it absence must not be taken to indicate that the physical signs are capable of another interpretation. If adhesions have formed between the perseardium and the left pleura, the heart is held in place and cannot be pushed aside by the effusion. The position of the heart may be also altered by contraction of the lung on one side, but in this case the heart is drawn towards the affected part. In fibroid induration of the lung, disease on the right side moves the heart to the right; disease on the left side draws the organ upwards and to the left."

Besides the position of the heart the exact level of the liver and spleen should be noted, as the position of these organs may help us to a conclusion in a doubtful case. These viscom are often sensibly displaced by the pressure of a liquid effusion in the chest, while displacement of the liver by the bulging of a croupous pneumonia is so rare as to be a clinical curiosity. If the lung be contracted, the liver or spleen is drawn upwards

into the chest.

Percussion of the chest in the infant and young child should be conducted with deliberation. If care be taken that the hands are perfectly warm, and that undue violence is avoided, the process seldom arouses any special opposition. It is sometimes recommended to reverse the ordinary arrangement and practise auscultation before employing percussion, but

this inversion of the customary rule is at least unnecessary.

In the young subject, except perhaps in the new-born infant, the resonance of the chest is greater than it is in after-life; and the percussion note obtained over an area of consolidation is often so modified by resonance from healthy fissue around that dulness is only imperfectly marked and may escape the notice of an unpractised ear. Percussion should be mediate; and it is advisable always to use two fingers in striking the finger placed upon the chest-wall. By this means, without employing undue force, a larger body of sound is elicited than if the chest is struck with one finger only, and dulness, if present, can be more readily appreciated. As we proceed we must be careful to make constant comparison between different parts of the cliest—between opposite aides, between the base and the apex, etc. To make the comparison an accurate one the same period of the respiratory movement should be chosen for striking upon the finger for if one part of the chest be percussed at the end of an inspiration, and another at the end of an expiration, the difference even in a healthy chest may be considerable. When the consolidation consists in scattered nodules, as in the beginning of catarrhal pneumonia or in lobular collapse, dulness, which escapes the ear when percussion is made in the ordinary manner may often be detected by using "broad percussion," i.e., by strik-

Displacement in the same direction upwards and to the left) may be a consequence of enlargement of abdominal organs or distention of the peritoneal cavity by fluid.

ing with three fingers upon three fingers placed upon the chest-wall as pleximeters. By this means the sound is collected from a larger area of lung-

tissue than if one finger only were employed.

But besides the character of the sound elicited in percussion, it is important to attend to the degree of resistance of the chest-wall. The resistance to the percussing finger varies greatly in different cases and is a sign of no little importance. In the consolidation of pneumonia and in that of palmonary atcleetasis, when the collapse occupies only a superficial layer of tissue, resistance is slight. In more extensive collapse, as when the condensed tissue embraces an entire lobe, and in fibroid induration of the lung, the resistance is greater; but the maximum of resistance is reached in cases of cirriousis of the lung, with superadded catarrial pneumonia, and in pleuritic effusion. The resistance is here extreme, and the sensation conveyed to the tinger is that of percussing a thick block of wood. It is very important to educate the sense of touch so as readily to appreciate the several degrees of resistance, as this faculty is a great addition to our

resources in the matter of diagnosis.

In percussing the supra-spinous fossæ it is very necessary to see that the muscles of the shoulders are equally relaxed on both sides. Elevation of the shoulder, or a cramped position contracting the muscles of one side, will modify the percussion note and make the sound more or less dull, al-Lough the lung is perfectly healthy. If an infant he placed in his nurse's ax ms in the position already described, and an older child be made to sit with arms folded, shoulders depressed and back slightly bowed, the re-Stalts of percussion may be depended upon. Too much stress should not hid upon slight differences between the two sides. A temporary colleap me of the air-cells at the apex is not uncommon from imperfect expanseem of this part of the lung, and therefore slight dulness noticed at one wisht may on the next have completely disappeared. There is also a specaral source of error in percussing the posterior bases of the lungs in chil-I wen which it is important to be aware of. In young subjects the liver is Latively large, and rises higher on the right side of the chest than it does 122 older persons. There is therefore normally a certain dulness of percus-*10. in the right infra-scapular region. This dulness is more extensive in The healthy children than it is in others. We may recognise the cause of the modified note by remarking that the breath-sounds at this point, 11 hough weak, are perfectly healthy.

Special varieties of the percussion note have little or no diagnostic value in young subjects. The tubular or tracheal) note is often obtained to ranous states of the lung-tissue, and is not characteristic of any special condition. The "cracked-jar" note is a natural phenomenon in early life if the yielding chest be percussed during expiration or when the mouth is

Upen.

In auxiliation of the chest, however young the child, the stethoscope should always be used. This instrument is even of greater value in the young subject than it is in the adult, for the chest being smaller, it is more important to limit as narrowly as possible the area under investigation. I have rarely known children object to its employment if the instrument had been first placed in their hands and spoken of as "a trumpet." Indeed, the use of this familiar word usually awakens their interest and actually facilitates the examination.

In the normal state the breath-sounds are coarser and harsher (puerile respiration) than they become in older persons, and this harshness in certain patients is so pronounced that it is not unfrequently mistaken by an

inexperienced observer for a sign of disease. The harsh character breath-sound is especially marked at the apices, and the expiration part of the lung is often prolonged without the peculiarity being mal phenomenon. Conduction of sounds from the pharvns and to the apices is especially common, and it is not rare to find the tion at the supra-spinous fosse curiously loud and hollow or although the lungs are healthy. This hollow breathing is no do ducted from the throat. It is often a sign of colargement of the chial glands, these bodies forming a medium of communication the windpipe and the wall of the chest. It may be heard, how cases of enlarged tonsils, and is sometimes present, while the closed, in children in whom no other morbid condition of any kind discovered. In such cases it is greatly modified in character w mouth is open. The source of this variety of blowing breath usually be detected by noticing that it is heard equally plainly apices, is chiefly marked in expiration, and is accompanied by to sound or any dulness of the percussion note.

Weakness of the vesicular murmur is much less common as a condition than loudness of the breath-sound. It is, however, pasome children as an individual peculiarity. If general over both is a sign of no importance. If limited to particular spots, it is of moment, and when noticed at the base of one side should not be garded. It may be an early sign of pleurisy or may indicate dat the apieces it often arises from insufficient expansion of lung and may be of trifling consequence. In such a case it usually particularly, and at the next examination may no longer be detected.

The readiness with which sounds are conveyed from one part chest to another is a common source of error. Thus, sounds generate the base of one lung may often be plainly heard at the corresponding of the other and healthy lung. In cases of dilated bronchus from induration it is not uncommon to find cavernous breathing with a gurgling rhonchus at both posterior bases—on the sound as well at affected side. So, also, a subcrepitant rule developed in one lune be plainly heard on the opposite side, perhaps over the site of a lapleuristy or collapsed lobe, and give rise to much perplexity. In that the origin of the transmitted sound can usually be detected by a that the quality and pitch of the conducted breath sound or rule are that heard on the affected half of the chest, only diminished in in the sound is identical in character but weaker in force. This is a ever the case with sounds generated spontaneously in two different

Bronchial, blowing and cavernous breath-sounds are produced dren by the same mechanism which gives rise to them in the adjuster correspond to much the same conditions. In the child, however, pittes in this respect are sometimes noticed. The morbid quality components in the adult. Thus, cavernous breathing is more asign of mere solidification of tissue, and is frequently present which is compressed by pleuritic effusion. So, also, the ampheric is sound with tankling resonance of the voice or cough is almost always consequence of a large cavity or great dilutation of a bronchus. It is a cases of pathisis, of cirrhosis of the lung, or of subscute of pneumonia. Pneumothorax, to which cause it is almost solely of the adult, is a very rare condition in the child, and the morbid seldom be attributed to this cause.

Although the auscultatory sounds are frequently magnified in the child, it sometimes happens that the contrary condition is found. A patch of consolidation, if covered by a layer of healthy lung-tissue, may give rise to no dulness or alteration of breath-sound, and a bronchophonic resonance of the voice and cry may be the only sign which betrays its existence, in crying infants the intensified vocal resonance is an important test of emploidation. If the resonance have an agophonic quality it is character-

sur of moderate effusion.

The examination of the chest should always be as complete as possible, it is not enough merely to examine the posterior part of the thorax, trusting that if this be healthy the anterior part is healthy too. A patch of coopens pneumonin or a loculated pleurisy may occupy any part of the lag or chest cavity. Either may be confined to the apex, may lie under one arm, or may be found seated anteriorly or laterally as well as behind. If therefore the front of the chest is left unnoticed, we may overlook discuss which closer examination would have discovered. Even if the child cry during the operation, much may still be learned. The cry usually cases each time the breath is taken in, so that inspiration is audible. Its public can therefore be ascertained at this time. Moreover, as the chest is expanded deeply after a prolonged crying expiration, the air-cells are folly inflated and few adventitious sounds can escape our notice.

CHAPTER II.

LABYNGITIS.

Inflammation of the larynx is a not uncommon affection in childhood. The disease may occur as a simple catarrh of the larynx or as a more severe inflammation resulting from a burn or scald. In these cases it is of course a primary lesion. It may also occur secondarily as a consequence of a constitutional disease, such as tubercle or syphilis. There is a special form of the primary affection which is accompanied by spasm and is peculiar to early life. This complaint is often confounded with membranous croup, and is the "catarrhal croup" of the older writers. It is soldon a fatal disease, although it produces very alarming symptoms. In the present chapter three varieties of laryngitis will be described, viz., simple laryngitis, stridulous laryngitis, and tubercular laryngitis. The lesions which affect the larynx in cases of inherited syphilis are referred to elsewhere (see page 204).

SIMPLE LARYNGITIS.

Causation.—On account of the sensitiveness of scrofulous children to changes of temperature and their liability to catarrh, lary ngitis is more common in them than it is in others who are free from this unfortunate disposition. In some the laryux seems to have a special proneness to suffer in the cold or changeable seasons of the year. No period of childhood is exempt from laryngeal catarrh, for although the disorder is more often seen in children over six years old, it may be met with as early as the end of infancy. In infancy, however, the complaint in the simple form is comparatively rare. At this period laryngitis is commonly the consequence of a syphilitic taint. Amongst the children of the poor severe laryngitis from burns and scalds is sometimes met with. This form of the disease is almost confined to children between two and three years old, and is due to an attempt to drink water from the spout of a kettle as this stands simmering by the side of the fire. A violent inflammation results from this accident and may quickly end in doath. An equally severe laryngitis with cedema of the glottis is sometimes met with as a secondary affection following serious acute disease. It may occur as a sequel of small-pox, erysipelas, or typhoid fever. Edema of the glottis without inflammation is also sometimes a symptom of scute Bright's disease.

Chronic laryngitis is less common than the acute variety, but some times occurs in weakly children as the result of an acute attack. It may follow measles or membranous croup, and is apt to prove obstinate.

Morbid Anatomy.—The mucous membrane and submucous tissue become congested and ordematous, and their colour is redder than in health. In cases of simple laryngitis the change is probably confined to the epiglottis and ary-epiglottidean folds, leaving the true vocal cords unaltered. me thick mucous is secreted. Ulceration is very rare in early life, and

goodly never occurs in the primary form of the disease.

in the severe laryngitis which is the result of a scald the soft palate lances are white and swollen; and the epiglottis and parts around are bedened and congested. A so-called false membrane often forms upon brairface. Thus to the eye appears to be identical with the false membrane of diphtheria, but is said to differ from it in its microscopical characters. It is probably, as Dr. Wallace long ago suggested, the natural

paurhal layer altered in structure.

Symptoms —In the mild form the child is house and soon loses his one more or less completely. His cough is house and infrequent; eactimes it occurs in paroxysms. There is little or no fever, and the restoring is not interfered with. If the houseness do not proceed to actually worse at night when the child goes to bed. The houseness of visce may be only noticed when the child is crying. If the patient be again a suitable temperature, the symptoms of cutarrh subside after a relays, and seldom last longer than a week. If the indisposition is have treated, and measures are not taken to protect the child from furbar exposure, the complaint may become more serious and may be combinated with spasm (stridulous laryngitis).

The name score variety is well illustrated by cases of scald or burn of burns, although, as has been said, the affection is sometimes due to

LIFE CALLSER

lame hately after the scald the child complains of pain in the throat, and this part on inspection is seen to look white and shrivelled; but there at first no difficulty of breathing and the larynx seems to have escaped. The patient screams violently and will not attempt to swallow; but after a size the immediate effects of the accident appear to pass off, and when put bed the child falls quietly asleep. After a few hours, however, usually the three to six, his breathing is noticed to be noisy and whistling. Arracius has now begun. The respirations become laboured and rapid; no ince is pale and tinted with hyidity about the extremities are cold; the aske is small and feeble; the skin is cool; the extremities are cold; and achild is drowsy, although he can be roused with difficulty. If at this large the finger be passed into the back of the fauces, the epiglottic will be felt hard and swellen to the shape of a geoseberry or small marble. There is recession of the soft parts of the chest in inspiration, and an amination detects sonorous and sibilant rules all over the lungs. There to dulness on percussion.

After a few hours all the symptoms become aggravated. The breathing of an and more behoured and "croupy," the larynx rises and falls rapidly, and at each inspiration the soft parts of the chest—the intercostal spaces, appearance of the analysis of the chest—the intercostal spaces, appearance of the head retracted, his face swollen and livid, his eyes injected, as are acting, and his mouth open, making convulsive gasps for breath. The intermities are cold, and his pulse is often too frequent and feeble to be muched. Although only half conscious the child is much agitated, his arms about and showing signs of the greatest distress. Personance of the back usually detects some want of resonance, and much bubbling is heard in the air-tubes. Sometimes there is local duliness to meaning the of lung. In this state the child may sink and die slowly, or

hapme more suddenly in a convulsive fit.

The above is an aggravated case, but unfortunately far from an uncom-

mon one. Death may occur as early as twenty-four hours after the accident. The end is not, however, always reached so rapidly. The child may linger for two, three, or four days before he finally sinks; or life may be prolonged to the end of the week. The duration depends in great measure upon the degree of interference with respiration and the patient's capacity for taking nourishment. If the edema of the glottis he less complete, the breathing after being laboured and stridulous for twenty-four or forty-eight hours, with signs of deficient aeration of the blood, may become easier, and then gradually return to a normal state. The voice is very hourse and the cough "croupy." In these cases the dysphoca varies in degree from time to time, being subject to occasional increase when the child is distressed or made to swallow. After the cessation of the more urgent symptoms the voice may remain hourse and the cough be occasionally "croupy" for some days.

A little boy, aged four months, was brought to the East London Children's Hospital at one r.m. On the previous might the bed on which he was lying had caught fire, and the child, who had been placed on a water proof cloth, was surrounded with flame and smoke. Happily he was quickly rescued, although not before the palhasse had been nearly destroyed. When taken out his body was blackened with the smoke. Soon afterwards his breathing became difficult, and at times the mother thought he would

be suffocated.

On admission the skin of the arms was seen to be tinted brown from the action of the heated air, but there was no external sign of burn. The infant's breathing was laboured, and his cry hoarse and weak. At each inspiration the soft parts of the chest receded deeply. The face was dusky, the mures acted strongly, and the external jugulars and superficial veins generally were unusually visible. The fauces looked red and swellen. Temperature, 98°; pulse, 160; respirations, 72. In the evening the temperature rose to 103°; pulse, 140; respirations, 80. The child slept fairly well in the night, and in the morning expectorated a piece of membrane one inch in length and a quarter of an inch broad. It had the ordinary naked-cyc appearance of false membrane. The next day the breathing was caster and the lividity of the face less. Two days afterwards signs of pneumonia were discovered at the left back; but this disease ran a favourable course, and in about ten days from the time of the accident the child was convalescent. He never had any difficulty in swallowing. He was treated with hot linesed-ment poultices and a saline mixture containing small doses of antimonial wine.

In cases such as these, if tracheotomy has to be performed on account of the intensity of the dysphara, the patient often dies from a secondary inflammation of the lung. The ordinary non-traumatic laryngitis in the child, if at all severe, is also usually associated with broughitis, pneumonia.

or pleurisy.

The chronic form of laryngitis is sometimes seen in connection with follicular pharyngitis. It is indicated by an altered quality of the voice, which becomes thick and veiled, and is sometimes quite hourse in the evening. There is also a hard cough, which may be paroxysmal, and is often accompanied by pain shooting up into the sides of the head or the ears. I have occasionally met with a simple chronic laryngitis unconnected with any abnormal state of the fauces, and apparently not the consequence of a constitutional cachesia. One such case, occurring in a child aged one year and eleven months, will be afterwards referred to.

Dwgnosis.—The simple form of the disease, where there is much

parseness of the voice and cry, a thick cough, and some redness of the tures, without fever, or with only moderate pyrexia, cannot be mustaken. I the symptoms become more urgent, and there is laboured breathing, a unions and bronchitis may be excluded by the absence of the characteristic physical signs about the lungs, and the normal or only slightly lessed temperature. Still, it must be remembered that these cases, whater due or not to a transactic cause, are often complicated by acute that theses.

It the case of scald of the laryny, the history will usually be sufficient a deade the nature of the illness. It must not be forgotten that in this party of laryngitis the symptoms seldom come on directly after the accident but that there is almost invariably an interval of some hours before the egns of dyspiness begin to be noticed. In every such case, then, we have been our guard, and must not conclude that all danger has passed

becase the child appears at first to have escaped serious injury.

In this case the illness came on at too late a period after the accident to the fairly attributable to the scalid; the symptoms were those of the more of the air-passages, the epiglottis and ary-epiglottidean folds are to extend as far as the tertiary brouch. Pieces of thinnish, red, and in this case the illness came on at too late a period after the accident to be fairly attributable to the scalid; the symptoms were those of a period dipatheria, and the anatomical characters were indicative of a period of a simple infiammation of the laryax and truchea.

In the shalt to use the laryngoscope wherever practicable. Children, unlocking the shalt to use the laryngoscope wherever practicable. Children, unlocking are usually troublesome subjects for this method of investigation, but if the child is old enough to understand the object of the example of the child is old enough to understand the object of the example of the instrument is applied, succeed in getting a view of the order cords. By this means we can sometimes exclude the presence of the instrument of a valuable hint for treatment. It must be transmissed that hoarseness may be the consequence of the imperfect promission of the vocal cords. Dr. Vivan Poore has referred to the large of a little boy who had been long under treatment for laryngitis. In the case the hoarseness was found by the laryngoscope to be due to excessive ansuma of the larynx, with failure in the power of the adductors; and last ur, good diet, and iron soon restored the lad to health.

Caronic laryngitis must not be confounded with the alteration of voice that occurs as a consequence of enlarged and caseous bronchial glands, into disease hourseness is a late symptom, and does not appear until pressure signs have been developed in the chest (see page 182).

Sections hysterical aphonia is found in girls. It is distinguished the chronic larying its by the history. It begins quite suddenly and is at

becomplete. Equally suddenly it subsides,

Agari, between cleven and twelve years old, was under the care of my observe. Dr. Donkin, in the East London Children's Hospital. The passure was one of fifteen children, and there was no neurotic tendency in the lang. One child had died of croup, and the girl herself had had a

"croupy "cough up to the age of seven years. She was of healthy appearance and secuned very intelligent. Twelve weeks before her admission she had been called in the morning and had answered in her usual voice; but when she was dressed it was found that she had complete aphonis. Her breathing was natural, and she was not subject to attacks of dyspaces. She had no cough or screness of the throat, but there seemed to be some tenderness at the angle of the jaw. Her voice was quite whispering, but she could laugh louder than she could talk. She did not appear to be troubled by her infirmity, but was anxious to get well on account of her education.

A galvanic current was applied to the larynx. The girl cried loudly during the operation. After a second application of the same kind the

voice suddenly returned; and she never relapsed,

Prognoss.—In uncomplicated cases of simple laryngitis, unless the inflammation be due to a traumatic cause, the child almost invariably recovers. In the traumatic variety the prognosis is very serious. In cases which are complicated by some scute lung affection the prognosis depends

upon the pulmonary rather than upon the laryngeal complaint.

Treatment. In ordinary simple laryngitis the child should be kept in an equable temperature; his throat should be enveloped in cotton wood or a cold-water compress; and inhalation should be prescribed of steam impregnated with tincture of benzoin (a teaspoonful to the pint of boiling water). The bowels should be relieved by a mercurial purge; and if there be much oppression of breathing, an emetic should be ordered of ipscacuanha wine. Afterwards, a saline diaphoretic can be given containing five or ten drops of antimonial wine to the dose. A mustard foot-bath is also useful. If the cough is troublesome and disturbs the rest, small doses of paregoric may be added to the mixture.

In severe cases, where the dyspines is distressing, a blister may be applied to the neck below the chin, or towards the top of the sternum. The clubd should be placed in a tent-bedstead, as in diphtheria, and the air around the patient should be kept moist by the steam boder, as recommended for that disease. The general treatment will depend upon the lung affection, which in these cases usually complicates the laryngitis.

In the violent and distressing cases which result from a scald of the glottis energetic treatment is required, as from the moment when the dyspaces becomes urgent the life of the child is in the greatest danger. Dr. Bevan, of Dublin, after considerable experience of this form of disease, powerfully advocates a return to the old treatment by repeated doses of calomel. He states that if this plan be adopted, immediate relief to the symptoms is noticed directly green stools begin to be passed, showing that the system is under the influence of the drug. Dr. Bevan gives a grain of the salt every half hour, and recommends that this medication be begun directly the child is seen after the accident, without waiting for laryngeal symptoms to declare themselves. He greatly prefers this method of treatment to any mechanical measures for admitting air into the lungs, as these, he says, are almost invariably followed by death from pneumonia. With our improved methods of after-treatment the operation of tracheotomy is, however, less often followed by fatal consequences than was formerly the case; and if the dyspace is urgent and threatens life, I should not hesitate to advocate the procedure, putting the child afterwards in a tent-hedstead in a warmed and moistened atmosphere.

The calomel treatment certainly seems to offer good results. In each of Dr. Bevan's cases the patient took between tifty and sixty grains of

come!; and of four children treated in this manner, although the symptos were excessively severe, all recovered without any sign of having been juriously affected by the remedy. In addition to giving calomel by the outh, mercurial inunctions were used in the worst cases to the skin; a release were applied to the upper part of the chest; and the bowels are releaved by a copious enema. In each case, too, the treatment was been by an emetic to clear out the stomach. Dr. Bevan states that green has may be expected in from eight to twenty-six hours after the first see of the calomel.

It is important to support the strength. If there is total inability to allow, the patient must be fed with white-wine whey by the stomach-

she passed through the nose.

In cases of chronic bryngitis the throat should be brushed every two three days with a strong solution of perchloride of iron. A little boy, solone year and eleven months, was under my care for chronic heatsest of three months standing. The child, although ansemic, had a healthy perrance, and there was no history of syphilis or trace of the disease bout the body. He was quickly cured by the application to the larynx method morning of a solution of perchloride of iron in glycerine (two necessary of the strong solution to the ounce). The application caused no passe or other unconsfortable symptom.

from and cod-liver oil are useful in these cases; and the throat may be

anted externally with functure of iodine.

STRIDULOUS LARYNGITIS.

Stridulous laryngitis (false croup, catarrhal croup, spasmodic laryngitis) a common affection in early life. For a long time it was confounded with diphtheritic laryngitis, and no doubt a sharp attack of laryngeal cause with spasm produces sufficiently serious symptoms. The disease,

ovever, is rarely fatal.

Cusation.—Strictulous laryngitis is especially a disease of childhood for the period of infancy has passed, for it is comparatively rare under use of two years. Between the second and seventh year the disorder common; but after the latter date it again becomes exceptional. I have to that it, however, as late as the fourteenth year. When it occurs in course of the second year the patient will be usually found on examination to be the subject of rickets. The complaint appears to be predisped to by an hereditary spasmodic tendency; but the patients are not seconly in any way feeble or under-nourished. As a rule, perhaps they a stard looking and strong. Boys are attacked twice as often as girls; and the affection is frequently seen more than once in the same individual; idead, it may be said to have a tendency to recur.

The exercing causes of the complaint are those common to laryngeal such. The affection is sometimes an early symptom of measles and beging-cough. It may occur as a complication in the course of the lost, and occasionally returns under the influence of a slight chill after

attack of pertussis is at an end.

Medid Initiony.—In the rare cases where death has resulted from complaint the glottis and vocal cords have been found little altered, here or less uniformly reddened. Sometimes they have been slightly rollen. An excess of mucus has been usually present. It is stated that half hear ulcers have been sometimes noticed on close inspection of the real cords.

Symptoms. - Stridulous laryngitis consists of a catarrh of the with superadded spasm—the spasmodic element being probably sequence of special nervous excitability in the individual patient, children (and these are usually rickety infants) a very triling of catarrh may induce spasm. These cases are very mild as a rule, and subside. In older children the catarrh is more serious. The of then lasts longer and is accompanied by more violent symptoms.

In the miklest form of the complaint the pulmonary catachvery triting. The child may be put to bed apparently well, or wia slight cold. About eleven or twelve o'clock he starts up suddlns sleep with a house, barking, sonorous cough, and a loud, what dor in his breathing. It will be noticed, however, that the character is confined to the inspiration, and that the expiration is comparatively noiseless. The movements of the chest are labor violent, the soft parts sink in at each inspiration, the narcs acteyes are staring and frightened-looking. If the impediment to is great, the face becomes livid, the eyes are injected, and the chcessively restless and agitated. His voice, however, remains he loud. It is rarely weak, and only becomes suppressed and what cases of exceptional severity.

The seizure lasts from a few minutes to half an hour, or ever for sometimes, after appearing to relax, the spasm becomes againing. In the end it subsides completely and the child falls is a may again be roused up by a milder seizure a few hours afterwat the following morning he may wake up apparently well, or wishight thickness of the voice and a loud ching in his cough, but the toms pass off after a day or two. In many cases the attack returned lowing night, and may be repeated yet a third time, but the care seldom so severe as on the first occasion. During the attack persuare may rise to 102° or 103°, or higher, but in the morning in a contract of the case of the contract of the case of the case of the contract of the case of

In more severe cases of stridulous laryngitis the complaint pass off so quickly. The catarrh is often not limited to the lar also occupies the bronchi. The attacks then occur not only at a also in the daytime, and in the intervals the breathing is more of pressed and "croupy," and the voice and cough hoarse. The dy these cases may be a very serious symptom, the child having the difficulty in obtaining even a minimum supply of air. Indeed, in cases during the access the face is livid, the hands and nails grow the eyes become fixed, convulsive twitchings are noticed in the blanes. In rare instances the patient dies suffocated unless relied complaint is accompanied by moderate fever which persists beightings, and the complexion remains pale, with some hydry about until the free passage of air is again completely restored. An exit of the urine seldom detects albumen, but in the worst attacks, from renal congestion, albuminum may be present.

A healthy-looking boy, aged four years and two months, was on March 1st with sneezing, coughing, and signs of tightness of the same night he was roused by a severe attack of dyspices, he ing was oppressed and stridulous, and his cough loud and clangthe next day his voice was weak and hourse, and his cough bar hard.

When the child was seen on March 4th, his cough was he

The breathing was laboured, 46; the pulse, 140; the temperature, 014°. The skin was moist. The respiratory movements were very laboured, the shoulders rising and falling, and the soft parts of the chest and be epagestrium sinking in deeply. The chest was resonant, and the breathouts were loud and snoring. One-sixth of a grain of tartrate of anti-active was given every three hours in a saline mixture.

On the night of the 5th the child had another severe attack of dysposa. He was accordingly put into a tent-budstead and the air was kept as timed by the steam-kettle. The next day the cough was loose, and the box, although house, was much stronger. The dyspnosa did not return, at the child was discharged convalescent on March 11th. The tempera-

are remained over 100, morning and evening, until March 9th.

In an ordinary case of moderate severity the cough loses its hard, barking character after a few days and becomes loose, the hourseness of voice dimension, and the child is soon convalescent. If, however, there be possil pulmonary catarrh, any neglect may easily aggravate the case into the inche-pneumonia, or in a weakly subject collapse of the lung may war In either case the child may die. Fatal cases of laryngitis striduloss in the large majority of cases so complicated, for few children die from

the lyspnora alone

In care cases strictulous laryngitis, like laryngismus strictulus, may be acceptated by carpo-pedal contractions. A little girl, between four and five present, was brought to me for contraction of the fingers, which had n uch the set that the child was "going to be publised." The patient was much emaciated from long-continued intesting entarch, and had a pamed expression of face. For a month she had not a cough, and at night was often roused by attacks of strictulous laryngias in which respiration became noisy, and she seemed to have much different in getting her breath. On examining her hands the fingers were faired to be unusually straight-looking, the hands being bent only at the limited. The child could, however, squeeze well with both hands. It wastated that the fingers would often become quite stiff, with the thumbs housed rightly into the palms of the hands. The girl was not rickety; her langs were healthy; and there was no enlargement of the abdominal cans or inesenteric glands. An iron mixture was prescribed, and the child was ordered some claret with her dinner. Under this treatment the tympoms soon subsided and the patient regained flesh and strength.

Detroits. Stridulous laryngitis must not be confounded with true beaternous croup—a disease to which it often presents a striking resemblance. A distinction between these two affections is of the utmost practice importance, for the operation of tracheotomy, which is especially indicated in cases of membranous laryngitis, is rarely if ever necessary in the callibus disorder, and if performed imports into the case an element of

ducer which would otherwise be wanting

In laryngatis strictules a the invasion is much more sudden, and the structure at once attains its maximum intensity; indeed, if the attack be reported it seldom reaches the violence of its first access. The voice in the map, although weakened and house, is rarely suppressed, and the left if persuaded to exert himself, can usually speak fairly loudly. Even long children, although silent and unwilling to cry when much hampered by treath, if disposed to do so, can often emit a considerable volume of the longith, too, is loud and clanging, and rarely assumes the latter whispering character so distinctive of membranous laryngitis.

expiration being much easier and comparatively noiseless. In false crop also, there is no enlargement of the submaxillary glands, such as 1915 to occur in cases of membranous laryngitis when there is any accompaning affection of the pharynx. An examination of the urms rurely discover the

presence of albumen.

In all these features the strictulous catarrh differs from the membranes inflammation. In the latter the dyspaces begins gradually and attansate maximum by degrees; the voice becomes entirely suppressed, the out is a hourse muffled sound which is almost pathognous ome; the streters as marked in expiration as it is in inspiration; and albuminum to some times met with. Listly, in true membranous croup the diputhente exudation can often be discovered in the pharyny. Still, absence of endation is not to be depended upon as excluding diphtheria, for the near brane may be limited to the air-passages, and fragments are not always coughed up. In a doubtful case, where the symptoms of spasmolic large gitis are exceptionally sovere, the points to be relied upon for exclusive diphtheritic croup are: The severe and sudden onset, the compastive absence of strider in the expiration; and the quality of the voice, what a not completely muffled or suppressed. The age of the patient is also if some practical value in diagnosis. In a child under twelve months of t over seven years, the case is very unlikely to be one of strululous largests.

Laryngitis stridulosa may be also confounded with laryngismus drawlus, with retro-pharyngeal abscess, and with cedema of the glotus. To distinctive characters of the first-named complaint are elsewhere described (see page 271). Retro-pharyngeal abscess is at once recognised by the aability of the child to breathe when lying down, the increase to his distresoccasioned by pressure on the larynx, and the presence of a swelling if the back of the throat. Œdema of the glottis is usually the consequence of scald or burn, or follows an attack of acute specific disease; the distress more continuous, without marked remissions in the dyspines, and its

thickened epiglottis can be felt with the finger.

Prognosa.—As a rule, the child has a good prospect of recovery, even a serious cases, if the operation of trachectomy be not performed. The and urgent dysphera usually subsides under suitable treatment, and it is set rare for the child to die suffocated. When the disease ends fatally, the affavourable issue is usually the consequence of an inflammatory compaction. Stridulous laryngitis sometimes accompanies the onset of a partmonia, or from want of proper precautions the tracheal catarrh may allowed to extend into the finer tubes. In such a case the prognosis and favourable, for attacks of suffocation occurring in a child the subject of bronchitis or pneumonia are necessarily dangerous. Still, even in these cases the child may recover, for often the spasm becomes less marked when the inflammatory complication declares itself.

Treatment.—In the milder attacks of laryngitis stridulosa the child should be at once placed in a warm bath (95 Fah.) for tifteen or twenty minutes and should be made to vomit by a dose of ipecacuanha wine. Afterward a small dose of chloral (gr. iij.—iv. to child of eighteen months old) may be given, with a few drops of sal volatile, to prevent a relapse in the course of the night. In the morning it is well to prescribe a diaphoretic maximum (such as vini ipecacuanha, Mx.; liq ammonim accetatis, Mxx; glyend mx; aq. ad 3 j.), to be taken every three or four hours, and to give directions that the child be kept in one room of a suitable temperature. If integrate is loaded, a grain of calomel should be given with two grains of

jalapine.

In the very severe cases a warm bath is also useful. Afterwards the child should be placed in a tent-bedstead, in a warmed and moistened atmosphere, as recommended for membranous croup. An emetic in all these cases produces great relief. A teaspoonful of specacuanha wine, or a squarter of a grain of sulphate of copper, may be given every ten minutes until the desired effect is produced. The vomited matters in all severe cases should be searched for shreds or patches of false membrane. As long as there is fever the child must be kept in bed, and while the voice remains hoarse it is wise to keep the air moistened by means of the steam-kettle (see page 103). Tracheotomy is rarely if ever necessary in mere spasmodic laryngitis. The most violent attack of suffection soldom fails to be relieved by a warm bath, an emetic, and steam inhalations. Graves' plan of applying a sponge wring out of hot water to the neck, below the chin, is also of service. It must not be forgotten to attend to the bowels, and a mereurial purge is a great help to the other treatment.

If the spasms, return repeatedly, which, however, is rarely the case if the above treatment have been adopted, an antispasmo he may be required. Chloral is perhaps the best, and may be given to a child of two

years of age in doses of three grains three times a day.

If any influence of complication arise, such as bronchitis, pneumonia, etc., special measures must be adopted as recommended for these diseases. If the case be uncomplicated, disphoretics should be given when the spasm subsides, and the child should be treated for an ordinary pulmonary catarrh, taking care to withhold all stimulating expectorants as long as the cough continues barking and hard. Sometimes a few drops of paregoric added to the sulme expectorant mixture seem to aid its effect in reducing the hardness of the cough. All the time the diet must be regulated as directed for pulmonary catarrh.

In cases where the attacks of larvingitis tend repeatedly to recur, and arours must be made to strengthen the child and diminish his susceptibility to changes of temperature. He should be dressed from head to foot in woollen underclothing; should pass much of his time out of doors; and should have a cold douche every morning, given with all the precautions recommended in a previous chapter (see page 17). Moreover, as children with this tendency often have cold feet, care should be taken that the extremities are thoroughly warm when the child leaves the house. A

little alcohol with the dinner is a useful medicine in these cases.

TUBERCULAR LARYNGITIS.

In childhood the laryngeal mucous membrane is comparatively rarely the seat of the gray granulation; for it is only in after-life that laryngeal phthisis becomes a common manifestation of the tubercular cachexia. Still, even at this early age tubercular granules and ulcerations are occasionally present; and these usually occur in cases where the force of the disease is expended more particularly upon the lungs, the other organs being comparatively unaffected.

Consider.—Ulcers of the larynx are much more common than tubercular granules without breach of surface. MM. Rilliet and Barthez state that they have only met with a single case of tubercle of the laryngeal mucous membrane unaccompanied by ulceration, and quote a second from M. Tounelé, which occurred in a child of fourteen. According to these authors, the ulcers are usually of small size, varying from the head of a pin to a large lentil. They are circular and cleanly cut, unless they occupy the vocal cords. In that case they are more commonly oval, with ther long diameter in the direction of the cord. Their borders are that and reddish in colour, and their base is usually composed of the science a tissue—rarely of the muscular fibres. The ulcers, for the most part in single, although sometimes more than one is present in the same case. The seat may be one or other of the vocal cords, or the posterior and the glottis, or the base of the epiglottis. The mucous membrate is matered or thickened; sometimes it is reddened.

The traches and larger bronchi may be also the seat of ulcers, but nonusually the trachest mucous membrance is merely reddened and their ast

Sumptoms.—The symptoms of the bryugeal complication are offer a definite. There may be merely some alteration of the voice, slight pare the region of the bryux, and if there is much swelling, dysphere. The voice is often thick and husky; it is never whispering as in the sold. The cough is little altered, and has no special quality pointing to the particular lesion. There is seldom pain or difficulty of deglutifion as it pain in the largux, if present at all, is rarely of much moment. The sessive and limited number of the sores is sufficient, no doubt, to account to the absence of special symptoms; for in the adult, when aphonia is present the alteration is generally extensive.

Dyspuces may be a marked symptom. A little boy, aged two years and nine months, whose father had died of consumption, was all the into the hospital, under my care, for difficulty of breathing. For six well previously his breath had been noticed to be short, and for a forting to be respiration had been accompanied by a studer. For three weeks held been unable to swallow any solid food, although he could take hunds water

out difficulty.

On a bussion his dyspace was marked. At each inspiration the low half of the breathone was bent deeply inwards, so as to leave a printer epigastrium. At the same time the intercostal spaces and super-circular hollows were markedly retracted. His nares worked, and all the access muscles of respiration were in strong action. There was some house the face, and the breath-sound was accompanied by a hourse studer the voice was hourse, but not whispering. The cough was little altered at had no metallic or ringing quality. On examination of the chest time we some duliness at each super-spinous fossa, and much course bubbles we heard all over both lungs. Temperature at 6 r.m., 101.6°, respirations to pulse, 136. There was no albumen in the urine.

The boy was in the hospital a week. His dyspace all the time of tinued with little change. There were no exacerbations or remission. His temperature varied between 100.6° in the morning, and 102° to 1.8° might. His bowels acted twice a day, as a rule, although in one day was purged seven times; and he never complained of pain in the absorber until a few hours before the end. His death occurred quite suiter. The child, after complaining of stomach-ache, which did not appear to be severe, suddenly sank into a state of collapse, in which he died.

On examination of the body many ulcers were found in the ilium of which had ruptured and caused profuse extravasition into the permutal cavity. The ulcers were circular, and did not follow the course of the vessels, as in ordinary tubercular or scrofulous ulceration. The liter of fatty, but the abdominal organs seemed to be healthy. No gray grantations were seen anywhere but in the lungs. These organs, however with stuffed with them; and there was some consolidation at the aprile mucous membrane of the larynx and epiglottis was excessively swell-and

red so that the glottis formed a mere chink. No ulcerations were discovered in this part, and my notes make no mention of gray granulations about the buyons. The truches was healthy, and nowhere was there any sign of talse membrane.

In this interesting case the larynx was the seat of severe chronic inflammation, and had the child lived a short time longer it is probable that where would have formed in the glottia. As it was, the intestinal compli-

cation carried him off before any further change could take place.

Ducquesis. In the child, on account of the extreme difficulty of using the larvingoscope, owing to the resistance of the patient, it is very rare to be able to ascertain by actual inspection the existence of ulcers or granules on the larvingeal mucous membrane. In children who have reached the age of ten or twelve years the instrument may, however, be sometimes used; but great irritability of the fauces usually attends any larvingeal catarrh.

and the attempt to inspect the throat has often to be abandoned.

In coming to the conclusion that a child has tubercular ulcoration of the glottes we must first exclude alceration from other causes. Syphilis must be set aside by inquiry into the family history, and special antecedents of the patient, and by careful examination of the body for signs of the mierited disease. We must also make sure that the child has not suffered lately from any complaint which tends to give rise to chronic inflammation or ulceration of the larynx, such as measles, small-pox, or membranous croup. If all these diseases can be excluded, and we find hourseness of the voice and cough, with stridulous breathing, in a child who is evidently suffering from tuberculosis, we cannot but explain the local symptoms in the light of the general disease. A persistent, steady dyspacea, without exacerbations or remissions, would add strength to the explanation. If, however, suffocative attacks come on, and the child is first seen when suffering from more or less paroxysmal dyspacea, an exact diagnosis may be very difficult. The history would, indeed, point to a chronic interference with the action of the glottis, but such interference might be produced by warty growths or polypi of the vocal cords, and without a laryngoscopic examination a diagnosis is probably impossible. Such a case as the following, for example, would give rise to great perplexity.

A little boy, four years old, but short for his age, and of rickety build, who had been treated for syphilis in his infancy, is brought to the hospital for difficulty of breathing. It is said that for four months he has been noticed to breathe stertorously and to have a hourse cough. The cough is worse at hight, and is often followed by vomiting. The child's face is rather turgid and congested, and the jugular veins are visible. On inspection of the chest it is seen that at each inspiration the ribs and lower half of the breast-bone are greatly retracted. At the same time the pulse fails in force, and there is a stridulous sound from the thront. Examination of the chest shows no sign of disease; resonance is normal, and a loud stridor conducted from the thront is heard at all parts of the chest-wall. The heart's apex is in the normal site. An attempt to make a laryngoscopic commination has to be abandoned on account of the child's struggles.

Temperature at 9 a.m., 101.8; pulse, 140; respirations, 36.

After admission into the hospital the temperature for the first eleven days is over 100, both morning and evening. The child is found to suffer from severe fits of dysphora, which come on usually at night. In these attacks he is excessively agitated, sitting up in bed and throwing himself about, his face gets livid and his lips are blue. He makes constant attempts to cough, as if to remove some obstacle, but the cough is very hourse

and smothered. In one of these attacks the distress is so great, and the signs of approaching suffocation so pronounced, that trachectomy a performed. After the operation the breathing is easier, but signs of premionia manifest themselves, and the child dies. After death an examinate of the larynx discovers several warty growths attached to the true wall cords. One of these growths is long and pedunculated.

In a case such as the above, if a correct diagnosis can be arrived at a the absence of a laryngoscopic examination, it can only be by exclusion but the elevated temperature would be an element of perplexity and would not be in favour of warty growths. A digital examination is of him value in such a case, for the growths, being seated on the true would read

are quite out of reach of the finger.

Prognosis.—The prognosis is always unfavourable, but the grant of the case depends much upon the general disease and little upon the are geal complication. It is only in cases where the inflammatory swellhas almost occluded the opening of the glottis that any special datagralikely to arise from the condition of the larynx. These cases, fortunated

appear to be very rare.

Treatment.—Little can be done in the way of special medication for a bercular laryngitis. The treatment to be adopted must consist of the measures recommended in cases of simple inflammation. The neck skep-be kept warm externally, and inhalations of steam, medicated with a compound tincture of benzoin, should be prescribed. If the court troublesome and disturbs the rest, small doses of laudanum, morphic paregoric may be administered. Two to three drops of liquor mapped with the same quantity of spirits of chloroform and ten of giverners tenspoonful of water, form a useful lineaus for these cases. The grant treatment must be that recommended for the constitutional affection.

CHAPTER III.

SUPPURATION ABOUT THE LARYNX.

The formation of an abscess in connection with the laryex is not a common complaint at any period of life. But the disease, when present in the child, causes so much interference with respiration, and produces symptoms which bear so close a resemblance to those of membranous croup, that it must not be passed over without a worl of notice.

Three cases of suppuration about the larynx were published some years ago by Dr. W. Stephenson, of Aberdeen. Two others have been placed upon record by Dr. John S. Parry, of Philadelphia. A few cases are also

scattered about in the various journals.

Causation.—A state of feeble health appears to favour the occurrence of the disease, for the patient is generally weakly and cachectic-looking. In two of Dr. Stephenson's cases the child was just convalescent from an acute specific disease (scarlatina and small pox). In a case narrated by MM Rilliet and Barthez, under the name of submucous laryngitis, the boy (age.) four years and a half) was still in a weakly condition after an attack of measles. A preliminary period of ill-health is not, however, indispensible, for in one of Dr. Parry's cases (a little negro baby of four and a half months old) the infant seemed to be in perfect health just before the first symptoms appeared.

Meriod Anatomy.—The abscess is usually situated at some point in the immediate neighbourhood of the larynx. In one of Dr. Stephenson's cases its seat was at the outer side of the right thyroid cartilage, laying bore the apper margin, and extending to the superior cornu. It had opened interbally. In another a sac containing pus was seated in front of the thyroid cartilage, and extended upwards on each side as far as the upper margin of the also of the cartilage, the pouch on the right side being somewhat larger than that on the left. In one of Dr. Parry's cases an exactly similar condition was met with. The thyroid cartilage itself may be eroded and

roughened and denuded of perichondrium.

Symptoms. The symptoms produced by suppuration around the largest are very similar to those which arise as a consequence of retro-pharyngeal abscess, for in both cases there is pressure upon the air and food passages. There is dyspace and laboured breathing; house, noisy inspiration, and increase of distress in the recumbent position. Swallowing is greatly impeded; the child, if an infant, refuses the breast; if older, ho cases when an attempt is made to force him to take nourishment. An effort to swallow is often followed by cough, and an increase in the dyspaces, with return of the fluid through the mouth and nose.

The most prominent symptom is the dyspines. The child's eyes are prominent and his face dusky. His breathing is hurried (40-50) and his ares not with respiration. If an infant, he lies back, with head retracted and the muscles of the nucha rigid. If able to sit up, he sits huddled

together in his cot instead of lying down, and whimpers if disturbed. Each inspiration is accompanied by a loud rattling stridor, and at the same time the soft parts of the chest are retracted and the epignstrium is depressed. The expirations are short and comparatively moseless. The difficulty of breathing varies in degree. It is subject to exacerbations, during which the child is in the greatest agitation, and seems on the point of suffocation. In the intervals, although quieter, he is still greatly distressed. Anything which irritates or disturbs the patient, such as attempts to give food or medicine, encourages the attacks; and if he try to swallow, the dysphoes comes on at once. The voice is almost suppressed, and the cry is hourse or whispering. Cough is either absent or is merely hourse with-

out clangor In one case it was paroxysmal.

The physical signs of the chest are normal, with the exception of the loud stridor which is transmitted to all parts of the chest-wall and quite obscures the normal vesicular murmur. On examination of the throat the fauces appear to be perfectly healthy, and the finger pushed to the back of the pharynx finds no tumour such as is present in cases of retropharyngeal abscess. At first, too, the most careful examination of the neck may detect no deviation from the normal state; but after a few days a little swelling may perhaps be discovered on careful inspection. In some cases the larynx has been usually prominent or pressed out of the mesial line. The swelling in most of the cases appeared at some part of the posterior border of the thyroid cartilage, just in front of the sternomastoid muscle, and in two cases it spread to the front. In one instance it was noticed to become more prominent in expiration, and to recede again in inspiration. The swelling is not hard, and rarely fluctuates; indeed, as Dr. Stephenson remarks, "it may feel more like air than fluid."

If the swelling is punctured and the accumulated pus let out, instant relief is obtained. The dyspnea subsides and rapidly disappears; the child takes food without hesitation or difficulty, and the cough improves. The voice may, however, remain feeble for some weeks afterwards. The duration of the disease is short. In all published cases the suppuration ran an acute course, and ended fatally in many instances. As in the case of abscess behind the pharynx, death may be the consequence of exhaustion, or the child may die suffocated in an access of

dyspacea.

Prognosis.—In reading the above description of the phenomena attending upon suppuration about the larynx the resemblance of the disease, in its course and symptoms, to retro-pharyngeal abscess cannot fail to be remarked. We find in each instance difficulty of swallowing, paroxysmal dyspaces and strictulous breathing, and a marked increase in the child's distress when he lies down. In either case, too, the traches may be pushed out of place and may be more prominent than natural. The chief distinguishing mark is the presence of a tumour in the fauces if the abscess is situated behind the pharynx; while if the suppuration occurs around the larynx the fauces are natural.

The distinction between such a condition and membranous croup is described elsewhere (see page 594). It may, however, be here noticed that in children who are old enough to sit upright, orthopnen is a very characteristic symptom of interference with the passage of air through the larrax and trachen from outside pressure. In membranous croup no such symptom is noticed, for in that disease there is no aggravation of the dyspners when the child is recumbent. On the contrary, he often breathes more easily in that position. Again, the progression of the symptoms is more gradual in

the case of abscess. The stertor comes on more slowly and increases in

intensity as the sac increases in size.

Prognosis.—The prospect of recovery depends upon the general health of the child, and upon the appearance of local swelling or fluctuation at some point in the front of the neck. If the abscess can be detected and its contents evacuated, recovery may take place; but if the child be a feeble relactic subject, especially if he be much exhausted by sleeplessness and wast of food, the operation may come too late to save life. In this disease the prognosis is distinctly less favourable than it is in retropharyngeal abscess.

Treatment.—If the presence of an abscess about the larynx be suspected, the threat should be enveloped in hot poultices, frequently changed, so as a basic the formation of matter and quicken its approach to the surface. If my swelling can be detected by the side of the thyroid cartilage, it shall be punctured with a small trocar without reference to the absence of flatuation. Even if no swelling can be seen, in cases where the symptoms are very urgent and we feel strong suspicions of the formation of pus a the neighbourhood of the larynx, it is justifiable to make exploratory partures. Some point on a line with the posterior border of the thyroid cartilage should be chosen for the operation. If the exploration be attended by no satisfactory result, and the symptoms continue urgent, trachecters should be performed.

At the same time every effort should be made to support the strength of the shid. Fort wine should be given, or the brandy-and-egg mixture; and pounded meat made fluid with gravy or strong beef-tea, eggs and milk, etc. must be administered in suitable quantities. If the child cannot smallow, he must be fed, if possible, through a stomach-tube introduced by

the nose.

CHAPTER IV.

CROUPOUS PNEUMONIA.

Caopeous or lobar pneumonia may be seen at any period of childhood, but in infancy is comparatively rare. Up to the end of the second year inflammation of the lung usually assumes the catarrhal form, and even in the third year pneumonia is more often catarrhal than croupous. After the third year both forms of the disease are about equally common, and with each succeeding year inflammation of the lung, if it occurs, is more and more likely to be of the croupous variety.

Causation.—Of late years a tendency has been growing to look upon croupous pneumonia as an acute general disease, of which the pulmonary consolidation is the anatomical expression, and no longer to regard it as a mere local inflammation. Some observers have compared it to acute rheumatism and tonsillitis. Others, who see in the affection the effects of a special poison, have even placed it in the same class with typhoid fever and

other similar specific distempers.

That the disease is a general one, with a marked local manifestation. seems to be evident, for the general symptoms are not proportioned in neverity to the extent of lung surface involved; they may precede by some days any evidence of local mischief, and the highest elevation of temperature is often reached before the point of most complete consolidation is arrived at. Moreover, the character of the symptoms differs in many respects from the ordinary type of constitutional disturbance set up by a local injury: head symptoms are more common, sweating is more frequent, and a herpetic eruption is an ordinary phenomenon. Again, the morbid exudation, which is the chief local expression of the disease, is of a kind peculiar to pneumonia, and cannot be produced by ordinary inflammatory agency. Still, although the affection may be a general one, it does not follow, as some observers are disposed to believe, that it ought to be classed amongst the diseases which result from specific infection. There are no doubt some facts which seem to favour this view. Thus, pneumonia has been occasionally known to occur in epidemics, and in some outbreaks facts have been noted which seem to point to personal communication of the disease by contagion. The illness sometimes appears to be preceded by a prodromal interval, and to pass through a stage of invasion before local symptoms are manifested; it runs a definite, uniform course, is often accompanied by complications which assume different degrees of prommence in different outbreaks, and its type varies in severity, the rate of mortality being higher in some epidemics than it is in others. In all these features the disease seems to incline to the class of acute specific maladies. The question whether or not the illness can be set up by impressions of cold, is one of great importance, for if it can arise from a simple chill, the disease can have no pretensions to be the consequence of a specific poison. There is a conflict of testimony upon this point. It is said that purumo

nia is most frequent in the tropica, and diminishes in prevalence as the distance from this zone increases. It is not especially common in cold hittudes; and Koch in his cases failed to trace any relation between the attack and the external temperature. Other observers, however, have noticed a connection between the illness and meteorological conditions; and there is no doubt that in seasons where the temperature is changeable and the weather damp the disease is more common than at times when the temperature is uniformly high or uniformly low. Biach states, as a result of his observations, that the coincidence of rapid atmospheric depression, a low temperature, and sudden changes of temperature tends to produce the disease

Perhaps in the present state of our knowledge it may be sufficient to class pneumonia with tonsillitis, and, indeed, it bears a great resemblance to that disease in the conditions under which it appears to originate. In addition to cold, but drainage seems to have a powerful influence in exciting the malady. Many mysterious cases of pneumonia arising in schools have been finally traced to contamination of the air of dormitories by sewergue, and have ceased after measures have been taken to rectify the faulty condition of the drains.

Pheumonia sometimes occurs secondarily to other forms of illness. Thus it may be a consequence of an altered state of the blood, as in the scute felimle diseases, or may be due to imperfect purification of the blood, as in Bright's disease. In other cases, again, it may be a purely accidental

complication

Lastly, although pneumonia often attacks children who are to all appearance strong and healthy, its occurrence, like that of other acute diseases, is favoured by conditions which reduce the strength and lower the resisting power. Therefore impairment of health must be looked upon as one

of the predisposing causes of the malady.

Morbid Anatomy — The morbid processes which constitute an attack of pneumonia are divisible into three well-marked stages. In the first—the stage of engagement—there is congestion of the capillary vessels which rundy between the air-vesicles and on the minute bronchia, and swelling of the alveolar epithelium. The organ is heavier than natural, and darker in tint—It still contains air, and therefore crepitates on pressure although less perfectly than natural; but its substance tears readily, retains the mark of the finger, and on section pours out a reddish, frothy fluid from the divided surfaces.

In the second stage—the stage of red hepatisation—the alveolar epithelium is swollen and granular. An exudation of the constituents of the blood coagulates in the air-vesicles. The alveoli and small air-passages connected with them are crowded with white and red blood corpuscles, which distend these little cavities and cause complete consolidation of the lung. The affected part, therefore, is airless and can no longer crepitate. It tears with the utmost case. Its bulk is increased; it sinks in water; and on section the surface is dryish and somewhat granular, although pressure causes a thick, turbid fluid to coze out. The colour is reddishbrown, marbled here and there with gray. Usually the adjacent pleura is also inflamed. It is opaque and congested, and adhering to it are patches of lymph.

In the third stage - the stage of gray hepatisation—the colour of the discussed part of the lung becomes gravish or whitish-yellow. White blood corpuscles continue to exude into the air-cells, and there is besides problemum of the alveolar epithelium; so that with the microscope we find

epithelial cells, granule cells, and leucocytes The fibrinous exadation deintegrates, and the cells quickly undergo fatty degeneration. The comis still heavy and airless, and is very soft in consistence, so that a link pressure breaks it down. The cut or torn surface is but slightly grange,

and on pressure gives out a puriform fluid.

These various stages of the disease may usually be seen to occur different part of the lung at the same time; for as the disease spreads for one part of the organ to another, it is far more advanced in the part first attacked. The extent of tissue involved is subject to great variety. The affection may be limited to a small patch, or may involve a whole like, w even the entire lung. It attacks the base by preference, but is fur fee uncommon at the apex, especially in the child. Usually the consolidates is confined to one side of the chest; but double pneumonia is said to le

more common in children than in adults.

The process of resolution in the affected part consists in a fatty deep eration and liquefaction of the contents of the alveoli and small air-tales Thus softened and liquefied the inflammatory products are readily abouted or coughed up; the air-cells are freed; and the circulation through the capillaries ramifying on the alveolar partitions is restored. Resolution the normal and favourable termination to a croupous pneumonia; wif the illness be primary is the common ending in the child. In exceptions cases, usually when the disease is secondary, suppuration may occur case the formation of an abscess, or the inflammatory process may pass uto gangrene. Still, gangrene is rare as a consequence of pneumons and probably never occurs as a result of the uncomplicated disease. It am however, follow in cases where emboli derived from ante-mortem chitical in the right heart are arrested in the pulmonary capillaries. If Boudhels statement that a peculiar tendency to the formation of such clots is a common feature of the true pneumonic disease be correct, it is surprise: that the gangrenous change is not more often met with. Croupous promonia is not a cause of plithisis. A simple unabsorbed consolutation such as is common after catarrhal inflammation of the lung, rarely if ever result from the croupous form of the disease.

On account of the apparent analogy between pneumonia and the serie specific diseases, pathologists have searched carefully amongst the mostal products in the lung for signs of microscopic organisms, such as have been shown to exist in cases of crysipelas. Friedlinder, of Berlin, in search, amongst the fibrinous effusions in the bronchial tubes, and in examinate sections of the lung-tissue and inflamed pleura, found in each of each cases submitted to investigation ellipsoidal interococci which were coloured deeply by the aniline dyes. The organisms were found, as a rule, arranged in pairs or chains; but in some parts they swarmed in enormous number. especially in the interior of the alreoli and the lymphatic vessels. Korn Klebs, and other observers have also described similar organisms.

Syngtoms.—The onset of croupous pneumonia is sudden, and is usually marked by signs of great perturbation of the nervous system. The cold is often convulsed, and the celamptic seizures may succeed one apoller with only short intervals of quiet, for hours together. In other cases the patient complains of severe headache and pains about the chest. He vorse repeatedly, shivers or cowers over the fire; and towards the evening more become delirious. From the first the temperature is high, the thermoreter marking 103 105', or a still greater elevation. From the first, too or wh is noticed, and is a source of much distress from the pain it excites in the chest. The cough is characteristic. It assumes the form of a short, starback, and in older children may be accompanied by the expectoration of a rusty sputum. The cheeks are brightly flushed; the eyes look heavy, and the face is distressed; the narcs act; the tongue is thickly furred; epistans is a common symptom; and the weakness is often from the first a notable feature in the case. This weakness often amounts to marked muscular prostration. An infinit hes quietly and takes no notice of what goes on around him. An older child seems stupid, and often makes no reply to questions addressed to him, as to do so requires an amount of exertion to which he feels himself unequal.

As the disease goes on there is little alteration in the symptoms. The child has on his back in his bed. He is very thirsty, but has no inclination for food. His face continues flushed, and often a patch of herpes is seen on the upper hp—His breathing is hurried and short; and its rhythm is altered, the pause taking place at the end instead of at the beginning of inspiration. This is probably due to an effort to suppress the cough. The peculiar character of the cough has been already referred to. It occurs in short single backs, one to each short inspiration; and these often

continue until the child seems quite exhausted.

After three or four days the flush disappears from the checks, and the face is left pale, with a little lividity about the eyelids and mouth. The nervous symptoms also subside, and the nocturnal delirium rarely lasts larger than three or four nights. Usually the period of completion of the exudation is marked by a subsidence of the more severe features of the case. The temperature remains elevated, but the child looks less dull and self-absorbed; his expression of distress passes away, and he takes some interest in what is going on around him. The period of resolution is marked by a sudden fall of the temperature, which sinks below the level of health, and the child passes rapidly into a state of convalescence.

The more special symptoms will now be considered in detail.

Nervous symptoms are, as a rule, more violent at the beginning of the disease. Convulsions cease after a few hours, and although dehrium may persect for several nights, it rarely continues after consolidation has been completed. Severe cerebral symptoms are said to be more common in cases where the apex of the lung is the part to be attacked, but they are not limited to such cases; indeed, in children they are often quite as marked when any other part of the lung is involved. It is very common to find a pneumonia of the apex unaccompanied by any sign of nervous irritation; and according to my experience inflammation of this part of the lung, in the large majority of cases, runs in the child an especially short and favourable course.

When nervous symptoms occur the form they take is subject to considerable variety. In mants there is usually great drowsiness, preceded, perhaps, by convulsions, and often accompanied by twitchings of the facial muscles and of the muscles of the limbs. Sometimes the child clutches at his mother's dress as if in fear of falling; and when the drowsiness passes off he eries fretfully as if in pain. In an older child severe headache and deliraum are usually the most prominent of the nervous symptoms. Thus, a little girl, aged mine years, cause back from school complaining of headache and pains in the chest and back. For the next two days she vomited repeatedly, greaned with the pain in her head, and was delirious at night, lying with her head back and her arms up to her forehead. There was no squint; her nose bled once, and she coughed and expectorated phlegmatreaked with blood. The child was seen at the hospital three days afterwards. Her temperature was then (6 p. m.) 103, and there was con-

solidation of the lower two-thirds of the left lung on the posterior as-

In many cases where nervous symptoms are prominent there is a sallow tint of the face, with tenderness over the liver, and a constipated state of the bowels. The symptoms of nervous excitement do not appear to be dependent upon undue elevation of temperature, for they do not necessarily occur in cases where the pyrexia is most marked; nor do they seem to have any connection with the ordinary reflex excitability of the nervous

system so common in the young child.

A little girl, aged three years, was noticed to be very restless and irritable for a fortnight. At the end of that time she had a fit while at dinner. The child was brought to the hospital and remained convulsed for two hours. She was kept in the hospital for about a week, on account of twitchings in the muscles and a certain excitability of monner, although she had no return of the fits and seemed to be perfectly intelligent. The bowels were costive and had been much confined, otherwise no derangement of organs could be discovered. After her discharge the child remained well for a fortnight, and was then brought back to the hospital with an attack of lobar pneumonia involving the lower part of the right lung. In this attack, although the temperature was high (about 104°, both morning and evening) the illness had not been ushered in by convulsions; there was complete absence of nervous excitement; and the disease ran

an exceptionally mild course.

The breathing in pneumonia is hurried from the first. There is no actual dyspaces, for in an ordinary case we find none of the distress which is seen when a child is consciously suffering from shortness of breath. He lies down in his bed and requires no support by additional pillows. The nares dilate widely, but the respiratory movements are merely increased in rapidity without being exaggerated in degree. The pulse is also quicker than normal, but is proportionately less hurried than the breathing. Consequently there is a disturbance of the relation naturally existing between the pulse and the respiration which is a very important symptom. The ratio from being 1 to 3.5 is reduced to 1 to 2.5 or even 1 to 2. Thus, a respiratory rate of 75 with a pulse rate of 140 is very commonly met with. Although the rapidity of breathing is not accompanied under ordinary circumstances by a feeling of dyspnoa, the child shows by his manner that the supply of air to his lungs is a pressing necessity, for he will not willingly allow the process to be interrupted. He will bear much discomfort without complaint, and indeed the passiveness of a young child under examination is a characteristic feature of the disease. If he begin to cry he usually ceases to do so very quickly. If he suck, he does so hurrically, stopping at short intervals to breathe through his half-open mouth, as air cannot be admitted in sufficient quantity through the nose.

The tongue is thickly furred, and in severe cases may become dry and brown. Vomiting often occurs at the beginning. The bowels are usually confined, but may be loose, and in exceptional cases there is profuse diar-

rhea. The appetite is completely lost, and there is great thirst.

The urine is diminished in quantity. Its specific gravity is high, and it is often thick with bthates. The excretion of urea and uric acid is above the average of health; but there is a great diminution in the amount of chlorides; and at the height of the disease these salts may disappear altogether from the urine. Occasionally there is albuminuma; and bile payment is often noticed.

The pyrexia is high from the first, and the remission in the morning is

often very slight, soldom exceeding a degree or a degree and a half. The temperature rises usually to between 103° and 105°, but may be higher. It often reaches its maximum on the third day. When the temperature falls it falls suddenly. Thus, in the case of a little girl, aged five years, on the evening of the fifth day the thermometer registered 104.2°. It then began to full. At 10 p.m. it was 101.2°; at 2 a.m. on the following morning it was 100.2°; and at 6 a.m. 99°. It remained all day at this level, being the

83me at 10 P.M.

Although in ordinary cases of pneumonin there is no actual dyspnea, in exceptional instances we find serious suffering from want of breatli. It occasionally happens that when a large area of lung has become rapidly consoli lated the heart's action is scriously embarrassed by the impediment to the pulmonary circulation. The over-distended right ventricle labours violently to force the circulation onwards; but its walls soon become weakened and dilated by the pressure to which they are exposed. We find the child propped up in his cot struggling for breath with a pale or heid face. His nares dilate widely at each inspiration; the chest-walls are forcibly elevated, but expand only imperfectly; and there is great recession of the suprasternal notch, the intercostal spaces, and the epigastrium as each breath is drawn. The child can hardly speak, but his expression indientes terror and distress, and beads of sweat often stand upon his brow. On inspecting the chest the right auricle can usually be seen beating in the second and third interspaces to the right of the sternum; the heart's action is violent, while the pulse at the wrist is so feeble as to be hardly perceptible. There is, indeed, little blood in the systemic circulation, but the pulmonary system is engorged. These cases are not so common in the chill as they are in the adult; but they are occasionally met with in early life, and unless prompt assistance be rendered may quickly prove fatal.

A physical examination of the chest may not at first discover any signs of the inflammatory lesion in the lung. Often two or three days chapse before any characteristic changes are to be discovered by the finger or the ear. Usually on the first day or two the percussion-note is normal, and with the stethoscope we find merely a sonoro-sublant rhonelius scattered more or less widely over the lung. Even when consolidation occurs, if this be situated in the middle of a lobe, we may find bronchial breathing, with a puff of fine crepitation at the end of inspiration, but the percussion-note may be normal as long as a thin layer of healthy lung-issue intervene

between the diseased spot and the surface.

In an ordinary case the physical signs of the disease are as follows:

During the stage of engargement inspection can seldom discover any impairment of movement on the affected side. In young children this is always difficult to detect, for the respiration being chiefly disphragmatic, the chest walls take a comparatively small part in the respiratory movement. There may be at first no dulness on percussion, or the note may have a slightly higher pitch than that over the sound lung. The breathing is very harsh and rather louder than natural, and towards the termination of this stage a fine puff of crepitation is caught at the end of inspiration. This is usually only to be heard when the child draws a deep breath. In or hancy breathing there may be a little coarse bronchitic rhonchus both with inspiration and expiration which presents nothing characteristic.

In the stage of hepatication a faint vocal vibration may be sometimes detected over the affected side when the child speaks or cries. This sign is a very capricious one. It may be noticed in very young subjects and be absent in a much older child. If present, it is a sign of value, but no

solidation of the lower two-thirds of the left lung on the posterior

pect

In many cases where nervous symptoms are prominent there is a sall a tint of the face, with tenderness over the liver, and a constipated state of the bowels. The symptoms of nervous excitement do not appear to be dependent upon undue elevation of temperature, for they do not necessarily occur in cases where the pyrexis is most marked; nor do they see to have any connection with the ordinary reflex excitability of the nervous

system so common in the young child.

A little girl, aged three years, was noticed to be very restless and intable for a fortinght. At the end of that time she had a fit while at dinar. The child was brought to the hospital and remained consulted for the hours. She was kept in the hospital for about a week, on account it twitchings in the muscles and a certain excitability of manner, although the had no return of the fits and seemed to be perfectly intelligent. It has bowels were costive and had been much confined, otherwise no deragment of organs could be discovered. After her discharge the remained well for a fortnight, and was then brought back to the happened with an attack of lobar pneumonia involving the lower part of the mailting. In this attack, although the temperature was high (about 104, low morning and evening) the illness had not been unhered in by convulsant there was complete absence of nervous excitement; and the disease of

an exceptionally mild course.

The breathing in pneumonia is hurried from the first. There is to actual dyspnœa, for in an ordinary case we find none of the distress who is seen when a child is consciously suffering from shortness of breats. It lies down in his bed and requires no support by additional prilows. To nares dilate widely, but the respiratory movements are merely mensal in rapidity without being exaggerated in degree. The pulse is also as the than normal, but is proportionately less hurried than the breathing. Cosequently there is a disturbance of the relation naturally existing between the pulse and the respiration which is a very important symptom. The ratio from being I to 3.5 is reduced to I to 2.5 or even I to 2. Thus a respiratory rate of 75 with a pulse rate of 140 is very commonly as with. Although the rapidity of breathing is not accompanied under or nary circumstances by a feeling of dyspnon, the child shows by his may ner that the supply of air to his lungs is a pressing necessary, for he was not willingly allow the process to be interrupted. He will bear much decomfort without complaint, and indeed the passiveness of a young class under examination is a characteristic feature of the disease. If he because to cry he usually ceases to do so very quickly. If he suck, he does so hurriedly, stopping at short intervals to breathe through his half-que mouth, as air cannot be admitted in sufficient quantity through the no

The tongue is thickly furred, and in severe cases may become dry and brown. Vomiting often occurs at the beginning. The bowels are usually confined, but may be loose, and in exceptional cases there is profuse in them. The appetite is completely lost, and there is great thirst.

The urine is diminished in quantity. Its specific gravity is high use it is often thick with lithates. The excretion of urea and uric act; is above the average of health; but there is a great diminution in the amount of chlorides; and at the height of the disease these salts may disapper altogether from the urine. Occasionally there is albuminums; and the pagment is often noticed.

The pyrama is high from the first, and the remission in the morney

then very slight, seldom exceeding a degree or a degree and a half. The paperature rises usually to between 103° and 105°, but may be higher, to distribute rises usually to between 103° and 105°, but may be higher, to distribute rises usually to between 103° and 105°, but may be higher, to distribute its maximum on the third day. When the temperature distributed its maximum on the case of a little girl, aged five years, to the evening of the fifth day the thermometer registered 104.2°. If then regan to fall. At 10° r.m. it was 101.2°; at 2 a.m. on the following morning 1 and 100.2°; and at 6 a.m. 99°. It remained all day at this level, being the lime at 10° r.m.

Although in ordinary cases of pneumonia there is no actual dyspness, a receptional instances we find serious suffering from want of breath. It commally happens that when a large area of lung has become rapidly small-litted the heart's action is seriously embarrassed by the impediment of the pulmonary circulation. The over-distended right ventricle labours faintly to force the circulation onwards; but its walls soon become returned and dilitted by the pressure to which they are exposed. We not the child propped up in his cot struggling for breath with a pale or will fare. His nares dilate widely at each inspiration; the chest-walls are breath its drawn. The child can hardly speak, but his expression into the supresternal notch, the intercostal spaces, and the epigastrium as any breath is drawn. The child can hardly speak, but his expression into the strong and distress, and beads of sweat often stand upon his brow. In inspecting the chest the right auricle can usually be seen beating in the second and third interspaces to the right of the sternum; the heart's cush is violent, while the pulse at the wrist is so feeble as to be hardly explible. There is, indeed, little blood in the systemic circulation, but the pulmonary system is engorged. These cases are not so common in the dark as they are in the adult; but they are occasionally met with in early lead unless prompt assistance be rendered may quickly prove fatal.

A parpicul examination of the chest may not at first discover any signs of the inflammatory lesion in the lung. Often two or three days clapse of the any characteristic changes are to be discovered by the finger or the ar Usually on the first day or two the percussion-note is normal, and with the stethoscope we find merely a sonoro-sibilant rhonchus scattered are or less widely over the lung. Even when consolidation occurs, if has be saturated in the middle of a lobe, we may find bronchial breathing, the apuff of fine crepitation at the end of inspiration, but the percussion-

between the diseased spot and the surface,

burner the stage of engargement inspection can seldom discover any important of movement on the affected side. In young children this is always difficult to detect, for the respiration being chiefly disphragmatic, the elect-walls take a comparatively small part in the respiratory movement. There may be at first no dulness on percussion, or the note may have slightly higher pitch than that over the sound lung. The breathing terr harsh and rather louder than natural, and towards the termination of this stage a fine puff of crepitation is caught at the end of inspiration. The is usually only to be heard when the child draws a deep breath. In a caucht the end of the course bronchitic rhonchus both with inspiration and expiration which presents nothing characteristic.

In the stage of hepatisation a faint vocal vibration may be sometimes to test over the affected side when the child speaks or cries. This sign a very capture one. It may be noticed in very young subjects and be sent in a much older child. If present, it is a sign of value, but no

inference can be drawn if it fail to be perceived. The percussion-note over the affected part is now dull; but the dulness is far from being complete, as in pleurisy. The sense of resistance, too, although increased. is not extreme, as in the case of effusion. It is rather greater than natural and that is all. In babies and young children the increase of resistance may be very triffing. Auscultation over the consolidated spot discovers a loud tubular breath-sound, and the crepitation, which was before heard at the end of inspiration, is now no longer to be perceived, although at the borders of the solidified region it may still be detected. If the child can be persuaded to speak, the resonance of the voice is high-pitched and sniffling, and is conducted with much greater distinctness than natural to the ear. This sign is, however, not always present, and in a case of undoubted consolidation the resonance of the voice may be normal. Indeed. in exceptional cases—owing possibly to plugging of a tube with mucus vocal resonance, and even blowing breathing itself, may be indistinct and distant-sounding, or even altogether suppressed. On the other hand, if the consolidated spot is in the middle of a lobe, completely surrounded by healthy tissue, and the patient be an infant, a bronchophonic resonance of the cry may be the only sign to be detected of the pulinonary lesion.

When resolution occurs in the affected part, crepitation returns, coarser and more like bubbling than before; the breath-sound becomes less high-pitched and metallic, and gradually loses its blowing quality. The dulness also diminishes and finally disappears. Returning crepitation is often absent in the child, and resolution frequently takes place without any moist rhonchus being heard. The excessive resonance of the voice and cry usually persist over the affected spot for some time, or until the consolidation has completely disappeared. Resolution is carried on more rapidly in some children than in others. In many cases, however, when dulness persists for some weeks after subsidence of the general symptoms, the impairment of the percussion-note is due to a layer of lymph over the pleurs at

the affected spot.

The physical signs just described usually occupy the lower two-thirds of one side; but may be found at any part of the lung. Often they are confined to the apex; or may be discovered over a limited area under one of the arms. As has been already observed, they are often slow to develope; and therefore, when from the general symptoms croupous pneumonia is suspected, frequent and complete examination should be made until the situation of the local lesion is discovered. An important peculiarity of this form of disease is that the physical signs, unless situated at the apex of the lung, are usually confined to one aspect of the chest. If they are detected at the posterior aspect, the signs are normal in front; white inflammation of the anterior part of the lung produces no alteration of resonance or respiratory sound at the back of the chest. Therefore a complete examination of the chest must be made before we are justified in saying that no signs of pneumonia are present.

Terminations.—In the large majority of cases in the child croupons pneumonia ends in resolution and recovery. In the primary form of the disease an unfavourable termination is very rare; and even in cases of secondary pneumonia, unless the child be a new-born infant or in a state of great weakness, it is exceptional for him to die. When death takes place it usually occurs on the fourth or fifth day as a result of failure of the heart. It may, however, happen later as a consequence of abscess or

gangrene of the lung.

When resolution occurs, the improvement is very sudden, and the dis-

case terminates by crisis. The temperature, which had given little or no sign of reduction, falls suddenly in the course of twelve hours to the normal level, and remains low for four-and-twenty hours, even if it afterwards undergo a moderate merease. The ensis often occurs on the fifth day, but may be deferred until the eighth or ninth, and in rare cases until later. The violence of the onset, the height of the fever, and the severity of the nervous symptoms are not in proportion to the extent of surface inrolled, nor are they to be taken as an indication that the course of the discuse will be prolonged; for cases in which the general symptoms are very pronounced may come to an end on the fifth day. The cessation of the pyrexia is followed by an immediate improvement in the child's condition. The skin becomes moist; the tongue cleans; the pulse and respiration fall in frequency and regain their normal relation to one another; the cough is loose and less frequent; the urine is more profuse; and the appetite returns. The favourable change in the general symptoms precedes the improvement in the physical signs, and for a day or two the resonance may continue to be impaired, and the breathing to be broughial or blowing over the affected part of the lung.

In exceptional cases the termination by resolution occurs more gradually. The temperature perhaps falls suddenly, but almost immediately rises again; so that for two or three days, a week, or even longer, the bodily heat may continue to be considerable at night, with a morning fall. Sometimes, after remaining low for two or three days the thermometer again registers a high degree of temperature and the child passes through a complete relapse of his illness. The relapse is, however, usually shorter

and less severe than the original attack.

The termination by abscess of the lung is not often seen except in cases where the pulmonary affection is secondary to pyromia. It does, however, occasionally occur in children of weakly constitution who are living in theoreughly insanitary conditions; and may also be seen in cases where inflammation is set up in the lung as a consequence of impaction of a foreign

body in one of the bronchi.

When abscess of the lung occurs in a case of secondary pneumonia the temperature remains high, or if it fall, rapidly rises again and assumes a bectic type; there is great weakness; the tongue becomes dry and brown, and the complexion dull and earthy in tint, with livid discolouration of the evelids and high. On examination of the chest the dulness is found to persist, and the breathing to be bronchial or blowing, with much large bubbling or even inetallic rhonchus. Unless the abscess burst into a bronchial tube, and its contents be evacuated, the physical signs are not characteristic of the lesson. If, however, the purulent contents are discharged, covernous breathing, whispering bronchophony, and the usual signs of a cavity may be detected at the seat of the disease. If the abscess be the result of premier infection, the general symptoms are those of the constitutional state, and the local signs, not being the consequence of any extensive local inflammation, may be overlooked, more especially as the abscesses are small and are often completely surrounded by healthy lung-tissue.

(langrene of the lung will be considered in a separate chapter,

Pneumonia is occasionally latent. This form of the disease is most commonly seen when the patient is a young child worn and wasted by chronic abdominal derangement, whose nervous irritability is almost completely lost. In such cases the ordinary symptoms of invasion are not noticed. There is no sign of pun in the chest. Even the cough may be infrequent or absent. A slight rise in the temperature, increased rapidity

of breathing, perversion of the pulse-respiration ratio, and indications of early prostration may be the only symptoms excited by the intercurrent mulady.

Complections.—Inflammation of neighbouring tissues often complicates a case of pneumonia. In the child a certain amount of broncatts is a common feature of the illness. In almost all cases we can detect some sonorosibilant rhonchus not only in the affected lung but also on the opposite and of the chest. In many instances there is also some most rhonchus. As a rule the amount of bronchitis is trilling, and the complication is rarely sufficiently marked to be a source of danger.

24

Plastic plearisy may also accompany the pulmonary inflammation, and sometimes there is a moderate liquid effusion. The plearisy is schlom of much moment, and absorption usually occurs rapidly when resolution of the inflammation has taken place. As has been before remarked, the persistence of dulness over the seat of disease during convalescence is commonly due to the presence of a layer of lymph upon the pleared lining of the chest.

Percurdates is sometimes induced by extension of the inflammation; but this complication is less common in pneumonia than in the case of pleurisy. In the child the inflammation of the pericardium, when it occurs in the course of a croupous pneumonia, is usually plastic, and is but rarely accompanied by effusion. In regard to prognosis it is probably of small importance.

Jaundier is sometimes seen, and is usually mild. It is due to pressure upon the bile-duets by hypersemic portal vessels, the circulation through the liver being impeded owing to the condition of the lung. It may also arise from gastro-duodenal estarth. If this be sufficiently intense to create an impediment to the introduction of neutrishment, the consequences may be serious. Gastric or intestinal catarrh may be present without jaundice. Diarrhosa is a symptom not unfrequently seen at the beginning of an attack of pneumonia. As a rule, the purging is not excessive, and ill consequences rarely follow from the intestinal derangement.

Diagnosis. In a well-marked case of croupous pneumonia the diagnosis is not difficult. The sudden occurrence of high fever, headache, pain in the side, short backing cough, perverted pulse-respiration ratio, and rapidly increasing muscular weakness is very suggestive of this disease. It is important to bear in mind the nervous symptoms which often accompany the onset of the illness, or we may alarm ourselves with suspicious that an inflammatory head affection is about to manifest itself. But although a feverish child is often light-headed at night, and wanders somewhat in his talk, high fever with early and marked delirum is not a common occurrence; indeed, this combination breaking in upon a state of health, if combined with a short backing cough, is almost peculiar to pneumonia. If, in addition, we notice that the narcs dilate at each inspiration, and that the breatling is quickened out of proportion to the pulse, we are justified in entertaining the strongest suspicions that the attack is one of croupous inflammation of the lung.

In some cases cough is absent, or is so slight that it passes quite unnoticed, and the narcs are motionless in inspiration. Still, the sudden occurrence of a high temperature, with pungent heat of skin, as estimated by the hand, combined with early delirium, should suggest the presence of pneumonia. In all such cases the chest should be minutely examined for confirmatory evidence. It must be remembered that the physical signs are often slow to appear, and that forty-eight hours, or even three or four days,

have pass without any consolidation of the lung being discovered. It must also be remembered that the severity of the symptoms is not in proportion to the extent of lung-tissue involved, and that after a violent onset the local signs may be confined to a mere patch of solidification at any part of an pulmonary surface. We must not, therefore, content ourselves with a number examination of the bases of the lungs. Careful attention must also be directed to the apices, and we must not forget to search the axillar carefular aide for evidence of disease. In cases of pneumonic consolidation the dulness is not complete, and is accompanied by little increase in reastance. Moreover, in the large majority of cases the signs are limited to one aspect of the chest. Sometimes a faint vibration of the chest-wall, inappreciable upon the healthy side, may be detected over the sail of disease when the child speaks or cries.

The combination of high fever, headache, and diarrhoea may be perpeting. If the patient be an infant, the symptoms may be ascribed to bething, and the condition of the lung may be overlooked. The nares, however, act, and the respiration, if counted, will be found to be hurried out of proportion to the pulse. If a physical examination be made, as it sught to be, a matter of routine, the nature of these cases will not escape according. In an older child the same combination of symptoms would be at a child the rapid breathing, the hacking cough, are very unlike the beginning of enterio fever; and if delirium come on, it begins very early (on the first or second day) in pneumonia, while in typhoid fever it is rarely

sen before the end of the first week.

In young children, in whom the disease may begin with violent convulsons, or with a drowsiness approaching to stupor, the diagnosis is very discut, especially as there is often no cough. Usually until signs of consolution are discovered at some part of the chest the nature of the illness must remain doubtful. Still, drowsiness and a temperature of 163° or 164, without signs of severe headache, but with rapid, regular, breathing, a percented pulse-respiration ratio, and pungent heat of skin should suggest the presence of pneumonia.

In the latent form, which usually occurs in wasted children, rapid breathme and active nares ought always to lead us to make careful and repeated

examination of the chest.

The distinguishing marks of catarrhal pneumonia and collapse of the

lang are considered in the chapters treating of those subjects.

Primary croupous pneumonia, unless very extensive, almost awars terminates favourably, and even in infants is seldom dangerous. Essentian takes place early, as a rule, and the consolidation clears completely away, leaving the lung as sound as before. The situation of the least sound has no influence upon the prognosis, and no special danger is connected with inflammation of the apex of the lung. The nervous symptom has however serious they may appear, need cause no alarm, for they subside altogs ther when consolidation becomes established. Delirium in itself, without other signs of nervous disturbance, is rarely an unfavourable symptom in a feverish child. It usually disappears after a few days, but may return again towards the end of the disease as a result of weakness; but the recurrence, if the inducation which it furnishes is attended to, is rarely fedured by dangerous consequences.

The secondary forms of pheumonia are more serious than the primary, for the tendency to failure of the heart's action is increased by weakness induced by previous disease. So, also, the existence of a depressing com-

plication adds to the danger of the case. Pneumonia occurring in the course of Bright's disease is an especially serious form of the complaint.

A very rapid pulse (over 140) is an unfavourable sign, especially if the pulsations are irregular in force and rhythm. So, also, a rise of temperature above 105' should be regarded with anxiety, although in early life this phenomenon is less serious than a similar elevation would be in the case of an adult.

Treatment. - In an ordinary case of primary croupous pneumonia little is required beyond keeping the child quiet in bed in a well ventilated room, wrapping the affected aide of the chest in cotton wool or linseed meal poultices frequently renewed, and administering a simple effervescing saline or other febrifuge draught several times in the day. The pain in the side is usually greatly relieved by the use of hot poultices and other applications. To be efficient, however, these should be used as hot as the skin can bear them; and dry heat, such as a bag filled with heated bran or salt, is perhaps better-it is certainly more manageable-than hot flannels. If any severe pain is complained of, a proportion of mustard (one-tifth or one-sixth) may be added to the poultice, and this may be allowed to remain for six or eight hours in contact with the skin. If the cough is distressing a few drops of ipecacuanha wine and of compound fincture of camphor may be included in the mixture; and a few drops of antimonial wine may be added with advantage on account of its diaphoretic action upon the skin. The old plan of attempting to reduce the inflammation by large doses of antimony is one to be very strongly deprecated. If the bowels are confined, or the complexion has a sallow cast and there is tenderness over the liver, an aperient powder should be prescribed, such as a grain of calomel with two or three grains of jalapine; but the aperient seldom requires repetition. Violent purgation in this disease is decidedly injurious.

The diet should consist of meat broths and milk until the consolutation is complete. When the establishment of blowing breathing and the disappearance of crepitation show that the process of repair is about to begin the diet can be improved. Strong beef-tea should then be given at proper intervals, and a yolk of egg may be added to the diet. The thirst may be relieved as often as the child requires drink, but he must not be allowed to take a large quantity of fluid at one time. In the case of an infant at the breast, or one who is brought up by hand, some thin barley-water should be given from time to time to relieve thirst, so that the

quantity of food the child takes may be restricted.

If the pyrexia rise to a high level and the child seem distressed by the intensity of the fever, the temperature may be reduced by sponging the surface of the body with tepid water; or if absolutely necessary, the child may be placed in a tepid bath of the temperature of 70°. If, however, the bath be used, great care must be taken not to depress the child, as failure of the heart's action is one of the dangers to be apprehended in cases of pneumonia. Both before immersion and after removal from the bath a stimulant should be given, and if the feet feel cold, a hot bottle should be put into the bottom of the cot. Quinine is strongly recommended by some authors as a valuable remedy at an early period of the illness. It is given partly as an anti-pyretic, for it is said quickly to reduce the temperature without weakening the heart; partly for its supposed influence in checking the spread of the disease over the lung. To be of service as an anti-pyretic the drug must be given in full doses; and it must be remembered that children bear the remedy well. For an infant of twelve months one grain should be administered three times a day. This

quantity can be increased by one grain and a half for every year of the child's life. Acousts and other depressing anti-pyretic drugs are dangerous remedies to employ in cases of pneumonia on account of their weakening influence on the heart.

In cases where great dyspaces and threatened cardiac failure arise from over-distention of the right side of the heart, it becomes a serious question whether abstraction of a small quantity of blood is not called for. If the danger is imminent I should not hesitate to take one, two, or more ounces of blood from the arm. Life can often be saved by this means. Even while the blood is flowing the inspiritions become slower and quieter and expand the chest more fully; the pulse gains in fulness and force; and the anxiety and feeling of oppression subside. I can look back upon several fatal cases which I now believe might have been saved had I had the courage to relieve the labouring heart by the judicious removal of blood. It is in such cases alone that bleeding is justifiable in this disease; and here the treatment is directed not against the inflammation, but against one of its consequences, viz., the overtaxing of the heart by the impediment to the pulmonary circulation.

It is not often that stimulants are required in cases of primary pneumonia in children, but if the disease is secondary they may have to be resorted to. Great rapidity of the pulse is an indication for stimulants which must not be disregarded; and if a pulse of 140 is found to be intermittent in force and rhythm, doses of egg-and-brandy should be given at

regular intervals until improvement occurs.

Dehrmm at the beginning of the disease, if noisy, may be usually quieted by topid sponging of the surface of the body. If necessary, a small dose of Dover's powder can be given at night. Chloral, on account of its depressing effect, must not be used. If dehrium occur later in the illness it is a sign of debility, and energetic stimulation will be required. Steeplessness can also be usually removed by topid sponging in the evening.

If diarrhea occur, it may often be promptly checked by a dose of castoroil or of rhubarb (gr. uj.-v.), with double the quantity of the aromatic chalk powder given every night. Astringents are rarely necessary in these cases; but if the purging continue, sal volatile may be given with spirits of chloroform and a drop or two of laudanum, according to the age of the child, three or four times a day. A layer of cotton wadding should be applied to the belly under a flamel binder for the sake of warmth; and food should be given in small quantities at a time.

Directly the temperature falls tonics should be given; and the diet of health may be returned to; taking cure that the food is digestible in kind,

and that it is given in quantities suitable to a convalescent.

934

CHAPTER V.

CATABRILAL PNEUMONIA.

CATARRHAL or lobular pneumonia, or bronche-pneumonia, is the common form of inflammation of the lung met with in infancy, and is frequently seen in early childhood. The disease is quite distinct from the cronpous form previously described, differing from it in its pathology, its symptoms, and its tendency to end in death. Catarrhal pneumonia is nearly always a secondary affection, and results from spread of inflammation from the bronchial mucous membrane to the alveoli. Consequently, the disease invariably attacks both lungs, although it may be more extensive on one sade of the body than on the other.

Causation.—As bronche-pneumonia is always preceded by pulmonary catarrh, the causes which induce bronchitis in the child may be looked upon as tending in a great measure to set up catarrhal pneumonia in the nir-vesicles. These are especially cold and damp, and the inhalation of dust

and other critating particles in the air.

A severe bronchitis in the young child always inclines to spread to the finer tubes and air-cells; but certain forms of illness have great influence in determining the extension of the inflammation. Thus, measles and whooping-cough number lobular pneumonus amongst their most frequent sequela, and the disease is also common as a secondary consequence of diphtheria. In scrofulous and tubercular subjects, and even in children who are merely weakly and under-nourished, lobular pneumonia is readily excited. Therefore any influence which diminishes the resisting power of the child and lowers his general health must be looked upon as a predisposing cause of the complaint. Thus, bad feeding, insunitary conditions, and depressing derangement or disease may all help to induce this form of pneumonia. It is very common in the case of young children for the illness to be preceded by a history of more or less persistent diarrhox. A young child who is subject to attacks of intestinal catarrh becomes excessively sensitive to chills, and after a time acquires a cutarrhal propensity which, combined with the weakness induced by the digestive derangement, is likely to result in an attack of catarrhal pneumonia. Acglected colds on the chest may set up broncho-pneumonia in the most robust subjects; but amongst the well-to-do classes it is comparatively rare to find this disease in children who are not strumous or delicate, or rickety, or who have not been lately suffering from an attack of measles or whoopingcough.

Morbid Anatomy.—Lobular pneumonia may arise as a consequence of direct extension of the inflammation from the larger tubes to the smaller, and thence to the air-cells; or may occur secondarily to collapse of the lung. In the infant the latter is the method in which the discuse usually originates, for in such young subjects, on account of the narrowing of the bronchial tubes, the feeble inspiratory power, and the normal softness and

compressibility of the chest-walls, collapse of the lung is a very common consequence of pulmonary catarrh. The special tendency of rickets to be complicated by bronchitis and catarrhal pneumonia has been elsewhere referred to. The difficulty of expanding the chest in this disease, owing to the softening of the ribs, greatly contributes to setting up collapse of the lung; and any additional impediment, such as a catarrhal state of the broughal membrane, promotes the exhaustion of the air-cells. Collapse of the lung is followed by congestion of the small vessels, owing to the impediment created by imperfect aeration of the blood, and to the absence of the expansion and contraction of the air-cells, whose movement in a state of health materially advances the pulmonary circulation. As a result of congestion of vessels there is ordena which causes great diminution in the consistence and cohesion of the tissue at the affected spot. In this state the part is ready for the development of inflammatory changes. Inflammation readily extends to it from the air-tubes; or the irritation induced by the penetration into it of secretion from the bronchial mucous membrane excites the inflammatory process.

Lobular pneumonia usually begins in isolated groups of vesicles, being often determined by the presence in them of inflammatory products drawn from the small tubes with which they are in communication. On inspection of the lungs we see scattered nodules of consolidation of a reddish gray colour scattered over the surface. They vary in size from a small peate a nut. Their consistence is friable, their substance smooth or faintly granular, and their circumference ill defined. As the process advances, the nodules which were at first isolated become united at their borders so as to produce considerable tracts of consolidation; and at the same time the soli littled parts become firmer, dryer, and of a yellowish gray colour. In their centres we can sometimes see divided air-tubes filled with purulent

matter.

The lung-tissue in which the nodules are embedded exhibits collapse, congestion, as lema, and emphysema in various stages and degrees. A certain amount of dilatation of vesicles is almost invariably present in the neighbourhood of collapsed portions of lung, and there is, moreover, an appreciable degree of cylindrical dilatation of all the minuter bronchi, aspecially of those portions which immediately adjoin the terminal alveoli. The walls of these tubes are excessively attenuated. The dilatation appears to be the consequence in some cases of accumulation of secretion. In others it is due to diminution of the respiratory surface, for plugging of some tubes with mucus causes an increased rush of air to the parts which

still remain pervious.

The consolidating matter itself consists in a very small degree of exaded corpuscles, as in the case of croupous pneumonia. On examination the abreoli will be found to be stuffed with cells, but these are in great part derived from proliferation of the epithelial lining of the vesicles. Mixed up with these cpithelial elements are leucocytes and much gelatinous mucoid matter—probably secretion from the inflamed bronchial mucous membrane which has been drawn into the alveoli. In all cases of catarrhal pneumonia large quantities of thick puriform bronchial secretion are found filling the air-cells and plugging the finest tubes. When this is very copious the amount of epithelial cells is comparatively insignificant. Thus, some of the nodules of consolidation appear to be composed almost exclusively of thick bronchial secretion; and a microscopic examination shows very few preliferated cells and little change in the epithelial lining of the alveoli. In other parts the nodules are composed almost entirely of epi-

thelial elements, and the epithelium lining the alveolar walls is swollen,

granular, and partially detached.

These lessons are found in both lungs; and the process begins in the most depending part, i.e., in the lower lobes at the posterior aspect, for gravitation greatly aids the passage into the cells of these parts of purulent secretion descending from the tubes. The extension of the inflammation laterally is always irregular, and the selection of the lobules for attack apparently capricious; for while some become consolidated, others in immediate contact with them remain healthy or merely congested. The nodules and patches of solidification are at first isolated, but tend to confesce, and in the latter period of the disease comparatively wide areas of consolidation may be found,

The pleura in the neighbourhood of the spots of consolidation is reddened with points of ecchymosis, and adhering to it is often a little plastic

lymph.

If the case do not terminate unfavourably, resolution usually ensues. A process of fatty degeneration takes place in the contents of the alveoli. The consolidating material becomes softened down and is removed more or less rapidly by absorption and expectoration. The process of resolution often occupies some time even when the lung finally returns to a normal condition. Often, however, the process of fatty metamorphosis becomes arrested. The cells then atrophy and become caseous, and a chronic consolidation is left which forms one of the varieties of pulmonary phthisis. In other cases an indurative pneumonic process is set up which leads to a great development of fibroid tissue in the part. The walls of the air-tubes and the alveoli become thickened and indurated and the tubes dilated. This condition forms a special variety of lung disease which will be afterwards described (see fibroid induration of the lung).

Symptoms.—Broncho-pneumonia is a secondary disease. Its symptoms are always preceded by those characteristic of a more or less severe pulmonary catarrh. In weakly, ill-nourished children, especially if they are suffering from an attack of measles, a computatively trifling catarrh will set up lobular inflammation of the lungs. In a robust child inflammation of the alveoli seldom ensues unless the preliminary catarrh has been long continued or very severe. When broncho-pneumonia follows an ordinary catarrh of the lungs, the disease usually runs a very acute and rapid course and commonly ends in death. When it arises in the course of an attack of measles or whooping-cough the complication is more subscute in character and the proportion of recoveries is greater. Still, such cases tend to

leave unabsorbed deposits in the lungs.

After the symptoms of pulmonary catarrh have continued for some time they suddenly change their character. The temperature rises; the cough becomes short and lineking; the pulse and respirations are hurried, the face is more or less livid; the nares act; and in the infant a well marked labial line becomes developed, passing from the angle of the mouth down-

wards and outwards to the rumus of the lower jaw.

The pyrexia varies in degree. In children in whom an ordinary bronchitis gives rise to fever, the temperature, when inflammation of the lung is superadded, may reach a high level. Thus, the thermometer may mark 104° or 105°, but undergoes more decided variations during the twenty-four hours than is the case in croupous pneumonia. In most instances there is a decided remission between 6 a.m. and noon; the chief elevation occurring between 10 p.m. and 3 or 4 a.m. Sometimes, however, for twenty-four or forty-eight hours the temperature may remain at about the same level.

arying only by half a degree. In spite of the pyrexia the skin is often

lest, and in some cases perspiration is profuse.

In catarriad as in croupous pneumonia the pulse-respiration ratio is averted; but the disproportionate rapidity of the breathing is variable cording to the acuteness of the case. In the severe scute variety the severally be 1 to 2 or even 1 to 1.5; while in the subscute form the ratio way be only 1 to 2 5 or 3. The pulse is very rapid (120 to 150, or even learn), but is small and feeble, for the impediment to the passage of blood arough the lungs obstructs the whole circulation. Consequently the arms are comparatively empty, while the venous system, as is shown by be follows of all the superficial veins, is congested.

The breathing besides being hurried is laborious, and there is evident repress. The child often cannot lie down in bed and has to be supported to plants. At each inspiration the nares dilate widely, and the shoulders now with the laboured action of the accessory muscles. Often the child aleasours to and the expansion of his close by grasping tightly the bars his cot. Still, with all his endeavours the patient is unable to fill his large with air, for at each movement of the chest the intercostal spaces and leavelular hollows become depressed, the epigastrium sinks in, and

he lower rabs are retracted.

The cough, when the air-cells become attacked, changes its character at seems painful. This change in the cough is a very valuable sign. Intend of the prolonged, rather paroxysmal cough of bronchitis, we hear that hard back of pneumonia; and this may be repeated with each parathon for many minutes together, causing great distress and exhaus-

Losseness of the bowels is a common symptom, the stools being slimy i thick, or thin and watery. Vomiting, induced by the cough, is also seen present; and much much is discharged both from the stomach and Nervous symptoms are sometimes noticed. In an uncomplicated convulsions do not occur in the course of the illness, although they are be present shortly before death when asphyxia is imminent; but twitches and spasmodic movements of the muscles of the eyeball are often

Wen during aleep.

At this time a physical examination of the chest discovers merely the was of branchitis; for the consolidation being limited to small scattered boines and surrounded by emphysematous air-cells, can rarely be directed by percussion. Sometimes, however, by employing broad reason, e.e., by striking with three fingers on three fingers applied the chest-wall as pleximeters, we notice some diminution of healthy prisonary tone; and in some cases a careful exploration distinguishes principals where there is more evident diminution in resonance, and p Haps bronchial breathing over the same limited area. If the pucuhas a occurs in collapsed portions of lung we can often find at each base symmidal strip of dulness reaching upwards for a certain distance, when Pression is made very lightly. With the stethoscope general fine bubby thouchus is heard, and in certain spots this will be noticed to be loss driver, and more crepitating in character. This crepitating quality peoperally noticeable over an area where the breathing is bronchial; for make croupous pneumonia, the crepitus is not lost when consolidation oc-

As the illness advances, and the nodules of consolidation grow larger collecte, more and more of the respiratory surface becomes involved, that evanotic symptoms are mainfest. The face grows excessively

pale, with a dusky tint around the eyes and mouth; the expression is anxious; the cycballs are staring and suffused. The respirations may rise to 70, 80, or even more in the minute; and the breathing grows more and more laborious. The child is painfully apathetic and dult. If an infant, he refuses his bottle, and can with difficulty be persuaded to swallow fluids from a spoon. His hands and feet are purple and often cold to the touch, although the internal temperature of the body is still febrile. At this period cough almost ceases, partly from exhaustion, partly from impaired irritability of the respiratory centre. In this state the child sinks and dies, the end being often preceded by a fit of consultions. Before death, when this takes place from asphyxia, the internal temperature may be subnormal. In the case of a little rickety boy, aged thurteen months, with only two teeth, who died on the eleventh day from extensive catarrhal pneumonia of both lungs, the temperature at 6 km. on the evening before death had fallen to 98° in the rectum.

At this stage of the disease percussion discovers more or less extensive dulness of the back on each side; and the breathing is bronchial or tubular, especially about the angle of the scapula. The respiration is accompanied by much fine metallic crepitation both in inspiration and expiration; and this is often very superficial-sounding, as if generated immediately underneath the stethoscope. In the front of the chest there is seldom dulness, unless perhaps the resonance at the bases is diminished; but usually a certain amount of coarse crepitation may be heard in the mammary and infra-mammary region on each side. A curious feature at this time is the indifference of the child to the discomforts of the examination. He allows himself to be placed in any position without complaint, and

seems to be quite careless what is done to him.

If the disease terminate favourably, there is no critical fall of temperature, as is the case with the croupous variety of pneumonia. On the contrary, the diminution in the pyrexia takes place very gradually, and the improvement in the general condition does not occur until the local symptoms have given signs of amendment. Thus, the pulse and respiration are reduced in frequency, the breathing becomes less laborious, the pulse fuller, and the superficial veins less distended. The pallor and hydrity of the face are less noticeable and the expression loses its distress. The tongue cleans, vomiting ceases, and the appetite returns. Still, the temperature, although it continues to fall, is some days before it sinks to a natural level. The physical signs are also very slow to improve, and absorption takes place very gradually. This variety of pneumonia, as has been said, is apt to leave behind it caseous unabsorbed masses in the lung which may lead to scrious illness in the future. Still, under favourable conditions these often become absorbed even although a period of months has elapsed since the attack was at an end.

If the disease do not prove fatal or show signs of resolution at the end of a week or ten days, it often takes on a subscute course. In some cases, especially where the catarrhal pneumonia occurs as a complication of measles or whooping-cough, the subscute character may prevail from the first. In this form the symptoms are less severe than in the acute variety, and the course of the disease is much longer. The temperature does not reach so high a level, remaining usually at about 102′, with morning remissions. Sometimes the pyrexia undergoes curious alternations. Thus, after being moderate for a few days (99′-101°) the temperature suddenly shoots up to 104° or 105°, and after a day or two sinks again to the same level as before. The pulse and respiration are both hurried, but their normal rela-

tion is comparatively little altered. As the disease advances the cough loses its lucking character and occurs in violent paroxysms almost indistinguishable from those of pertussis. Their duration is, however, shorter, and inspiration is noiseless or less decidedly crowing. They may be followed by vomiting. This character of the cough should lead us to sus-

pect considerable dilatation of the bronchi.

Vomiting and some looseness of the bowels are common symptoms. The tongue is furred; the appetite is impaired; the strength is diminished; and the child wastes rapidly and becomes very feeble. In these cases, in addition to the physical signs of broncho-pneumonia which have been already described, we find very clear evidence of dilutation of bronchi. At each posterior base, but more pronounced on one side than on the other, cavernous breathing is heard with a coarse metallic ringing crepitation, sounding very close to the ear; or the respiratory sound may be amploric and tunking echo. In many cases, too, the vocal resonance is bronchophonic, and the faintest laryngeal sound is conducted clearly to the end of the stethoscope.

These cores often continue for weeks, but under judicious treatment generally end in recovery. There is, however, a great tendency to imperfect absorption of the deposit; and unless the child be placed under favourable samitary conditions a chronic consolidation may be left which is afterwards a source of danger. Sometimes, too, these cases pass into fibroid

induration of the lung.

Complications.—The complications of simple catarrhal pneumonia are not numerous. The illness sometimes begins with strictulous laryngitis, and in the rare cases where the spasmodic disease ends fatally death is usually due to the presence of the pulmonary inflammation. Gastric and intestinal catarrh have already been mentioned as frequent complications of the pucumonia. In the child a catarrh is seldom simple; often several

tracts of mucous membrane share in the derangement,

Catarrhal pneumonia is itself also a common complication of other forms of illness. Measles, whooping-cough, and rickets have already been referred to. General tuberculosis in many, perhaps in most, instances becomes complicated with this form of pulmonary inflammation; and in the case of fibroid induration of the lung the danger of the disease consists in a great measure in the repeated attacks of catarrhal pneumonia to which children with this form of lung affection are peculiarly

prone.

Pragnosis.—At the beginning of the illness we have to found our diagnosis upon the general symptoms alone, for there is at first no sign of consolidation, and physical examination of the chest only reveals the presence of severe bronchitis. Mere elevation of temperature is no proof that the inflammation has spread to the alveoli, for in many children—especially those with scrofulous tendencies—a pulmonary catarrh is accompanied by moderate pyrexia. If, however, the temperature reach 104 or 105, and at the same time the cough get suddenly short, backing, and painful, while the breathing becomes disproportionately quickened so as to cause notable perversion of the pulse-respiration ratio, this combination of symptoms is very suggestive of catarrhal pneumonia. A perverted pulse-respiration ratio alone is not characteristic, for this may occur in cases of collapse of the lung. Still, if with great hurry of breathing we find the respiratory movements laborious, and notice that the soft parts of the chest receile dieply at each breath, the sign is in favour of pneumonia; for in pulmonary collapse the breathing, although excessively hurried, is shallow,

and unless the ribs are much softened from rickets the recession at the base of the chest is slight.

Quite at the beginning of the illness it may be difficult to distinguish the disease from the croupous form of pneumonia where the signs of consolidation are delayed. At this time the age of the child, the history of the attack, and the character of the breathing are important points of distinction. In an infant the inflammation is probably catarrhal, and if the child is frail or badly nourished, is almost certainly so. The history of previous cough points strongly to the lobular form; and laborious breathing, great recession of the chest-walls in inspiration and a very evident feeling of dyspace are distinctive of catarrhal rather than of croupous pneumonia. The latter disease rarely attacks a feeble, ill-nourished intant; it comes on suddenly without previous catarrh; the breathing, although hurried, is not laborious; and there is no true dyspacea, the child not being distressed by the recumbent posture.

When extensive areas of lung have become consolidated, the catarrhal origin of the lesion is distinguished by attention to the crepitation. This rate in croupous pneumonia ceases to be heard over the solidified area and can only be detected at its confines. In catarrhal pneumonia the crepitating rhonchus becomes finer and crisper towards the centre of the consolidation, and is heard with the most typical bronchial or blowing breathing, being sometimes, indeed, so copious as almost or entirely to cover the breath-sound. Moreover, moist and dry bronchitic rales are heard over the lungs generally. In croupous pneumonia this is not often the case, for although some sonoro-sibilant rhonchus is occasionally present, this is trifling

in amount, and, as a rule, is not accompanied by moist sounds.

One of the chief difficulties in the case of catarrhal pneumonia is to exclude tuberculosis. That we should be able to do so is of the greatest importance with regard to prognosis; for while, if the inflammation be uncomplicated, recovery may take place, if the child is tubercular death is certain. The subscute form of the disease occurring in a weakly child and accompamed by diarrhoes and rapid wasting, presents symptoms which are identical with those resulting from acute tuberculosis with secondary lung complication. The physical signs are also the same, for no additional feature is furnished by the presence of the gray granulation in the lungs. Family history is here of importance. If we can discover that other children of the same parents have died with symptoms of tubercular meningitis, the history is suggestive of tubercle. If, again, we can learn that before the onset of the disease the child was losing strength and growing pale and thin without evident cause, the fact is also in favour of tuberculosis. Again, the age of the patient must be considered. Over the age of six years catarrhal is less common than croupous pueumonia. Therefore, if the catarrhal inflammation occurs in a child more than six years old, who has been previously wasting without apparent reason, and has not lately suffered from measles or whooping-cough, we have here strong evidence in favour of tubercle. Of the actual symptoms the only one which in any way points to a constitutional cause for the illness is the presence of ordema without albuminums; but this phenomenon, although it may add weight to other evidence, is in itself of little value in a weakly child. If, however, any serious symptoms arise pointing to the brain, and convulsions occur, followed by squint, unequal pupils, ptosis, or rigidity of joints, we can have no hesitation in concluding the case to be one of acute tuberculosis. It must be remembered that terminal convulsions are common in catairbal pneumonia from asphyxia, and are quickly followed by death. But convulsions occurring in

the course of the illness and not evidently the consequence of impurity of blood, are very suspicious of tuberculosis, even although no other sign of

nerve-lesion be immediately manifested.

When dilatation of the bronchi occurs in an advanced case of the subacute variety of catarrhal pneumonia it is important to exclude ulcerative destruction of lung. Thus, in the fifth or sixth week of a broncho-pneumoma a child is seen with a temperature of 100' in the morning, rising to 102' or 103' at night. At the same time an examination of the chest discovers a fine crepitating rhonchus at the base of each lung, with impaired resonance over the lower half posteriorly of each side, and at one base dulness, loud cavernous breathing, metallic gurgling rhonchus, and brouchophony. These latter signs are evidently significative of a cavity; but the cavity may be a dilated bronchus or a vomica in the lung. To which of these causes the physical signs are to be attributed must be decided by reference to the general symptoms and the progress of the case. The position of the cavity, indeed, at the base of the lung, points rather to bronchiectasis than to a vomica, but this is not conclusive proof. If, however, we find that the temperature begins to fall, the child's appetite to return, the general nutrition to improve, and at the same time notice that the cavernous sounds become less intense, the respiration less shrill, and the gurgling less metallic, we may safely infer that no disintegration of lung-

tassue has taken place.

Prognosis.—The prospect of the patient's recovery in a case of bronchopneumonia is always doubtful. In new-born infants, indeed, the illness almost invariably terminates fatally; but even up to the end of infancy the rate of mortality is very high. When the disease surreeds to measles or whooping-cough its course is less acute than when it arises as a consequence of simple pulmonary catarrh, and in these cases there is a greater propor-tion of recoveries. If, however, the lobular pneumonia come on during the spasmodic stage of pertusais, or towards the beginning of an attack of measies, it is very commonly fatal. The existence of any debilitating condition or exhausting disease increases the danger of the case. Thus in diphtheria the occurrence of secondary broncho-pneumonia is an event of the utmost gravity; and in rickets the local weakness of the softened riba, combined with the general want of power in the patient, militates powerfully against a favourable termination to his illness. The danger is usually great in proportion to the degree to which acration of the blood is interfered with. Therefore lividity of the face, blueness of the nails, lips, and eyelids, smallness and rapidity of the pulse with dilatation of the superficial veins great perversion of the pulse-respiration ratio, suppression of the cough, and marked apathy or somnolence are symptoms indicative of serious danger. If convulsions occur at a late period of the illness we must prepare

the chil's relatives for the worst,

Treatment.—The occurrence of catarrhal pneumonia may often be prevented by judicious treatment of the preliminary catarrh, and especially by the employment of energetic measures on the first sign of collapse of the lung. This subject is discussed elsewhere.

When lobular pneumonia has supervened, the indications to be fulfilled are three in number. We have to reduce the temperature, to promote ex-

pansion of the lung, and to support the strength of the patient.

In order to lessen the temperature tend bathing is often resorted to. The child should be placed in water of the temperature of 70°. In this he may remain for ten or lifteen minutes at a time. The bath must be repeated more than once in the four-and-twenty hours, for the reduction of

temperature is only a passing improvement, and the pyrexia quickly returns. This method is highly spoken of by Rilliet and Barthez, who recommend its employment in every case, unless the prostration of the patient be extreme. Another method is that advocated by Bartels—It consists in packing the child in a cold, wet sheet, covered with a thick folded blanket, for three or four hours at a time. The process in this case also requires to be repeated at intervals, so long as no signs of exhaustion are noted, in order to maintain the improvement. The effect of either of these measures is not only to lessen the fever, but also to increase the depth and reduce

the frequency of the breathing.

Another very valuable resource is energetic counter-irritation of the skin of the chest. A large poultice of mustard and lineed meal (one part of the former to five or six of the latter) should be applied for six or eight hours to the back. Afterwards a similar poultice should be allowed to remain for a like time on the front of the chest. On removal of the poultice the chest should be covered with cotton-wool. These applications will often have to be repeated several times, for in this disease there is great tolerance of irritation of the skin even in the case of a young infant. Even if the surface is blistered by the application, no harm will be done. Indeed, I have been in the habit of ordering the poultices to be continued until some signs of blistering of the skin have been noticed. The chest can then be covered with cotton-wool. In bad cases, instead of the mustard poultice, dry cupping of the back is useful. In one severe case of this disease—a child of three years of age—I attribute the recovery of the patient entirely to the timely use of this energetic application.

While these methods of treatment are being carried out, the strength of the child must be upheld. Stimulants should be given early, and no attempt to lower the temperature should be made without at the same time administering brandy or the brandy-and-egg mixture. In this disease, as in all others which rapidly depress the powers of the patient, children respond well to stimulants; and alcohol should be given every two or three hours, or oftener, according to the strength of the pulse, the rapidity of the breathing, and the degree of pallor and lividity of the face. The effect of the stimulant is to give strength to the circulation, to reduce the number of the respirations and to further the acration of the blood. If the child cannot or will not swallow the remedy, it may be administered, as in other exhausting forms of illness, by the syringe and elastic tube (see page 15), or through a caoutchout tube passed into the stomach through

the nose.

The diet must consist of milk diluted with barley-water and guarded by a few drops of the saccharated solution of lime, of strong beef-tes, yelks of eggs, and meat essence. In the case of young infinite the breast milk, white wine whey, and milk and barley-water with Mellin's Food should

be given.

With regard to medicines:—Emetics are useful at the beginning of the disease. A drachm of ipecacumha wine, or half a grain of sulphate of copper dissolved in a dessert-spoonful of water, may be given every ten minutes until vomiting is produced. This remedy must not, however, be repeated after the first two or three days, as the strength of the child quickly fails. Narcotics are to be avoided, for our object is in every way to promote cough in order to maintain efficient expansion of the air-cells and aid the expulsion of secretion. The best form of mixture is that which combines alkalies with stimulants. Thus, we can order a few grains of bicarbonate of soda or potash with four or five drops of sal volatile and an equal quantity

A spirits of chloroform in glycerine and water every three hours. Later, the infusion of senega or serpentaria may be substituted for the water in the draught. Medication by drugs is, however, as a rule, of very secondary importance in the more acute forms of the illness; but if the disease occur macomplication of pertussis, the special antispasmodic treatment for that

disease may have to be continued.

When the inflammation runs a very subscute course much benefit is often derived from the free administration of iron. For a child five or in years old ten drops of the tineture of the perchloride of iron may be given every three hours, freely diluted; and a rapid improvement, both in the physical signs and general symptoms, often follows very quickly. Directly the pyrexia subsides quinine and other tonics, and cod-liver oil should be given; and the child should be removed, as soon as he is fit for the journey, to a bracing seaside air.

CHAPTER VI.

PLEURISY.

Prevenue is a very common disease in young subjects, and one which, although seldom immediately fatal, often produces remote consequences of a very serious kind. In childhood the effused fluid becomes purulent at a very early period; and the retention in the chest-cavity of a collection of purulent matter seriously hinders the nutrition of the patient, and may

lead to various forms of disease, both general and local.

Causation.—Pleurisy is comparatively rare during the first twelve months of life. It becomes much more common during the second year, and after that age is one of the most frequently met with of all diseases of childhood. The inflammation may be primary or secondary. In the first case it appears to be often the consequence of exposure to changes of temperature; at least it is difficult to discover any other cause for it than a chill. It may be also excited by mechanical causes, such as direct irritation from injury to the chest-wall, or rupture into the chest-cavity of abscesses or hydrid cysts. Secondary pleurisy may arise from extension of inflammation from the lung, the pericardium, or the peritoneum. It may occur in the course of acute rheumatism, scarlatina, measles, typhoid fever, small-pox, and inherited syphilis; and is very often a consequence of renal disease, and sometimes of tuberculosis.

Morbid Anatomy.—Inflammation of the pleura is usually confined to one side of the chest, and may be general over that side or limited to certain regions (localised or loculated pleurisy). The inflammation begins with hyperemia of vessels and infiltration of the serous and subserous tissues. An effusion of inflammatory lymph then takes place, and of fluid which may accumulate to a large amount in the pleural cavity. The serous membrane is rough and lustreless, and becomes coated with a layer of effused lymph. This is at first merely a thin, coherent membrane; but gradually its thickness increases. The surface is sometimes ribbed or honeycombed in appearance, and we occasionally see strings or bands of lymph passing between the opposed surfaces of the pleura, connecting them with one another. The lymph consists of albumen, fibrine, and corpuscles derived from proliferating epithelium. It is at first loosely attached to the scrous membrane beneath, but gradually becomes more firmly adherent. Eventually new vessels form in it, so that it is organised and converted into connective tissue. In this way the opposed surfaces become firmly united, and the pleural cavity, where these adhesions occur, is obliterated.

The effused fluid is at first yellowish or greenish, and transparent, but it soon becomes turbid and opaque, and in children very quickly purulent. The scrous effusion contains both albumen and fibrine, and coagulates spontaneously after removal. The pus is usually quite healthy in appearance and without unpleasant smell; but in exceptional cases it is dark coloured and very offensive. Sometimes it is stained or streaked

with blood. The quantity of effused fluid is very variable. It may be merely an ounce or two, or may reach two or three pints. When thus appears, the whole side is dilated, the intercostal spaces are widened, and beyelbouring organs are displaced. The lung is compressed, and if, as accumes happens, although very rarely in the child, it is bound down by a thei layer of false membrane, it may not expand again as the fluid becomes absorbed. In that case it leads to the same deformities as are noticed under similar conditions in the adult. It is, however, very rare to the agreatly contracted chest from an old pleurisy in the child. Even if the chest fall in at first, it will be often found to right itself in a surprising my in the course of time; and a child who was left with curved spine and intracted ribs may be seen again, after an interval of twelve months, with a thest as symmetrical as if it had never been affected. It is rare to find a child permanently deformed by this means.

In some cases the amount of fluid is small. This is most commonly seen then the pleural inflammation is secondary to peritoritis, pericarditis, or position is Sometimes the pleural cavity, instead of forming one large alcess, may be divided into several distinct sacs by false membrane and a lemma, so that one of these may be emptied without draining the others. It is not so very uncommon to meet with more than one loculated empyema in the same subject; and great difficulty is found in such cases in com-

pletely reheving the chest of its purulent contents.

A large collection of purulent fluid in the pleural cavity rarely becomes absorbed. If not removed by operation, a spot at some part of the chest-ral-usually the fifth interspace in the inframanmary region—is noticed to be red and very tender. This soon becomes prominent and forms a large superficial abscess, which, if not opened artificially, bursts and the pusheds drains away. By this means caries of a rib is sometimes produced. The abscess does not always point low down. It may appear higher up in the chest, as above the clavicle, or in an upper intercestal space; and I have the me it to open in the supraspinous fosse. In some cases, instead of bursting externally, the purulent collection opens into a bronchus and the mater is coughed up through the lung. In others it perforates the diaphram and passes downwards like a passas abscess behind the peritoneum, steper in one case saw it open into the gullet.

Whether the fluid be removed artificially or escape by perforation of the chest-wall, it may after a time drain away completely and leave the patent convalencent. Sometimes, however, a discharging sinus is left which because open for years. In these cases amyloid disease of organs often

blows or the child may die from general tuberculosis.

Sumptoms.—The onset of pleurisy, although sudden, is not often violent, builty it begins with a feeling of chilliness, or in older children with a stor and with pain in the side, followed after an interval by cough. It is not ushered in by a convulsive seizure, as is so commonly the case with premium. The pain is often severe. It is felt in the side or is referred to the epigastrium or the stomach. In infants who cannot speak, its existence is aunounced by violent fits of crying, which may be excited at once by pressure on the chest as in lifting the child up. An older child complians interly of the pain, and often gives evidence of his suffering by the discussed expression of his face, especially if a cough cause any sudden movement of the side. There is also tenderness of the chest-wall over the life of discusse, for pressure is evidently painful. In addition to the above the interval of the chest-wall over the life of discusse, for pressure is evidently painful. In addition to the above themselves and for the first few days there is always fever, oven in cases

where the temperature is afterwards normal. The pulse is quickened, and the respirations are more hurried than natural; but they are not, as is the case with pneumonia, increased out of proportion to the pulse. Consequently, there is little or no perversion of the pulse-respiration ratio. The cough does not usually begin until an appreciable interval has passed from the onset of the illness. Often, for the first twenty-four or forty-eight hours, little cough is noticed. When it comes on it is hard and dry, and the increased movement of the chest-walls by which it is accompanied is a cause of much suffering. The strength of the child fails comparatively little. There is by no means the marked muscular prostration which is so noticeable a feature in pneumonia. On the contrary, if the pain be not severe, the child seldom takes voluntarily to his bed, but will walk about as usual without any pronounced sense of fatigue. If the pain is severe, he is quiet and indisposed to exert himself; but this inclination to rest is the consequence of pain, which is increased by movement, and is not due to any sense of muscular weakness.

The degree of fever varies. Usually for the first few days the temperature rises to 102" or 103" in the evening, falling to 99° or 100" in the morning. After the first week the fever may either persist, or the temperature may fall gradually to the normal level. In a child of perfectly healthy constitution, if the pleurisy be primary and uncomplicated, the fever usually is moderate and quickly subsides. Persistent high temperature in a case in which the pleurisy is primary and uncomplicated is usually

a sign that the patient is of strumous constitution.

It is not in every case that the onset of the disease is so marked as described above. The illness often begins insidiously and is only discovered by the pallor of the child, and the shortness of his breath on any exertion. The latent form of the disease is especially common in infants, particularly if the child is suffering at the time of the attack from any wasting disease. In these cases there is often no fever, or only a trifling rise of temperature; there may be no cough; and attention may only be directed to the chest by noticing that the child is breathing quickly and has less appetite than usual for his food.

The pain of pleurisy is usually only severe at the beginning of the illness, and often subsides as effusion takes place into the pleura. This is not, however, always the case. Sometimes it continues with extreme tenderness of the affected side until towards the close of the disease. Unless the tenderness be great, the child usually has on the affected side for the sake of giving increased freedom to the healthy lung, which has to do double duty as a respiratory organ. If the tenderness is marked, the patient lies on his back. It is not often that he is seen resting on the sound side.

If the disease continues for two or three weeks, the fluid usually becomes purulent. There are, unfortunately, no positive symptoms which indicate that the effusion is no longer serous. Even the time which has elapsed from the beginning of the illness is no positive guide, for in some children the fluid becomes purulent much more quickly than it does in others; and in exceptional cases it may be purulent from the first. The tint of the face is, however, often a suspicious symptom. For many years I have been accustomed to note the colour of the face in children the subjects of pleurisy. In many it assumes a peculiar straw-yellow hue which is unlike the complexion of any other disease. This symptom is rarely seen during the first week of the illness, and seldom attracts the eye before the end of the second week. If well defined, it is often coexistent with purulent

ange in the contents of the pleural cavity. Still, I have seen it well marked a a case where the fluid withdrawn by the aspirator was perfectly clear. A oven the East London Children's Hospital, aged six years, was noticed to save a most marked straw-yellow tint of the face and neck. The left side of the class was full of fluid, which had pushed his heart into the epigastram. With the aspirator, nineteen ounces of clear pale yellow fluid were trawn.

When the fluid has become purulent (empyema) the chikl usually wastes; by great differences are observed in the extent to which nutrition suffers ers a these cases. Much, probably, depends upon the temperature, as has may be taken to indicate with fair accuracy the degree to which the estem is fretted by the purulent contents of the thorax. If there be much for, wasting is rapid. The child has a distressed expression and becomes polandly amenic; his strength diminishes; the straw tint of the face my spreud more or less over the whole body; the skin becomes dry and hanh, and the fingers get clubbed at the extremities. In very rare cases a trace of ordema may be detected in the legs without albuminuria; but I have known this symptom to occur only in one instance, and in this albumisans followed after a few weeks. Empyema in scrofulous subjects is al-ast invariably accompanied by fever. The temperature rises to 102° or 10.1 at night, sinking in the morning to the natural-level. In children of bulths constitution the presence or absence of fever appears to depend in agreet measure upon the natural nervous excitability of the child and his takency to respond readily to any source of irritation. In many children But a chest more than half full of purulent fluid the temperature is norhal and the nutrition fairly good; and although signs of ansemia may be blook, the strength and spirits are not greatly depressed.

The physical signs in cases of pleurisy in the child must be studied with thation, for they often resemble those of croupous pneumonia very closely. On account of the weakness of vocal fremitus in early life no assistance is to be stained from the presence or absence of vibration of the chest-wall—a sign which in the adult is of extreme value in the detection of fluid. The assentiatory signs, also, may present so close a similarity to those of influentation of the lung that, in themselves, without reference to the situation in which they occur, they are not distinctive of pleurisy. Indeed, in they cases it is only by a comparison of the physical signs with the general frames of the disease that we can arrive at an accurate conclusion as to

tw nature of the illness.

On inspection of the chest-wall we can often detect a certain impairment of movement on the affected side; but the intercostal spaces are not secondly bulged and motionless even in cases where the amount of fluid in age. In young children, whose respiration is principally disphragmatic, the walls of the chest move comparatively little in inspiration; and the class inspection can often discover no difference in this respect between the two sides. Although the intercostal spaces may move as in health, the whole of the affected side is fuller than the other. It may not, indeed, as his been pointed out by Dr. Gee, show any difference to the measuring tape; but the outline, as taken with the evitometer, is much squarer than another from a bulging at the antero-lateral angle of the chest-wall. If the second from a bulging at the moderate, the neighbouring organs are implaced by pressure of the fluid. The liver and spleen can be felt more distantly than in the normal state, and the heart's apex is pushed to one let. In cases of right-sided pleurisy the apex is displaced to the left, and the felt beating outside the nipple line. If the effusion occupy the left

side, the cardiac impulse may be felt near the ensiform cartilage. These signs, especially the latter, according to my experience, are as well maiel in the child as in the adult, and should be always looked for Design ment of the heart to the right is sometimes prevented by adhesions kined between the pericardium and the left pleura. Sometimes an alterator p the size of the heart may prevent the displacement of the organ from here noticed. Thus, if the left ventricle is much hypertrophical, the apearest under ordinary circumstances is felt to the left of the number line in said case displacement of the heart to the right by fluid in the left plum case do no more than restore the apex-beat to the normal position. A late girl, aged nine years, with old-standing heart disease and hypertraph of the left ventricle, was admitted into the hospital with considerable pleaner effusion of the left side. The heart's apex was felt beating being the sixth rib in the left nipple line. After absorption of the fluid the carries apex had moved one inch to the outer side of the mpple line.

Palpatum of the affected side does not always discover obliteration of the intercostal depressions, although sometimes it will do so. Often epecially in cases where there is little thickness of lymph lining the plant. a tap with the finger between two of the ribs will be readily trap-puted through the fluid to a second finger resting upon a distant part of the same interspace. Vocal vibration of the chest-wall is, as a rule, completely absent in the healthy child. Sometimes, however, if strong on the soul side, it may be conducted by the chest-wall to the other half of the chest, and be felt distinctly over the whole of the affected side. I have known this phenomenon to be present in a case where ten ounces of fluri way removed by paracentesis. Immediately before the operation the total vibration was little less strong than on the sound side. On account of its frequent absence, and uncertain value when present, vocal fremus b not to be depended upon in the young subject. If, however, we can fee's distinct fremitus over the sound lung, its absence over the affected side of

the chest is important; but this is exceptional.

On percussion of the affected side there is complete dulness with greater increased sense of resistance. These are very important signs. In no furn of pulmonary consolidation—except, perhaps, in extensive fibroid industrice of the lung with secondary pneumonia is such a dull, that note, with so marked a sense of resistance to the finger, to be found. The impression to the ear and the touch is exactly that derived from percussing a thick block of wood. The dead, flat note is not, however, to be obtained all over the affected side of the chest. In the upper intercostal spaces in front and along the side of the spine behind, a tubular (tympanitic) note is often elicited, due to the presence of under-lying relaxed lung-tissue, and in the infra-axillary region it is common to find a well-marked resonance owner to the transmission of the stomach note through the lower part of the fuel This pseudo-resonance is often a source of perplexity; but we usually field that on employing very gentle percussion in this region the note is did while a sharper stroke in the same spot produces a loud resonance such 25 was heard at first. It is very important not to be misled by this source of confusion, for one of the distinctive marks of fluid in the pleura has in the general distribution of the dull percussion note on the affected anie la ordinary cases of pleurisy the dulness extends all round the side of the chest, both behind and in front, although the upper limit of the dulness rises to a higher level at the back than it does anteriorly.

Besides the general distribution of the dulness, the alteration of the percussion note on change of position is a valuable sign of fluid in the chest If the amount of fluid is moderate, and is not confined within narrow limits by adicesions, it tends to gravitate to the most depending part, so that the ade of the chest which is turned uppermost gives a clear note to the permusing tinger. This sign is almost invariably present during the stage of

description.

The auscultutory signs of pleurisy in the child are often very peculiar. Sometimes, as in the adult, we find weak, almost suppressed, breathing over the area of dulness, with an occasional graze or scrape of friction above the opper border of the effusion. Often, however, the signs are much less interacteristic. It is not uncommon to find a loud blowing, tubular, or even avernous breath-sound over the scapula behind and in the axillary region. Sometimes this is heard almost as far as the base, and usually it can be desected below the level of the effused fluid. This character of the respiratory sound is not confined to cases where the lung is consolidated from pneumonia, for it is often present when the temperature is normal. The total resonance may be evaggerated, and about the lower angle of the capula is frequently bronchophonic. Often it has a pronounced agoniconic quality. The bronchophonic character is not, however, always ound in places where the breathing is bronchial or blowing. Over a spot where the respiration is typically tubular, vocal resonance may be completely suppressed.

The characters of the friction-sound in children are also peculiar. It is exceptional to hear the common rub or scrape which is so familiar a sign in the adult patient. In the child the friction-sound has often a rackling or crepitating character, which to the inexperienced ear is suggestive rather of intra-than of extra-pulmonary mechanism. It has not, however, the puffy character of pneumonic crepitation; and is very uperficial sounding, as if generated close to the ear. Often, from the character of the sound alone, it is difficult to say whether it is produced in the lung or in the pleura, especially as a large, hard, bubbling rhonchus is cometing the ard, which is evidently of intra-pulmonary mechanism and is

due to caturch of the air tubes. This disappears after a cough.

The friction is not limited to spots in the pleura above the level of the last. In pleurasy, as in pericarditis, effusion does not necessarily suppress faction. It is not uncommon to hear an unmistakable friction-sound at a last where immediately afterwards the aspirating needle withdraws several

nunces of fluid.

In cases where the effusion is very copious the symptoms may be distressing, and the child shife be placed in the greatest danger. This is especially the case when the fluid occupies the left side of the chest. In this iteration it may push the heart so far to the right that the apex is felt beiting under the right nipple. Consequently, the large vessels may be bent out of their natural course, and great obstruction to the circulation language result from the interference with their calibre. The healthy lung, hampered in its functions, may become engaged, and the difficulty in the return of blood to the heart may produce great congestion of the least, face, and extremities. The child is seen sitting up, gasping for breath, with an agonized expression on his dusky face. His eyes are starting and congested; his hands and feet are purple; his skin is cold and bathed in sweat, the veins of the neck are swellen; his pulse is small, reble, and frequent; and unless the distress be quickly relieved death is certain.

Terminations —In cases where the fluid remains serous, it usually be-

subside, and the physical signs return to a state of health. In these cases dulness on percussion and weak breathing can be detected longer in the infra-axillary region than elsewhere. If absorption of the fact is slow, some retraction of the side is often observed for a time; has a succases it is usually slight, and is seldom noticed to the degree which is common after removal of a purulent fluid from the class. If the opposite complete, the deformity soon passes away and the class recovers

symmetry.

When the fluid has become purulent, absorption goes on very slowh It is only when the quantity is very small that anything approaches 12 completeness of absorption is found. It is in cases of empreus that distortion of the chest is commonly noticed. The spine becomes cared with the concavity towards the diseased side; the shoulder, name, at i inferior angle of the scapula sink, and the lower part of the slatterblade projects backwards from the chest-wall. Such retraction of the stfected side takes place before absorption has ceased. Indeed, as I'r I Barlow has very justly pointed out, the fact that retraction of the sale use occurred is by no means a positive proof that absorption has been retain pleted. On the contrary, if the deformity continues without improvement it rather tends to suggest the possibility of some unabsorbed puralent matter remaining at the base of the lung or between the lobes. In many of these cases a layer of cheesy matter is left coating the base of the lang. and a quantity of thick creamy pus is often found on dissection collected in a limited abscess on the surface of the diaphragm.

If the amount of purulent fluid is large, it sooner or later, unless with drawn by the aspirator, points at some part of the chest-wall. If this cour in an upper intercostal space, the contained fluid cannot be complete, evacuated, and a continuous discharge occurs through the opering. The child grows daily weaker and thinner. His breath is short; his face get sallow and often earthy in tint, with lividity about the eyes and next his fingers become clubbed; his digestion is impaired, his torque for and his breath offensive; the liver and spleen become enduged from abuninoid degeneration; the cough is spasmedic and painful, and the child sinks and dies from asthenia. Death may be precided by profine diarrhosa, which, sometimes at least, is due to albuminoid change in the

coats of the bowel.

If the abscess point in a lower intercostal space, so that the class cavity can be completely drained, recovery may occur without operation interference. I have met with at least one such case where, although there was at first some deformity of the affected side, this entirely despected; but it must be confessed that such a fortunate result is not common.

Sometimes the purulent fluid, instead of discharging itself through the chest-wall, perforates a bronchus and is coughed up through the last Large quantities of purulent matter may be thus expectorated, but contrary to what might be supposed, no air enters the pleural cavity and the physical signs are not found to have undergone any special alterates. Indeed, if the case terminate fatally, it is very rare to find on the classed examination any direct communication between the lung and the discussion. Spontaneous evacuation through the lung is not confined to associate a part of the contained fluid has been attempted. It may also need after a part of the contained fluid has been removed by parace thesis. The mode of ending is often followed by complete recovery. If the pictod cavity can be thoroughly evacuated by this means, and the lung is not continued to a process.

bound down beyond possibility of expansion, recovery may take place with-

out any permanent retraction of the affected side.

Abtile boy, aged five years, was brought into the East London Children Hospital for an empyema of six weeks' standing. The effusion occupied the right side and appeared to be copious, for the intercostal spaces are diliterated and the heart's apex was felt beating to the outer side of the left implied him. On percussion, duliness was complete over the whole of the right side, both back and front; there was marked sense of resistanc; and the breath-sounds, although blowing in quality, were excessively work. The temperature was normal.

A few days after the boy's admission eleven ounces of thick, greenish, molecus pus were withdrawn by the aspirator. After the operation the draws and weak blowing breathing remained the same, but the intercostal spaces had become visible, and the heart's apex had returned as far as the apple line. A week afterwards the boy coughed up twelve ounces of thick pas and in a few days a further four ounces. After this the percussion not was decidedly less dull; the resistance was diminished; and the breathing was lond and tubular over the whole of the upper half of that side,

caremous below. Vocal resonance was loud and egophonic.

For some weeks the boy continued to spit up several ounces of purulent matter every few days; and in the end made a perfect recovery without any contraction of the chest-wall. The temperature was normal as a rue; although sometimes it would suddenly rise to 103° or 104°, but never runned elevated more than a few hours. These elevations did not correspent with or precede the passage of pus through the lung. A year afterwards the boy was readmitted with acute pleurisy of the opposite side (the left); and this attack also was perfectly recovered from.

In many cases of perforation of a bronchus there is the same difficulty in completely exacuating the pleural cavity as is found when the discharge takes place through the chest-wall. Sometimes the opening into the bronchus classes, and pus ceases to be expectorated. Retention of purulent matter then occurs, and the chest may become much distorted, or the

related after a lingering illness, may die of asthenia.

Even when the operation of paracentesis is performed and the purulent fad is removed artificially, the case is by no means necessarily at an end. Sometimes, after withdrawal of as much fluid as can be made to pass through the apprator, no further accumulation occurs; absorption of what remains in the pleural cavity goes on uninterruptedly, and the child is soon well. These cases are, however, exceptional. It is often necessary to repeat the previous several times, and not unfrequently, as the purulent fluid containing ally reaccumulates, other measures have to be adopted as will be afternable described. In prolonged cases, whether a fistula be present in the best-wall or not, secondary tuberculosis is hable to occur; and it is not uncommon to find great enlargement of the liver and spleen from a blad degeneration.

Another occasional consequence of long-standing pleurisy is a fibroid true at the base of the lung leading to induration of the tissues and distant on of bronchi. This subject is elsewhere referred to (see Fibroid In-

H Patum)

Faretres.—Certain varieties of the disease are commonly met with. In the cases the lymph exudation is unaccompanied by liquid effusion (plasser dry pleurisy). In others, the inflammation, instead of being general the whole side, is confined within certain limits (localised or loculated leaversy). In others, again, the disease may attack the two sides simultations.

neously. Double pleurisy is often in the child the consequence of tuber-culosis.

Plastic Pleurisy, although sometimes primary, is for the most part in young subjects secondary to some other disease. It is common in cases of phthisis, and sometimes occurs in the course of catarrhal pneumonia. Dry or plastic pleurisy is often overlooked, as it may give rise to but few symptoms, or to symptoms so alight that they are masked by the other more prominent manifestations of the disease in the course of which they have arisen. This form is of little importance. It is usually accompanied by some pain in the side and a teasing cough. On examination of the chest, dulness is discovered at the seat of pain, and a little crepitating friction or a superficial rub can be heard with the stethoscope. The inflammation leads to adhesion between the opposed surfaces of the pleura.

Localated Pleursy is very common in children. The inflammation may occupy any part of the serous surface. It may be limited to the membrane covering the diaphragm or to that surrounding the base of the lung; it may be sented at the upper part of the pleural cavity, such as the infra-clavicular region; or it may occupy the space between the lobes. In many cases the localisation of the disease is due to old adhesions resulting from a previous attack, so that the fluid thrown out is prevented from gravitating downwards or spreading over the general cavity of the pleura; but in

others no history of a similar illness can be discovered.

In ordinary cases of loculated pleurisy the general symptoms do not differ from those met with in the more common form of the disease. But the physical signs are more characteristic. Over the collection of fluid the percussion-note is completely dull, with great sense of resistance; the respiration is weak, and may be of bronchial, blowing, or cavernous quality; there is seldom any friction-sound to be heard, and the vocal resonance is ordinarily suppressed. Such signs may be discovered over the whole front of the chest; they may be limited to the infra-clavicular or infra-mammary regions; they may be found in the scapular region behind, or at the lower part of the axillary region at the side. The most difficult to detect of these partial pleurisies is no doubt that variety in which the inflammation and effusion are confined to an interlebar space. In such a case there may be considerable retraction of the side from compression of the lung; or the physical signs may occupy so limited an area as to escape recognition, and there may be no displacement of the heart. After the fluid has become purulent, the cough, the wasting, and the cachectic appearance of the child, coupled with the insignificant character of the physical signs, often suggest tuberculosis.

Disphragmatic pleurisy is rare in the child. The disease begins suddenly with a severe pain shooting across the chest and great oppression of breathing. The child sits up in bed with a distressed face. His skin is hot, and every attempt to draw a deep breath is a cause of great suffering. The physical signs are often very indefinite; but usually some dulness may be discovered at the extreme base on one side, with weak breathing; and often after a day or two the ordinary signs of pleurisy can be detected at the lower part of the same side; for disphragmatic pleurisy rarely remains limited to the disphragm in early life.

Tuberculous Pleurisa.—When pleurisy occurs as a consequence of tuberculous it is usually double; but every case of double pleurisy in the child is not necessarily tuberculous. Nor, again, in every case of pleurisy in a tuberculous subject is the serous inflammation always secondary to the diathetic disease. It has been already stated that tuberculous

a common sequel of empyema of long standing; and a purulent collectic a in the chest precedes tuberculosis much more often than it follows it, in cases where pleurisy is met with as a secondary disease the inflammation is usually of the plastic variety; although sometimes there is also seems or purulent effusion in the chest-cavity. We can only say positively that tuberculosis is the primary disease when the symptoms of the constitutional makedy—wasting, moderate fever, loss of colour and strength, a distressed expression of face and occasional cough—have preceded by a definite interval the local signs of scrous inflammation.

When tuberculosis follows empyema the temperature, if it had subsided, need between 101 and 102 or higher every evening, falling again to between 99 and 100° in the morning. The child loses flesh, colour, and streight more rapidly than the condition of his chest is sufficient to expand His face is haggard and careworn; his skin harsh and dry; often darther comes on; sometimes he vomits; his belly swells; and an attack

of base meningitis usually brings the illness rapidly to a close.

the plantame.—Besides tuberculosis and amyloid disease of organs (which have been already alluded to), there are other complications which may be present in cases of pleurisy. Percurdatis is not uncommon as an accompaniment of the pleural inflammation. This subject is referred to the state of page 158). Moreover, serous inflammation in the chest sometimes appeared a upwards from the peritoneum. More often, however, it pencions downwards through the disphragm to the abdominal cavity. It is

then usually fatal (see page 685).

of phenoma, pleurisy is often mistaken for that disease. The difficulty it making the distinction is due principally to the absence of vocal fremitis in the child; to the occasional loud blowing or tubular breathing which is often heard over the seat of dulness; and to the crackling character of the friction, which suggests rather an intra-pulmonary crepitation than a pieural rul. In order to distinguish between the two diseases we must take into account the mode of invasion, the nature of the symptoms, and the character of the physical signs; for in all these points great differences

are to be observed.

The occurrence of pain in the side and fever, followed after an interval by cough, is characteristic of pleurisy. In pneumonia cough is usually present from the beginning, and pain in the side, unless pleurisy accom-Pary the inflammation of the lung, is moderate or absent. The after by toms also are different. In pleurisy the cough is dry and painful: the poulse-respiration ratio is unaltered; the face is pule or congested at first, afterwards straw yellow; and there is little less of muscular strength. In pursumonia the cough occurs in short backs, accompanied in the older children by the expectoration of rusty sputum, the pulse-respiration ratio is perverted; the face has a bright flush on the cheeks; and muscular prostration is a marked feature. The physical signs also are distinctive. In pleurise the chest, even if not enlarged to the measuring tape, is square in our Line; the heart's apex is displaced; the dulness is complete, the note being perfectly that, and the sense of resistance to the finger extreme, the Paper sounds, although they may be as tubular as in a case of typical pulma wary inflammation, are always less loud at the base than above; and the caracking fraction has not the "puffy" character of pneumonic crepita-The chief difference, however, consists in the fact that in an ordinary of pleurns the abnormal physical signs are found both at the back and front of the affected side. In pneumonia there is no displacement of the heart's apex; the dulness is not complete; the sense of resistance, although greater than natural, is only moderately increased; the resonance of the voice at the angle of the scapula is never ægophonic; and the physical signs, unless the inflammation occupy the apex of the lung, are limited to the anterior or posterior aspect of the chest, and are only in

very extreme cases found over the whole of the affected side.

Between an ordinary case of pleuritic effusion and an ordinary case of lobar inflammation of the lung the differences are so great, that there is little difficulty in making the distinction. But to decide between a localised pleurisy and a case of lobar pneumonia is not so easy. Still, even here, by attention to the mode of invasion and the character of the symptoms, and by remarking that, although limited to one aspect or one region of the chest, the percussion-note is completely toneless, the sense of resistance is extreme, and the weak breath-sound is not accompanied by crepitation at the borders of the dull area (for, in localised pleurisy friction is rarely to be heard), we can usually come to a satisfactory conclusion. The very fact of these physical signs continuing for a considerable time unchanged is in itself a strong argument in favour of the pleuritic nature of the complaint. Dr. Wilks, indeed, lays it down as a rule that local dulness with distant tubular breathing, or absence of breath-sound, persisting after an inflammatory attack in the chest, indicates the presence of a local empyema; and if no adventitious sounds accompany the respiration, we may, no doubt, commit ourselves to this diagnosis without hesitation.

Ordinary cases of catarrhal pneumonia, where the inflammation occupies both lungs, can rarely resemble pleurisy closely enough to be confounded with it. Unless the catarrhal pneumonia be accompanied by plastic pleurisy, the percussion-note is only moderately dull; the resistance is httle increased; there is usually loud tubular or cavernous breathing at the extreme base from dilatation of the brough; and the profuse crepitation has a crisp metallic quality which bears little resemblance to the sound produced in an inflamed pleura. It is in cases where the catarrhal inflammation occurs secondarily in a lung which is already the seat of fibroid induration that a real difficulty is found. Here the inflammation is confined to one lung and spreads rapidly, so as to involve the whole thickness of the Consequently, the lung, already indurated by the fibroid change, gives a character to the percussion-note which is indistinguishable from that produced by pleuritic effusion; and we find a complete, toneless dulness with marked sense of resistance all round the affected side -- both at the back and front. In the indurated lung, however, the tubular or cavernous breath-sound is accompanied by a large metallic bubbling rhonchus. In pleurisy the breathing is usually accompanied by no adventitious sound: but if a little crepitating friction be present, it is much drier in character, and has not the loud ringing resonance which is given to a rhonchus generated in a rigid dilated air-tube. In both the vocal resonance may be bronchophonic, but in pneumonia it never has an agophonic quality.

Collapse of the lung in exceptional cases may present a very close resemblance to pleurisy; but the dulness on percussion is rarely so complete, and the sense of resistance seldom so great in collapse as in fluid effusion. The resistance in the latter case to the percussing finger is an element of the utmost importance in the diagnosis, and is only equalled in point of intensity by a fibroid induration of the lung with superadded catarrial

pneumonia, as already described.

With regard to the varieties of pleurisy, it is often very difficult to say whether the fluid is serous or purulent, or, indeed, whether the physical

signs are not due to a coating of lymph without liquid effusion at all. If a change in the percussion-note and the character of the physical signs follows a change in the position of the patient, the presence of fluid is placed beyond the possibility of doubt. But if no such characteristic sign of fluid can be discovered, it is no proof that fluid is not present. The offusion may be kept in place by adhesions, or there may be sufficient lymph coating the pleura to produce a dull percussion note, although fluid be no longer in contact with the wall of the chest at the point of examination. An a gophonic resonance of the voice is a certain sign of effusion; but its absence is by itself no sufficient proof of the absence of fluid. If, however, the outline of the affected side be elliptical and the heart's spex in the natural position; if the intercostal spaces sink in normally, the percussionnote be dall in all changes of position, the respiration be weak over the affected si le without blowing quality, and the vocal resonance not at all regophonic, it is almost certain that no fluid is present. Even here, however, no passive conclusion can be arrived at, for with such signs there may be an enersted collection of pus at almost any part of the chest.

The distinction between a serous and a purulent effusion is very difficult. No information can be gained from the temperature, for this may be elevated or not without reference to the character of the fluid. It is often high with a serous effusion and perfectly normal with a large purulent collection in the chest. Again, the physical signs are the same whatever be the nature of the pleural contents; for Bacelli's sign (i.e., the clear and articulate conduction of the whispered voice to the chest-wall as indicative of serous and evolusive of purulent effusion) has not infortunately the value attributed to it by this physician. The tint of the face, however, if the complexion have assumed the straw yellow hue, although not a decisive proof, is very suggestive of empyema; and marked clubbing of the fingerends, according to Dr. T. Barlow, is never the consequence of serous effusion. In every case of doubt an exploratory puncture with the hypodermic injection syringe, by withdrawing a specimen of the fluid, will at once

decrete the question.

Hydrothorax is as a rule readily distinguished from pleurisy by noting the evidences which are always present of interference with the general circulation. Dropsy of the pleura is almost always a part of general anasarca. There is disease of the heart or kidneys; the effusion occurs on both sides annultaneously; and there is also ascites or more or less general cedema.

Prognosis.—In cases of pleurisy the prognosis depends in a great measure upon the age and constitution of the child. Under the age of six months the disease is a very serious one, and often ends in death. After that early period the prognosis is good, as a rule, if the child be not the subject of a disthetic taint. The scrofulous habit is, however, a distinctly unfavourable element, for although the disease may eventually end happily, the fluid tends to become quickly purulent; the febrile excitement is usually great; interference with nutrition is marked; and not unfrequently the fluid is continually reproduced as often as it is evacuated.

If the fluid remain serous, recovery is certain unless the fluid accumulate to such a degree as to dislocate the heart and interfere with the passage of the blood through the large vessels. In such cases death may occur unless the child be rapidly relieved by operation. When the fluid has become

It may be observed, with regard to making exploratory punctures, that the operation is less painful if a spot be selected where the skin is thin, as in the axilla, than if the accedir be introduced in the back, where the cutis is thick and resistant.

purulent the prospect is more serious, but less so in childhood than is after years; for if proper measures be adopted a large majority of these cases recover. A high temperature is an unfavourable sign, and the continuance of the pyrexia after discharge of the purulent matter by operation should occasion great anxiety. Still, even in these cases recovery one follows. Again, the sudden sinking of the temperature to a point below the level of health is, as Wunderlich has pointed out, a sign of unfavourable import.

If the empyema burst spontaneously through the chest-wall, recomparely takes place unless the opening be seated in a lower interestal space, or unless an artificial opening be established in a more suitable position. Spontaneous cure is more likely to follow evacuation through a bronchus; and a large proportion of these cases get well. Still, if the creamstances are such that retention of purulent matter takes place, the

child, if left alone, may sink exhausted.

Fetor of the pus is a bad sign. Unless prompt antiseptic measures as

adopted, these cases always end fatally.

Secondary pleurisy is much more dangerous than the primary form of the disease. The fluid is more likely to become purulent at an early date, and the child, already weakened by his first illness, is in an unfavourable condition to support the exhausting influence of a chronic empyona open his nutrition.

Treatment.-A child attacked by acute pleurisy should be at once part to bed, for absolute rest is of the highest importance. A febrifuge unture should be ordered, and the diet should consist of milk and be the If the pain in the side be severe, a leech or two may be applied if the cha! is robust; or a hypodermic injection may be given containing one-trellab of a grain of morphia for a child of four years of age. A firm banks round the chest is often successful in giving great rehef; and a thick layered wadding around the affected side is useful for the sake of warmth. Some physicians advocate a careful strapping of the chest over the affected has with broad strips of adhesive plaster. I have made use of this plan, but cannot say I have noticed any distinct advantage from its employment in diaphragmatic pleurisy where the pain is severe, a firmly applied baring to the abdomen, so as to limit the action of the displaragm, often affirb ease. The bowels, if confined, must be relieved by mild aperious, set as the liquid extract of rhamnus frangula or the compound liquotes powder; but violent purgation is hurtful and should be avoided. Meecury, the favourite remedy in former days, is now seldom recommended Still, in some cases, one grain of gray powder given twice a day with an equal quantity of quinine, or with five grams of the percende of iron be sometimes seemed to me to be beneficial. Indide of potassium is, however usually to be preferred, and this salt, given in full doses, I believe to be d distinct advantage to the patient. I am in the habit of ordering fors child of four years old, five, eight, or ten grains of the iochde, to be taken every six hours, and look upon the remedy given in such doses as a valable promoter of absorption. The internal remedy should be always any plemented by counter-irritation of the chest-wall. Directly the tempers ture falls, or earlier if effusion appears to have ceased, the heiments tincture of iodine (according to the sensitiveness of the skin) shad! to painted over a limited surface every night. This application is in at usful if applied over an area of two or three inches in diameter-repainted the same on each occasion. When the skin begins to look dry and crackel another spot is selected, and the process is repeated regularly as before

If after a week, the fluid remains stationary, without sign of absorpa it is better to clunge from the include to a chalybeate, or to add five an errors of the tartrate of iron to the mixture. In scrofulous children, an effusion has ceased, it is advisable to improve the diet; and pounded at strong ment broths, yolks of eggs, and inoderate quantities of stim-

at are usually required.

If at the end of a fortnight the effusion has been unchanged in amount, a probably purulent. An exploratory puncture should be made with a needle syringe, and if pus be withdrawn, measures should at once been to avacuate the chest. If the fluid is found to be serous it is adable to wait for a few days, for this small operation and the abstraction even the limited quantity withdrawn by the test puncture, may act as a nulus to absorption and be followed by the rapid removal of the fluid natural means. At the same time the quantity of liquid taken by child should be restricted; for a dry diet in such cases by stinting blood of fluid often greatly promotes the action of the absorbent

Often when effusion is undoubtedly present the introduction of the loring needle is followed by no appearance of fluid; or although pustoen withdrawn by the test puncture the aspirator needle is introced without any result. The instrument may have entered the chestity at a spot where the lung is adherent to the parietes, or the layer false membrane lining the pleura may be so thick that the needle to penetrate into the sac. In choosing a place for the puncture is advisable to select one where the dulness is complete; and it is layer and a place of the intercostal space, as here the false membranes are scanty if thin. Often it is necessary to puncture several times, on each occurs selecting a fresh spot, before we succeed in obtaining evidence of the

In some cases the difficulty met with in withdrawing the fluid is due to play of the chest-walls. If the walls of the empyema cavity cannot lapse, there is no expolsive force to drive out the fluid. As Mr R. W. wier has pointed out, the pleural cavity is emptied by the pressure of amosphere acting in three different ways. It acts on the condensed a causing it to re-expand, on the displaragm causing it to ascend, and a the thoracic wall causing it to fall in. If for any reason pressure cannot be brought to bear on the confined fluid, no amount of suctem force have any power of with-frawing the liquid contents of the chest. In at a few cases, the aspirator being found to be useless and no fluid aparts of druinge-tube in order to evacuate the pleural cavity. Mr Parker levised an apparatus to meet this difficulty, by means of which filtered, and carbolised air can be pumped into the upper part of the chest has done passes out through the aspirator needle introduced into the

The above are not the only causes by which thoracentesis is rendered foult. Large thick thikes of lymph may be present and obstruct the mag of the needle or drainage-tube. A child, aged one year and eight with was admitted under my care into the East London Children's capital, with the physical signs of a large effusion on the left side of the Au exploratory puncture showed pus to be present. Many attempts invite to aspirate the chest, but only small quantities of pus could be the leave. After repeated failures it was determined, in consultation with

my colleague Mr. Parker, to incise the wall and put in a drainage-tube. This was done, but even then pus did not flow freely. Mr Parker then put in his finger through the opening in the chest-wall and found large flakes of thick membraniform lymph which had to be removed by the forceps. A large quantity of pus was then expelled, containing smaller flakes of lymph, besides pultaceous matter. Listerian precautions were observed and the case did well.

When the effusion of fluid has accumulated to such a degree as seriously to hamper the circulation and produce a cyanotic tint of the skin, the impirator should be used at once, as instant relief is required to avert death. If, however, the effusion be more moderate and no danger be anticipated, the question of operative interference will depend upon the nature of the pleurid contents, and the presence or absence of signs of absorption. If the fluid be purulent there is no likelihood of a spontaneous cure by absorption. Therefore retention of the purulent contents can in any case only do harm; and in children with tubercular or scrofulous tendencies a collection of pus should not be allowed to remain in the cliest a day longer than is necessary. Even if the fluid be still scrous, it is well to remove it if after three weeks no sign of absorption has been noticed. In many of these cases the scrous fluid is not renewed after emptying the chest; and often if only a portion of the contents be evacuated the remainder is rapidly taken up by the absorbent vessels.

In cases of empyema it is best in the first instance to employ the aspirator, as sometimes after the chest-cavity has been evacuated by this means the fluid is not reproduced. During the operation the child should be in a semi-recumbent position, supported by the nurse, and the needle should be introduced, as recommended by Bowditch, in an interspace immediately below the inferior angle of the scapula, unless the empyema be loculated. The operation often provokes cough; but this may be disregarded unless it grow excessive, in which case the needle may be withdrawn. If there he any sign of faintness, we should at once remove the aspirator and close

the wound.

Sudden death, although fortunately a very uncommon catastrophe, is sometimes a consequence of the rapid withdrawal of fluid from the chest. The accident may arise from syncope, from rapid interference with the function of the healthy lung, or from cerebral embolism. If the effusion have been copious enough to produce marked cardiac displacement and interfere with the circulation through the large vessels, the muscular substance of the heart may be in a state of temporary mal-nutrition from having been supplied for some time with imperfectly purified blood. The sudden withdrawal of the pressure, combined with the slight shock of the operation, may so impress the weakened organ as completely to paralyse its action; or if this be borne without result, a sudden movement of the patient which throws extra work upon the circulatory centre may prove fatal.

Death sometimes occurs through asphyxia. The disappearance of fluid from the pleura is followed by an afflux of blood to the capillaries not only of the lately compressed lung, but also of that on the sound side; for the latter has been likewise relieved from pressure by the return of the heart and mediastinum to their normal position. If the afflux of blood becomes a distinct congestion, acute codema may result, unless the vessels retain sufficient tonicity to enable them to resist the abnormal pressure. Again, cerebral embolism may occur, as in a case reported by M. Vallin, in which this observer attributed the catastropho to the sudden disengagement of

fibrinous clots which had formed in the pulmonary veins of the affected so by. Such clots are hable to become detached as a consequence of exponent of the lung, of a sudden movement, or of washing out of the pleutral civity.

If after one or more applications of the aspirator we find that purulent is always reproduced, or if the fluid withdrawn is fetid, it is better to raide an opening in the chest and introduce a drainage-tube. Opinions are divided as to whether a single or double opening is to be preferred. It a single opening allows of perfect evacuation of the pleural cavity, it seems to be preferable to a double aperture, for the drainage-tube passing from one opening to the other may, as Dr. Allbutt has suggested, act as a set on and keep up a constant irritation. If a single opening be made, the spot selected should be at some point on a level with the lower angle of the scapula. One end of the drainage-tube should be passed through the opening, and the other may be allowed to dip into a large bottle half full of water. The operation should be performed with antisciplic precautions. If chloroform be given, great care must be exercised in its administration. It is better to do without aniesthetics and produce local insensibility by

freezing the skin at the site of the operation.

After the tube has been inserted the chest should be bound round with an antiseptic bunder, and the pleural cavity may be left to drain itself. It will not be necessary to wash it out with disinfecting solutions unless signs of decomposition have been noticed. If, however, the pus which flows after the operation is fetid, injectious of a solution of iodine may be emplayed, diluting one drachin of the tincture with one ounce of water; or carbohe acid may be used diluted with thirty times its bulk of water. This measure will not be required when the pus continues to be perfectly sweet. In such cases the introduction of antiseptic solutions seems to keep up an irritation which it is desirable to avoid. Moreover, the operation is usually distressing to the patient, and is not without danger, for syncope and other alarming symptoms have sometimes been seen to follow the intro luction of the fluid. In cases where the empyema is fetid, Mr R. W. Parker recommends a double opening to be made in the chest-wall through which the drainage-tube can be threaded, and prefers, to injectious of an antiseptic fluid, placing the child daily in a warm bath with sufficient depth of water to cover the upper opening. The water can be medicated, if desired, by a weak antiseptic solution. It is needless to say that all instruments used in operation upon such cases should be scrupulously clean and be carefully disinfected before use.

Complete drainage of the cavity is followed in most cases by great improvement in the condition of the child. His temperature, if it had been elevated falls; his appetite improves; and if diarrhee had been present, the stools become fewer in number and much healthier in appearance. Anyafter-elevation of the temperature or return of the signs of distress and irritation should lead us to suspect some retention of fluid in the pleural cavity, or the ons-t of some complication, such as a secondary tuberculosis. In the first case it will be well to wash out the chest thoroughly. In the second, special measures must be resorted to for the treatment of the complication. If secondary tuberculosis have come on, the prospects of the child are most gloomy, and little can be done to arrest the downward progress of the dis-

C. 625G.

In cases where the above method of drainage fails to bring about closure of the cavity, owing to imperfect expansion of the lung or rigidity of the chest-walls, which are slow to adapt themselves to the diminished size

of the organ, resection of a portion of the rib seems often to be of alms-

tage in helping the disease to a favourable termination.

In all cases of chronic empyema the strength of the child should be apported by a free supply of nourishing food. Meat (pounded if necessary) strong meat essence, milk, eggs, etc., should be given in quantities such a the patient can digest; and port wine, St. Raphael tannin wine, or the brandy-and-egg mixture should be offered in sufficient doses. Codime oil is also, especially in children of scrofulous constitution, an important addition to the treatment.

CHAPTER VII.

COLLAPSE OF THE LUNG.

charge of the lung is a common lesion in infancy. In some new-born the the lungs after birth are imperfectly expanded so that the alveolity a larger or smaller area remain closed as in the feetal state. This arety is called congruid attrictions. In other cases, although perfect expansion has been effected after birth, and the respiratory functions have for thoroughly established, collapse is induced in the lung as a consequence of disease, and a tract of variable extent becomes again condensed districts. The latter lesion, which is called post-natal attrictors is more muon than the former, and indeed is one of the most familiar of pulconary lesions in the young child. These varieties will be considered parately.

CONGENITAL ATELECTASIS.

This variety of pulmonary collapse was first described in the year 1832. Dr. Edward Jong, who gave it the name which it still retains. Congenial atelectasis rarely occurs except in feeble infants, such as have been an prematurely, or are the offspring of weakly mothers, or have entered a under conditions unfavourable to the efficient establishment of the restratory functions. A tedious labour producing long compression of the old; too energetic uterine contractions causing a too early separation of placenta from the womb; a low temperature of the external air; a high imperature with imperfect ventilation and deficiency of oxygen—the imperfect expansion has been attributed to all these causes. In addition, the essence of mucus or fluid in the air-tubes may act as a direct mechanical impediment to the entrance of air and prevent the inflation of a part of the monary tissue.

Morbel Anatomy.—On inspection of a lung which is the seat of this is on the unexpanded portion is at once recognised by its dark red or implish colour, contrasting with the rosy tint of the inflated tissue. Bespecietly airless, it looks shrunken and depressed, does not crepitate the squeezed, and feels tough and dense like soft leather. If a portion cut out and placed in water, it sinks instantly to the bottom of the cells may be visible; but if the child have survived for some weeks, it vesicular structure can often hardly be perceived. The parts of the lag which thus remain airless after birth are most commonly the least like portions, such as the thin lower borders of the lobes, especially the ferior lobes and the middle lobe of the right lung. Often, however, the lapse is not contined to these parts, but extends for some distance over posterior surface, and penetrates pretty deeply into the organ.

If the child die early, the unexpanded lobules can be readily inflated or death by a blow-pipe passed into the bronchus; but if life has been

prolonged for a period of weeks, re-inflation is not so easy and may only be effected by the expenditure of considerable force.

In cases of congenital atelectasis other parts besides the lungs often remain in the foctal state. The foramen ovale is usually open, and perhaps

the ductus arteriosus may still remain unclosed,

Symptoms. - In a new-born infant, when expansion of the lungs is imperfect, the child is usually small and ill-nourished. His appearance and manner show great want of power, and his muscles feel soft and flably. His complexion is dirty white or pale, with lividity about the cyclids and He lies quietly without movement, and seems very apathetic, soldom attempting to cry. If he do, he utters only a feeble whimper and never makes a loud sound. Often he merely draws up the corners of his mouth without making any sound at all. The fingers and toes are of a dark red or purple tint, and feel cool to the touch; indeed, the interpal temperature of the child is below the normal level, and often reaches only 97.5 in the rectum. The respiratory movements are not laboured, or the contrary, they are shallow and short, and evidently expand the clest very imperfectly. As in all cases where the bases of the lungs fail to expand in a young child, the corresponding ribs sink in to a certain extent at each inspiration. Still, on account of the feebleness of the inspirator movements the depression at the bases is less noticeable than it is in some other diseases. When put to the breast the child is unable to suck, all has to be fed with a syringe or a spoon. Sometimes he cannot swallow. The pulse is very feeble and the fontanelle is more or less deeply depressed. A warm bath seems to revive the child for the time, and even gives a little colour to the skin; but after removal the infant sinks into his former as-

An examination of the chest furnishes little information. If the unexpanded area is small, we may detect no sign to indicate the nature of the lesion. There may be a little want of resonance at the bases of the lungs posteriorly; but on account of the small size of the thorax at this period of life, and the facility with which sounds are conveyed from one part to the other, the vesicular murmur may appear to be as loud at the bases as at any other part of the chest. It is only in cases where the collapse is very extensive that any suppression or alteration of the respiratory sound can be detected.

The after symptoms vary according to the extent of the useless pertion of the lungs. If this be considerable, the weakness continues; the breathing remains shallow and short; lividity increases; the eyes are motionless; the pupils dilated, and the skin is cool. Soon the temperature falls still further, twitches and spasmodic movements are noticed in the face and limbs, and the child sinking into a state of stupor, dies asphyxiated on the

second, third, or fourth day.

In the less severe cases, or in cases where judicious treatment has succeeded in increasing the area of inflated tissue, the child at first may seem to be going on well, although he never exhibits in his movements the vigour of one whose lungs are well expanded. His movements are more or less languid, and he sucks feebly or cannot be persuaded to take the bottle or the breast. After a time he seems to grow weaker and can only be kept warm with difficulty. His respirations get more and more shallow and his cry feebler. The child is always sleepy, and lies dosing with had mouth and eyelids, the latter often incompletely closed. The fontanelle is depressed. From this point he may sink gradually and die after a series of convulsive fits, or may be roused by energetic treatment which

again inflates the closed air-cells. But in such a case, although the child may be apparently restored, the unfavourable symptoms usually return, and it is rare for the patient to recover. In most cases after a time remedies seem to be useless and the infant can no longer be revived. Thrombosis of the cerebral sinuses, according to Stiffen, is often found in these cases.

Even in cases where recovery is apparently complete, the lung is not always perfectly expanded, and a slight catarrh may cause sudden and unexpected death. Mr. W. Burke Ryan has related the case of a child, aged five weeks and in good condition, who one evening was noticed to cough, and the next morning died quite suddenly. On examination of the body, both lungs were found to be shrunken and firmly contracted so as to leave the greater part of the pericardium exposed. They sank instantly in water; and when cut into little pieces, not the smallest bit floated. An examination with a small lens showed no trace of cellular structure, and an examination by Mr. Quekett of small sections with a higher power discovered many of the alveoli to be filled up by small granules or cells which rendered them solid.

Cases of congenital atclectasis which recover completely are usually those in which energetic treatment has been adopted within a few hours of birth and has resulted in healthy inflation of the whole lung. In the beginning this may be often accomplished; but delay leads to such change in the closed air-cells that they can be rarely sufficiently inflated to take useful part in the respiratory process. Moreover, from the observations of F. Weber and Stiffen, it appears that in cases where the child survives with permanent atc-cetasis of a portion of the lungs, the constant obstruction to the pulmonary circulation leads to hypertrophy of the right side of the heart, prevents the closure of the foramen ovale and ductus arteriosus, and may eventually induce hypertrophy of the left auricle and ventricle.

Despuss. The history of these cases reveals a constant state of weakness and torpor. This want of power, combined with hydrity of the face, inability to suck, shallow breathing, and low temperature, is very suggestive. If in addition we notice the aigns and symptoms of imperfect expansion of the chest, and on a physical examination fail to find evidence of marked consolidation, we can have little difficulty in ascribing the symptoms to

their true origin.

Promotes—The prospect of recovery depends partly upon the cause of the atelectasis, partly upon the strength of the child, and partly upon the period after birth at which restorative measures are adopted. If the imperfect expansion of the lungs be due to some obstacle in the tubes themselves, or to some temporary accident occurring at the time of birth, the child's strength is usually good and treatment employed promptly is generally successful. If, however, means are not adopted early to enforce expansion of the unused alveoli, the prognosis is little less unfavourable than when the atelectasis is due to general weakness of the patient. In the latter case the chances of permanent improvement are not good, but vary according to the strength of the child. The unfavourable signs are: inability to suck; increasing livibity; a sub-normal and falling temperature and great apathy of manner. If the child ceases to be able to swallow, or if tonic or clonic spasms are noticed in the muscles of the face or limbs, we can entertain little hope of his recovery.

Treatment When a child is born apparently lifeless after a tedious libeur measures must be at once adopted to promote efficient expansion of the lungs. It is important, however, that whatever is done should be done with due deliberation and care, avoiding unnecessary hurry or vio-

lence. In a new-born infant the organs are especially tender, and men te fatally injured by heedless energy. Cases have been met with in start the liver and spleen have been ruptured by an over-zealous practicated his haste to promote inflation of the lungs. The chest of a new-on infant is in a state of absolute airlessness; and therefore methods of the citation which depend for their success upon elastic recoil of the chewalls are without any value. So, also, the method of mouth-to-and insufflation, pressing at the same time the larynx backwards agains the gullet so as to close the latter passage, fails to introduce air into the hand Dr. F. H Champneys, from a series of elaborate experiments upon the bodies of new-born infants, concludes that the best method of respectives is that of Dr. Silvester. The child is laid on his back on a take witt i pillow under his shoulders, and the operator standing behind the bolgrasps the arms above the elbows and everts them. He then in success: movements raises the arms upwards by the side of the child's lead extends them gently upwards and forwards for a few seconds, then tenthem down and presses them gently and firmly for a few moments are as the sides of the chest. While this is being done the tongue should be adforwards by an assistant. The movements should be repeated fifteen tacin the minute, and should be continued for at least half an hour if to alfactory result be previously obtained.

M. Greult advocates placing the infaut in water as hot as the hard on bear which he finds to be about 113 F. -and employing artificia to piration while the child remains in the bath. He relates the case of primipara who after a tedious labour was delivered by forego I infant, when born, was breathless, cold, with scarcely any movement of the heart and but feeble pulsation in the cord. The child was at ouce that in water which felt burning hot to the hand, and artificial respirate and begun. At the end of one minute the skin reddened, and a slight name ment of the chest indicated the beginning of respiration. At the end if two minutes the child began to cry, to breathe, and to move his hala

In cases where the infant breathes, but is evidently labouring under imperfect expansion of the lungs, he should be warmly covered or es-1 wrapped in cotton wool, and kept perfectly quiet in a room heated to a telperature of 70 ' or 75." The best position is that recommended by the at-Dr. C. D. Merga viz, upon the right side with the head and shower raised at an angle of 45. If the patient cannot suck he should be frow the breast milk or some efficient substitute, as directed elsewhere use too 603). The food must be given with the syringe and clastic tube (see 16.2) Stimulants are indispensable. Five drops of brands can be _____ in a syringeful of the food every two, three, or four hours, or the et al. in be fed with white wine whey. If the hyddry mcreases and other units, at able signs are noticed, attempts should be made to force the chall to engasp by slapping the chest with the corner of a towel wetted nith water. Emetics are also useful in freeing the tubes of mucus and fee ... the patient to respire deeply. Sulphate of copper in quarter of a zero in a teaspoonful of water) is the best form in which they can be given Emetics, however, must not be used if the child is very feel-le-

Stimulating embrocations rubbed into the chest are often of service sel immersion in a strong mustard bath (one ounce of mustard to each gales of water) until the skin becomes very red is a stimulant of very peaced. efficacy. The internal administration of stimulants should be continued long as the cluld is able to swallow. Unfortunately in bad cases the results

of all these measures are far from encouraging.

POST NATAL ATELECTASIS.

The form of collapse of the lung which occurs in infants whose lungs have been fully expanded at birth is a very common lesion. It occurs almost invariably in the course of a pulmonary catairth, and is one of the accidents which render this form of derangement so fatal in weakly or

rickety children.

t amaton. - The immediate cause of collapse of the lung is the presence in the bronchial tubes of mucus which the child is unable to expel by reason of feebleness of the respiratory apparatus. Dr. Gairdner, of Glasgow, in his treatise explains very clearly the mechanism by which exhaustion of the lobules is effected. In the act of inspiration a plug of muchs is carried inwards along a tube the calibre of which is constantly diminishing. When the narrowness of the tube prevents further advance, the mucus forms a plug which completely obstructs the channel. During expiration the plug is slightly dislodged so as to permit of the escape of some of the air contained in the lobule; but at each inspiration it is again drawn backwards so as to close the tube completely against any air entering to replace that which has just escaped. In this manner after a time the lobules beyond the point of obstruction are completely exhausted and the tissue becomes shrunken and condensed. Even if the plug of mucus be completely unpacted in the tube so that it cannot be dislodged during expiration, collapse may still occur, for the pent-up air in the alveoli is exposed to such pressure by the elasticity and contractility of the alveolar parieties that it is absorbed.

The retention of mucus in the tubes is the consequence of inability to cough it away, and any cause which diminishes the energy of the inspiratory act increases the difficulty of drawing in air past the impediment in the bronchus New-born infants do not know how to cough, for the act of coughing is only purtly involuntary. It is in part an effort of volition to remove an obstacle to the free passage of air in the tubes. An infant who has not acquired a knowledge of the means by which the impediment may be expelled, suffers the obstruction to remain without employing the necessary force to effect its removal. Even if the child knows how to cough, he may not have the power to carry out the act with sufficient energy to make it effectual. In the act of coughing a full inspiration is first taken. The glottis is then closed, and pressure is brought to bear upon the lungs by the muscles of expiration. While this pressure is at its height the glottis is relaxed, and the rush of air passing out carries with it the mucus which was obstructing the tubes. If, however, the lungs cannot be sufficiently filled, or if, owing to weakness of the patient, the force of the expiratory muscles is insufficient to bring adequate pressure to bear upon the lungs, the cough is ineffectual in freeing the tubes of their contents.

Weakness of the inspiratory act is a powerful agent in preventing the entrance of a sufficient supply of air. In ordinary respiration the elasticity and contractility of the lung have to be overcome by the muscles of inspiration. If these muscles are feeble, as they are in a weakly infant, the obstacle to efficient indation of the lungs is already great. If, however, in addition, the respiratory muscles are opposed by reflex contraction of the bronchial muscles, owing to the irritation of the catarrhal process, and also by mucus in the tubes, they may prove quite unequal to the task. Therefore any cause which increases the child's general weakness predisposes to pulmounty collapse. Thus vomiting, diarrhea, insanitary conditions, im-

30

proper feeding, and all the exhausting forms of illness may have this result.

Besides the causes which have been enumerated, the force of the inspiratory act may be weakened by mechanical means. Interference with the action of the diaphragm may have important consequences in this respect. This influence is especially seen in the case of young infants. For some time after birth respiration is principally diaphragmatic on account of the circular shape of the chest, which allows of little lateral expansion. Therefore any resistance to the descent of the diaphragm, such as would be produced by ascites, or great increase in size of the abdominal organs, or flatulent distention, may so weaken the force of the inspiratory act that a very trifling catarrh determines wide-spread and fatal collapse of the lung.

Another mechanical means by which the force of the inspiratory act may be interfered with is deficient rigidity of the chest-wall. Abnormal softening of the ribs is a very important agent in the production of collapse, and the frequency and danger of the lesion in rickety subjects is mainly owing to this simple cause. The paracties of the chest in the infant are naturally more flexible than they are in the adult. Even when the ribs and their cartilages are perfectly sound, considerable recession of the lower ribs may be seen at each inspiration if an impediment exist at any part of the air-passages to interfere with the ready entrance of air into the lung. If the ribs are softened, as in rickets, the same recession is noticed although the passages may be perfectly free; for the softened ribs cannot resist the pressure of the atmosphere, and the force of the inspired air is insufficient by itself to prevent the thoracic paractics, where least supported, from sinking in. Consequently in this disease the lower lobes of the lungs are very insufficiently filled with air. If such a child suffer from pulmonary catarri, the additional obstacle to efficient inspiration created by the mucus in the tubes may lead to complete collapse of the inferior parts of the lungs. On account of the mechanism by which it is produced, collapse of the lung must always be a secondary lesion. It is found as a complication of various forms of illness. Diseases of which pulmonary catarrh is a common symptom, as whooping-cough and measles; diseases which interfero directly with the passage of air through the glottis, as diphtheria, laryngitis stridulosa, post-pharyngeal and other abscesses in the neighbourhood of the larvax; diseases which diminish the force of the inspiratory act, either by mechanical opposition as in abdominal tumours and rickets, or by impairing the muscular strength of the patient-in all these cases collapse of the lung is liable to be found.

Morbal Anatomy.—The extent of the collapsed area is in proportion to the calibre of the tube at the point of obstruction. According, therefore, as the lesion involves many lobules over a considerable surface, or is limited to a few, the collapse is said to be diffused or lobular. The airless part of the lung is shrunken and therefore depressed. It is purple in colour and to the touch feels soft and dense. It does not crepitate. On section the surface is smooth, and blood or bloody serum exudes on pressure. Around the collapsed portion the air cells are emphysematous.

Lobular collapse is often situated at the anterior edges of the lungs, but may occupy any other parts. The diffused variety is most common at the posterior surface, but may be seen elsewhere. It penetrates for a variable distance into the organ, and sometimes an entire lobe or even the greater part of the lung may be found shrunken and airless. After death, if the lesion be recent, the collapsed tissue can be completely reinflated through the bronchus.

Symptoms.—The symptoms are found to vary considerably in different sex according to the extent of the collapse and the degree of strength of potient. In a very weakly infant rapid and extensive collapse is often cruse of sudden death. In such cases the preliminary catarrh is not severe. Often, indeed, it is trifling; and the rapidity with such death occurs gives rise to much surprise and consternation. apaction in a large bronchus of a single plug of mucus may be thus folwell in a young and feeble subject by rapidly fatal consequences. An-Dir common result of the lesson is a convulsive seizure; and sometimes he fits succeed one another with great rapidity, each attack increasing the measurement of the patient and aggravating the pulmonary mischief until esth ensues. These cases are not, however, always immediately fatal. is a sensitive child collapse of comparatively limited extent, if it occur plicity, may gave rise to an eclamptic seizure; but this may not be reparel, and perhaps by judicious and energetic treatment the clukl's life hav be mived

Such severe symptoms are, however, exceptional. In most cases the securence of collapse is indicated by less striking phenomens. A weakly latt is suffering from the ordinary symptoms of bronchial entarch. He coughs more or less loosely and his breathing is moderately hurried, but there is nothing to excite apprehension. Suddenly, however, a change occur. The child becomes restless and evidently distressed; his face gets districtly livid, especially about the eyelids and mouth; his breathing, which had been more laboured than natural, increases in rapidity but dimenshes in depth, the cough ceases or is feeble and faint; and the intercease in reportative of the body is found to be below the level of health.

The face usually indicates profound depression. The features look peoched; the eyes are dull and hollow; and the forehead is often most with a cool, claiming perspiration. The naives act in respiration, and the breathing is very impal. The number of respirations commonly reaches for so in the minute, and the perversion of the pulse-respiration ratio is extense. In very young infants the breathing is usually very shallow, with little movement of the chest-walls; but in infants eight or nine with old, whose ribs are softened by rickets, the bases of the chest sink in to some extent at each inspiratory movement. The child refuses to suck the late, seems to have difficulty in swallowing, so that he can hardly be

presiled to take milk from a spoon.

The physical signs, if any are to be discovered, consist in slight dul
signs at the posterior base of one lung, or extending upwards in a narrow

verteal strip at each side of the spine. The dulness can often only be

discovered by very gentle procussion, as a sharp blow with the fluger brings

out the resonance from healthy tissue underlying the condensed layer.

The breathing conducted from healthy tissue around is of bronchial quality,

that may be weak or family loud, according to the strength of the respiratory

strength. Vocal resonance is usually annulled. Sometimes coarse crep
flation, a heard at the confines of the collapsed area. These signs are only

to be becovered when the lesion is of the diffused variety. In lobular col
lapse my dulness which may be occasioned by the presence of the soludi
the law is neutralised by the compensatory emphysema set up in their

out the posterior base of the compensatory emphysema set up in their

out the posterior base of the compensatory emphysema set up in their

When the above symptoms and signs are noticed, the infant's condition itery serious one; and unless prompt measures are taken to excite explain of the collapsed tissue and expel the obstructing mucus, death must mentably ensue. The lividity increases or changes to an asby hue,

the breathing grows more and more shallow, and the child dies in a state

of stupor from slow asphyxia, or expires in a convulsive attack.

In children over a year old, who are not the subjects of rickets, the symptoms are usually less severe, and the physical signs more nearly resemble those which exist under similar circumstances in the adult. If the ribs are softened from rickets, the impediment thus ruised to efficient inspiration greatly aggravates the effects of limitation of the respiratory surface, and in children as old as two or three years the signs of suffering are well marked. If, however, the chest-wall preserves its normal rigidity, the symptoms are much less characteristic. The respiration may be hurried. although this is not always the case, and the complexion may allow some signs of deficient aëration of the blood; but the child is not prestrated by the lesion; he can cry fairly loudly, and his cough is not suppressed. On examination of the chest, we find dulness of variable extent on one side, usually at the base; the respiration is weak and harsh over the same area with absence of vocal resonance, and large moist rules are heard about the back. In some cases, as when the collapsed area immediately surrounds a large bronchial tube, the rhonchus may be metallic and ringing as if produced in a cavity.

If the lesion occupy the apex, the breathing is often loud and bronchial or blowing, and the dulness may be complete. In this situation collapse is very likely to be mustaken for consolidation arising from other

causes.

A rickety little boy, aged eighteen months, who had cut only sixteen teeth, was being treated in the Past London Children's Hospital for chronic diarrhora arising from ulceration of the bowels. The chest was not deformed and there was no softening of the ribs. An elder sister had died in the hospital from tubercular peritonitis. About a week after the child's admission he began to cough, and in a few days it was noticed that the percussion-note at the right supra-spinous fossa was decidedly high-pitched, and that the respiration there had a faint bronchial quality. There was a little coarse hubbling about the back on each side. The temperature had been generally about 100° at night, sinking to 99° in the morning. The pulse was 96–100; the respirations 26–30.

Some days afterwards dulness at the right apex behind had become complete, and the breathing was bronchial with a click in the middle of inspiration. In front the percussion-note was quite healthy. The moist riles over the back persisted. Temperature in the evening, 99°-100°; pulse, 80-102; respirations, 20-30. All the time the diarrhola centimed and the child wasted rapidly. There was more or less general orderna. The urine was albuminous and contained renal epithelium. A few days

afterwards the child died quietly.

On examination of the body, both lungs were found to be emphyse-matous with scattered patches of lobular collapse. At the posterior part of the apex of the right lung was a patch of collapse which occupied the upper third of the lobe. Ulcers were found in the lower part of the sygmoid flexure and rectum. The kidneys were congested. There was no sign of gray granulations or of caseous nodules anywhere about the body.

This case was mistaken for one of acute tuberculosis with tuberculous ulceration of the bowels. The moderate pyrexia, the cedema, the albuminuris, and the increasing signs of consolidation of the right apex seemed to justify this view, especially when considered in relation to the history of

tubercular peritonitis in the elder sister.

In some cases of lobular collapse where the symptoms are not very

severe, a considerable change all at once is found to occur. The temperature rises, the breathing becomes laboured, and the lividity and signs of distress increase. These symptoms indicate the beginning of catarrhal pneumonia.

Sometimes after an attack of pleurisy the lung is left condensed and airless and adherent to the chest-wall, without any marked contraction of the side. This condition may produce very puzzling physical signs.

the side. This condition may produce very puzzling physical signs.

A little girl, aged fourteen months, with eleven teeth, was said to have been a fine child until the age of ten months. At that time she had begun to suffer from a cough which was called whooping-cough by the medical at-The child was brought to the hospital for the cough, which had continued for four months, and for general wasting of two months' stand-On examination, although there was no obvious contraction of the right side of the chest, the respiratory movement of that side was seen to be impure I. The lower intercostal spaces, however, sank in fairly well, although less deeply than on the opposite side. On percussion, complete dulness with increased resistance was found over the greater part of the right side. It extended over the whole posterior region, and reached upwards in the axilla to the second rib, and in front to the third. Towards the spane behind the note had a wooden quality. Posteriorly and laterally the breath-sounds were cavernous with abundant crisp, clicking sounds. In front the breathing was bronchial. The resonance of the cough was abnormally strong.

On the left side there was no dulness, but the breathing was blowing towards the spex, and some clicking rhonchus was heard all over the left back. The heart's apex was in the fourth interspace slightly to the outer side of the left mpple line. The edge of the liver could be felt one inch

below the ribs.

The chest was twice explored with a fine aspirating syringe, but no fluid could be detected. The child eventually died. Her temperature until

shortly before death was normal.

On examination of the body the right lung was found to be much shrunken and to be universally attached by old but readily separable adhesions to the chest-wall. It was almost entirely non-crepitant, and felt very tough and firm in texture. Inflation only partially succeeded in dilating the condensed tissue and much force had to be employed. On section the texture of this lung was found to be throughout excessively tough and firm. It was thought there was some slight dilatation of the bronchit. A few nodular caseous masses were found scattered over the parenchyma. The left lung was generally emphysematous, with the exception of the inferior part of the lower lobe, which was collapsed, but could be reinflated with the blow-pipe. This lung passed across the middle line of the chest and encroached largely upon the right pleurid cavity. On section it was pale and contained little blood. The kidneys looked fatty. The heart and other organs appeared to be healthy.

This case had been, no doubt, one of pleurisy in which the effusion had become absorbed, leaving the lung in a state of condensation and collapse, similar to the gray induration described by Addison. The physical signs were very similar to those of fibroid induration of the lung; indeed, this was the opinion expressed as to the nature of the case, in spite of the tender

age of the patient.

Designors. When the collapse assumes the lobular form, the diagnosis has to be made without the aid of physical signs. In a well-marked example, however, the symptoms are so characteristic that an accurate opinion can

be formed without much hesitation. Our conclusion is based upon the let that in the course of a pulmonary catarrh signs are suddenly observed a dicating feebleness of inspiratory power and deficient afration of the basis. Thus, a weakly or rickety infant, who has been noticed to cough for a major two, all at once begins to exhibit signs of restlessness and distress. Recough ceases, his cry is replaced by a feeble whimper or a mere distorted of the features without sound; the eyes are hollow; the complexion is but the nares act; the breathing is shallow and is hurried out of proported.

the pulse and the temperature is low

If pulmonary catarrh attack a feeble infant, we must always be perfect for the establishment of collapse, and the sudden occurrence of the suptoms enumerated, combined with a low temperature and the absence of the pulmonary and signs connected with the chest, leaves us no other explanation of the child's condition. The only other disease which would be accompanied by a similar train of symptoms and an equal perversion of the pulmonation ratio, without any abnormality of the physical signs, is actually breathing very laborious, and the cough loud and hacking In palmonary collapse the temperature is normal, or even below the natural based health; the cough is feeble or suppressed, and the breathing is shaker, for even if there is recession at the base of the chest from mekets there is no laboured movement of the shoulders or upper part of the thousas will

A difficulty sometimes arises from the slightness of the pulmonary catarrh. The cough may be unnoticed by careless attendants, and the occurrence of such symptoms without being preceded by any last of cough may excite some surprise. It is necessary, therefore, to the that attelectasis may be the consequence of a very slight catarrh, and the we are justified from the symptoms alone, and without the pressure of physical signs, in drawing the conclusion that the child is suffering how

collapse of the lung.

When lobular collapse occurs in the course of an attack of mild beachitis, the presence of the lesion may be inferred by remarking that the symptoms of prostration and deficient oxydation of the blood are example atted out of all proportion to the physical signs. If the bronchitis becomes we may conclude that attelectasis is present if the breathing becomes widenly shallow and rapid; if the cough and cry become suppressed; while the lividity and general distress are still further aggravated, and the ta-

ternal temperature of the body falls below the level of health.

In cases of diffused atelectasis an examination of the chest revels dulness bronchial breathing, and a sub-crepitant rhonehua. The disess may then be mistaken for croupous pneumonia or pleurisy. In a conginfant, however, little heatation is occasioned, for the symptoms indeed by atelectasis are very different from those resulting from either in the diseases which have been mentioned. It is principally in cases where delesion occurs after the end of the first year that any perplexity is the perienced. At this age the general symptoms are usually less severe in the child's weakness much less pronounced. Still, the history of the interestive very different in collapse from that of a case of inflammation either dethe lung or the pleura. Moreover, in pneumonia the high temperature is a destinguishing mark of great value; and tubular breathing, with a first puffy crepitation noticed at the borders of the dull area, are signs which are not heard in collapse of the lung. From a localised pleurist the lesses not always so easily distinguished. Collapse of a mere tayer of tissue of the surface of the lung gives rise to only moderate dulness quite manner.

dead, toneless note over even a thin stratum of fluid. If, however, an re pulmonary lobe be collapsed, the dulness may be very marked and resostance notably increased, although perhaps to a less extent than is d in cases of pleurisy; still, the difference is one only of degree. To to the resemblance, the breathing in either case may be weak and school without rhonelius or other adventitious sound. If, however, the I resonance be agophonic, the agu is characteristic of pleurisy and power found over merely collapsed lung-tusue. In most cases the grows. In atelectasis the distress is greater, and the signs of lividity hore noticeable than in the case of pleurisy of equal extent; for in latter disease, unless a great accumulation of fluid occur, or the pain to re, the child, as a rule, appears little inconvenienced by his illness.

When the collapse occupies the apex of the lung, as in the case narrated be, it is often distinguished with difficulty from an ordinary caseous soldistion, especially if any complication be present, as in that case, to the temperature of the body above the natural level. Still, one discoshing mark which was present in the case referred to might suggest aple condensation of tassue, viz., the limitation of the dulness to one set of the chest. Complete dulness arising from consolidation would certainly accompanied by a corresponding alteration of the percussionwow and above the clavicle as well as at the supra-spinous fossa.

Permoss. -Post-natal atelectasis is always a grave lesion, especially in the children. Indeed, if the collapse occur in the course of a severe but of bronchitis, and the patient be a feeble or rickety infant under age of twelve months, death may be looked upon as inevitable. Even at the preliminary catarrh is less severe, the life of the child is placed must danger; and if the collapse be extensive, or the softening of the settreme, treatment must be very prompt and energetic indeed to afford r prospect of success. The occurrence of convulsions greatly increases danger of the case; and marked apathy and torpor, persistent increase by hty, great shallowness of breathing, and inability to swallow are all sploms of unfavourable import. On the contrary, if the face become acr and the breathing deeper, and especially if the child begin to suck figures, to take his bottle readily, or to show any interest in what passes

bund him, we may have hopes of his recovery.

Trustment -- Re-inflation of the collapsed air-cells in cases of atelecan only be effected by measures which increase the vigour of the inintery movement. To attain this object we must make use of energetic make in both internally and externally. The child should be placed quely as possible in a hot mustard-bath of the strength of one ounce in start to each gallon of hot water. In this bath he should be alel to remain until the arms of the person supporting him begin to and tingle uncomfortably. After being removed and dried, the should be wrapped loosely in cotton wool, and the child be laid beds in his cot with head and shoulders raised. The temperature of from should be between 70° and 75°. If any signs are observed of sua pation of phlegm in the tubes, an emetic is useful; and a quarter had a grain of sulphate of copper (according to the ago of the child) begiven in a teaspoonful of water every ten minutes until vomiting is blacel. The emetic is also valuable in forcing the child to take a deep th Mechanical means of increasing the depth of the inspirations on an important part of the treatment. The infant should not be alsel to sleep too long at one time. Drowsiness is one of the commonest

symptoms of this legion; but a careful eye should be kept upon the pe tient during his sleep, and if signs of increasing lividity are noticed by must be taken up and put into a mustard-bath, or made to cry by freeze to the soles of his feet or by the application of a strong stimulating mi-ment to the chest-wall. The limitentum ammonuse of the British Plan macopæia, diluted, if necessary, with an equal quantity of olive-oil, a var

useful for this purpose.

If the child can suck, he should take white wine whey with crear for a bottle. In many cases, however, on account of his mability to draw a the fluid through the tube, it is necessary to feed him with the spring In addition, or as a variety, the child may be fed with milk and lang-water with Mellin's food, and five or ten drops of pale brandy was a given at regular intervals. In the case of a weakly infant, when the tensor toms of prostration are great, the stimulant will be required ever a hour until the child revives. Older children may take milk, strong let

tea, and the brandy-and-egg mixture.

The above measures must be put in force directly any signs are covered indicating the occurrence of collapse. The earlier special test ment is begun, the more likely is it to be successful. It is of the cine importance that the child be not allowed to sleep himself to death as will probably do if left alone. He must be roused at intervals and male to inspire; and our efforts must be continued perseveringly until again noted of returning vigour or of improved acration of the blood In then he must be carefully watched that he may not relapse, and stan lation must be continued until all danger has passed.

Drugs are not of much value in this lesion. Opnum is to be careful avoided. Diffusible stimulants may, however, be given if thought and able. The best of these is quinine dissolved in sal volatile in the property tion of one grain to the drachm. Three or four drops of this second

may be given occasionally in a spoonful of the food.

CHAPTER VIIL

PIBROID INDURATION OF THE LUNG.

Fisson induration of the lung (cirrhosis of the lung, interstitial pneumonia) is not very uncommon in children, and is often mistaken for phthisis. The complaint gives rise to a chronic derangement of health which is subject to marked variations according to the season of the year. In cold and changeable weather the patient suffers greatly from attacks of bronchitis and catarrhal pneumonia. Consequently, at these times he is apt to be feverish and grow pale and thin, even if his life be not put in actual perul. In warmer and more settled weather he usually greatly improves and gains considerably both in flesh and strength. Cases of very chronic "consumption," in which the patient is constantly ill and failing during the winter, but revives and regains flesh during the summer months, are often examples of this form of pulmonary disease. Cirrhosis of the lung rarely attacks infants. It is usually found in children of five years old and upwards.

Pathology.—Fibroid induration is always a secondary complaint, and usually owes its origin to an attack of inflammation of the lung. Both croupous and catarrhal pneumonia tend to promote a multiplication of the connective tissue elements; but in children the fibroid increase is commonly due to the lobular form, especially to the subscute variety which is apt to follow attacks of measles and whooping-cough. Catarrhal pneumonia is always accompanied by dilatation of the bronchi, and this condition of the air-tubes favours the catarrhal process. It hinders the escape of secretion and so maintains a state of continual irritation of the air-tubes and their terminal alveoli. As a result, the persistence of the pulmonary inflammation tends to promote a fibroid thickening of the walls of the bronchi and air-cells, the dilatation of the tubes becomes a permanent lesion, and this, again, helps in its turn to perpetuate the irritation.

Croupous pneumonm is less often than the preceding a cause of cirrhosis; but sometimes, if the disease is protracted, thickening and induration may occur in the walls of the alveoli, and the indurating process may continue after the original disease is at an end. Weber has reported the cases of three children in whom the disease had this origin, for he had himself treated the patients for the primary attack of pneumonia.

Sometimes, although rarely in young subjects, inflammation of the pleura may lead to the fibroid overgrowth. It is in cases where the long has been subjected to long-continued compression that this consequence is most likely to occur. The thickening in this form is limited at first to the superficial interlobular septa; but the process may afterwards penetrate more deeply and be accompanied by dilatation of the bronchi.

Induration of the two lungs as a consequence of the inhalation of grit in the course of industrial labour is not found in children. Young persons under twelve years of age are not exposed to this source of disease; and even in adults whose employment obliges them to breathe continually a nir filled with irritating particles, disease of the lung thus induced a parably chronic, and only becomes developed after an exposure extra-

ing over many years.

Morbid Anatomy. On examination of a lung, the seat of fibroid industion, a great development is noticed of fibro-nucleated tissue in the also of the alveoli, the interlobular connective tissue, and the bronched interaction is increases it involves all the connective tissue of the lung. The algum becomes excessively dones and shrunken. Its substance is firm all tough, and a section shows a smooth or faintly granular surface, iron-gray or grayish-red in colour, intersected in all directions by white it has builded. Dotted over it are white rings of various sizes, which are the n

vided walls of thickened and dilated tubes.

The fibroid material is not spread evenly over the parenchusa is often surrounds islets of more healthy tissue, which are thus separate from one another by the dense fibrous bands. Sometimes in the neighbourhood of the fibroid parts the uninvaded tissue may be emphysemators. Small cavities containing cheesy matter or thick purulent fluid an ser here and there in the dense tassue. Some of these are dilatinous of the bronchi; others are the result of ulceration which has spread from the enlarged tubes. Sometimes, as in the case of a child five years old the was under my care in the East London Children's Hospital, large expended channels are found radiating from the root of the lung and energy abraptifike the fingers of a glove, at the surface of the organ immediately universeath the pleura.

When the disease follows upon an attack of croupous pneumona the change principally involves the alveoli. The walls of the an cells became greatly thickened, and in some cases, at least, as in an instance reported by Dr. Sidney Coupland, the exudation products filling the alveoliberca conganised into a fibrillated and at first vascularised mesh-work. By the means the alveoli are either compressed or filled up, and in either case of faced; and as the tissue shrinks, the new vessels which had been designed.

oped in the growing tissue become obliterated.

If the cirrhosis originate in a broncho-pneumonia the alveolar walk at thickened as in the former case; but in addition there is great deadyment of fibroid tissue in the walls of the bronchi and in the content tissue between the lobules. In these cases whitish bands are seen made

ting from the thickened walls of the air-tubes.

When the morbid process starts from the pleura, dense fibrous lates pass inwards from the surface. The pleura itself is greatly thickered with lung-tissue underlying it may be converted after a time into a dessembly fibrous substance. At first, however, the fibroid degeneration is not partial than in cases where the disease is the consequence of parameters.

Microscopic examination discovers closely packed wavy libres in the denser portions, or even a homogeneous or faintly fibrillated material with

a few small round or fusiform cells.

The alveeli, where not completely compressed and efficed, are related empty or are filled with nucleated and epithelial cells, granular corpus

and granules.

The bronchi are either obliterated or are greatly thickened and district especially in parts where the disease is most advanced. The tubes are in some cases regularly enlarged, but sometimes more local dilutations are seen forming cavities of various sizes. The lining mucus membrane and be ulcerated, and in very advanced cases ulcerative destruction of table

as have penetrated from these spots into the lung. This form of the

Fibroid induration is usually limited to one lung, the other being athy or emphysematous. It may occupy any part of the organ but more

or monty affects the base than the apex.

In addition to the mischief in the lung, disease is often found in other att. The liver, spleen, and sometimes the kidneys may be the seat of all all degeneration. In some cases the liver has been found to be cir-

bette and the kidneys to be granular,

Symptoms.—In the early stage of the disease the development of fibroid issue in the lung is accompanied by no special symptoms. The process ast commonly begans at the end of an attack of catarrhal pneumonia. In one enddren we find a peculiar tendency to recurring attacks of this form I socumonia of very unusual duration. Between the attacks the child was almost well, and an examination of the back detects morely a slight parment of resonance on one side (best detected by "broad percusa upon three fingers at once), with perceptible increase in the resist-The respiratory sounds, however, are normal. When an attack of warl d pneumonia comes on, the symptoms and signs are those peculiar blad form of inflammation of the lung. If death occur after a prolonged well of broncho-pneumonia, we may find one of the lungs small, shrunken, is particularly firm to the touch; and notice on section that the interbedar septa and walls of the bronchioles are much thickened, especially the base of the organ, and that the bronchi are dilated, Such a con-I'm constitutes an early stage of the fibroid change in the lung. The incposed fibrosis, beyond conferring a certain high-pitched quality upon the prussion note and this sign is but an indefinite one gives rise to no Nutrition is not interfered with, the appetite is good, and the Pyrexia, cough, loss of appetite, and impairment Manuation only occur as a result of an intercurrent inflammatory attack; is at these times only are any pronounced physical signs to be detected to unimation of the chest. Dulness is then marked and extensive; the reating becomes blowing or tubular; and coarse bubbling or sub-crepiat riomehus - more or less metallic and ringing according to the degree d scate dilatation of the tubes is to be heard with the stethoscope. Moreach of these attacks the long is left in a distinctly worse condition bu before. The libroid overgrowth increases in the lung; the broachi it to be permanently dilated; and the lining membrane of the air-tubes tomes the seat of more or less persistent entarch.

Even when the libroid overgrowth has increased to such a degree as a month to impure the usefulness of the lung as a respiratory organ, the there of the disease upon general nutrition may be comparatively slight and is the chest is free from intercurrent attacks of bronchits or calculated pneumonia. Special symptoms arising from contraction of the upon consequent obstruction to the pulmonary and systemic circulation to be noticed, but if no secondary disease of organs has been induced as illness, the child is often fairly stout and strong. Therefore, in warm that the weather, which brings with it freedom from catarrh, his health is afford little subject for complaint; but in changeable seasons, and established during the winter months, he wastes rapidly and exhibits all the

my toms of "consumption"

When the disease occurs as a sequel to an attack of pleurisy, the early phone vary according as to whether the pleuritic effusion and consecut compression of the lung have been moderate or excessive. In the

first case, unless a local catarrh be present the general symptoms may be insignificant; and a physical examination may only detect duless at the extreme base behind, with very weak bronchial breathing and some case bubbles with respiration. The child may be subject to paroxysmal care but need not for a long time necessarily suffer in his nutrition through the condition of his lung. If, however, effusion have been copious and though lung be bound down by thick bands of lymph, the symptoms and through signs are those of pleurisy with retraction, combined with par years, cough, profuse expectoration of offensive muco-purulent sputs, and to other phenomena which attend a case of pronounced cirrbosis of the land.

In the fully established disease we find the following signs:

On account of the dimenution in size of the affected lung, the chest-will corresponding to the shrunken organ is retracted. The ribs are flattered over the seat of disease, and the respiratory movement is improved or seppressed. If the lung is much reduced in size, the shoulder, the title and the inferior angle of the scapula are lowered, the ribs are aprecemated, and the circumference of the chest on that side is dimmed and the measuring tape. An outline of the chest drawn from the car use. shows this difference between the two sides very clearly. In addition certain displacement of soft parts in the neighbourhood is to be note. The mediastinum is drawn towards the affected side, and the opposite had is found on percussion to project across the middle line of the chest. T. heart is also displaced, unless adhesions between the pericardium and sjoining pleura retain it in its normal position. If the upper part of we left lung be the sent of disease, the heart is drawn upwards. If the rest lung be affected, the heart is pulled towards the right side, and in extreme cases may be felt beating to the right of the sternum. Vocal ubratical sometimes plainly perceptible over the indurated organ, although at is also sent from the sound side. In other cases no fremitus may be percent over the affected half of the chest when the child speaks, although it can be felt over the healthy lung. The percussion-note is of wooden or tal av quality, and there is usually marked resistance of the chest-wall. These crease of resistance is especially noticeable when the diseased lung by seat of an intercurrent attack of broncho-pneumonia; and the particle note at this time may be as completely dull and toneless as in case. pleuritic effusion. The breath-sound is found to vary according to be amount of secretion retained in the tubes at the time of examination 1 the dilated tubes are full of muco-pus, the breath-sound is weak and leschial, with little rhonchus; and resonance of the voice when there ... speaks is faint or suppressed. If the air-passages are comparatively the the respiration is foul and blowing, often intensely covernous, et examphoric, with metallic echo; and large, crisp metallic bubbles, with in creaking sounds, are heard with both inspiration and exparation. Take signs are in most cases limited to one-half of the chest.

The symptoms noted in a case of pronounced currhosis are in part to the condition of the lung itself, but in part they are the consequent

of the obstructed pulmonary circulation.

The cough is a very characteristic symptom. Owing to retents: a secretion in the dilated tubes, and to loss of elasticity in their in later walls, cough is severe and spasmodic. It occurs at comparatively rive a tervals, and consists in a rapid succession of loose-sounding lacks with often continue for many minutes. The child's face becomes consistent and his cyclids suffused, and his whole body often shakes with the blance of the paroxysm. After lasting a variable time the cough each is

spasmodic contractions of the diaphragm, and enormous quantities of offensive purulent matter are retched or expectorated. The unpleasant unell of the morbid secretion is due partly to its retention and consequent putrefaction in the dilated tubes, and partly to the presence in it of gangrenous shreds of nuccous membrane. The same causes communicate a feture to the child's breath, which can be perceived at a considerable distance from his cot. Sometimes the expectorated matters are tinged with blood; but haveoptysis from this cause is not common in the child. Epistaxis may, however, occur, and the blood from the nose may be swallowed and retched up again at the end of a cough, so as to appear as if brought up from the lungs.

The respirations are usually from 30 to 35 in the minute. If brouchopacumona be superadded, the breathing becomes much more hurried, and

the pulse-respiration ratio is perverted.

The appetite is often good, and although the child is pale as a rule, his autration, as has been said, unless interfered with by an intercurrent indammatory attack, may be fairly satisfactory. During the attacks of catarrhal pneumonia, however, he was es rapidly; and if the disease has produced marked contraction of the side, the child is usually greatly emeriated.

Pyrexia is not a symptom of the uncomplicated disease. When present, it usually melicates the occurrence of bronchitis or pneumonia, and is then 102° or 103°, or even higher. A more moderate pyrexia may be the consequence of ulceration of the bronchial tubes. In these cases a microscopical examination of the sputum will discover the presence of fibres of clustic tissue.

In addition to the above symptoms others are present which are the consequence of interference with the pulmonary circulation. The right side of the heart becomes hypertrophied, and the systemic venous system is fuller than natural, so that the veins of the neck and chest, and often of the limbs, are abnormally prominent. The fingers are clubbed, and in advanced cases there may be a congested, turged appearance of the face.

Amyloid disease of the liver, spleen, and kidneys is commonly present in advanced cases. If this be marked, there may be great anomia and

general dropsy.

Although in most cases fibroid induration of the lung is accompanied by marked contraction of the side, this symptom is not always present. In one of the most pronounced examples of the disease which has come under my notice -a child of five years old -the chest was well-shaped, and the affected half, although slightly flattened posteriorly and at the junction of the lateral and anterior thirds, was little inferior to the healthy side in actual measurement. In this case dissection of the body showed that the shrinking and condensation of the lung tissue was compensated for by enormous dilatation of the air-tubes, so that the space occupied by the organ in the chest cavity was little diminished. Even if the lung be condensed so as to reduce its volume much below the standard of health, marked contraction of the chest may be prevented by the drawing into the affected side of movable organs in the neighbourhood. Thus, in a log--aged eleven years -in whom the shrunken right lung was reduced to a mere mass of gristle, the enlarged amyloid liver was drawn upwards so that its upper border was at the level of the third rib. This displacement prevented the chest from falling in, and the contraction of the side was limited to a little flattening under the clavicle.

In cases where ulcerative destruction of lung ensues (fibroid phthisis)

there is great interference with nutrition. The temperature is desict there is often heetic, and diarrhoes may occur with ulceratum of the bowels. The symptoms are those common to the third stage of consulption, and the physical signs are such as have been described as accordanting confirmed pulmonary circhosis. In these cases the destructive process is soon followed by signs of deposit at the apex of the opposite land

Fibroid induration does not always go on to fibroid pathers. It children, at least, this is an exceptional mode of ending of the least. As a rule the child succumbs to one of the intercurrent attacks of logs be-

pucumonia, or falls a victim to a secondary acute tuberculosis.

Diagnosis.—In the early stage of fibroid induration of the lung a crise diagnosis is impossible. We may suspect that the process is present, a child be subject to repeated attacks of inflammation of the lung, and after an unusually prolonged attack of entarchal procumonis the per use, note remains high pitched, and the indications of dilatation of the level are slow to subside; but no positive opinion can be hazarded upon an insufficient data.

The diagnosis of the confirmed disease rests upon the signs of shriding and condensation of lung tissue combined with evidence of ddata. It the brenchi. There is great retraction of the affected side, in Leaf 1 to falling in of the chest-wall, lowering of the shoulder, nipple, and infeat angle of the scapula, with curving of the spine—the concavity locationards the affected side. Neighbouring organs are displaced. If unight lung be diseased, the liver is drawn upwards, the heart is felt being to the right of its normal position, and the resonance of the laft to passes across the middle line of the chest. If the left lung be contract, the heart is drawn upwards and the right lung encroaches upon the appleural cavity.

On examination of the chest the percussion-note is wooden or the with marked resistance, the breath-sound is weak or bronchial if the contain much secretion, while after cough and expectoration loud blood or cavernous breathing is heard, with large metallic bubbling the and intense bronchophonic resonance of the voice. We find, also, and tions of interference with the pulmonary circulation. The right voter is hypertrophold; the veins of the neck, chest, and arms are false to

natural, and the fingers are clubbed.

The violent paraxysmal cough ending in retching, and the disclar, a large quantity of offensive purulent mucus is very characteristic this symptom, combined with the sudden change in the physical of which is noticed at once when the dilated tubes have been relieved of the contents, is a strong argument in favour of fibroid induration.

Pleurisy, with retraction of the side, presents physical signs very in to the above. But in this case, although the breathing in the child structure frequently hollow, it is rarely cavernous, and is not accompanied metallic gurgling. Moreover, the cough is not paroxysmal, and expertion is scartly or absent. Cirrhosis of the lung may, however, foll supplying standing pleurisy. It is detected by the gradual supervention of appropriate distribution with copious purulent sputs.

If on account of extreme dilatation of the bronchi no retraction 'the side is present, the characteristic cough, the profuse sputh, the change in the physical signs after expectoration, and the history of a perfailure of health, with rapid improvement under favourable con lates.

living, are symptoms of the utmost value.

Ordinary pulmonary phthisis is usually combined with a certain degree

of fibroid overgrowth. The distinction between dilated bronchi and cavities due to ulcerative destruction of lung is elsewhere considered (see page 514). In any case the strict limitation of the disease to one side of the chest is a strong argument in favour of the fibroid disease, for pulmonary pathwas in the third stage is never confined to one lung. It must be remembered that cavities resulting from ulceration of lung may be combined with dilated bronchi (fibroid phthisis). In such a case the apex of the opposite lung is probably also the seat of disease. The diagnosis will then rest upon the history of the illness and the evidence of marked contraction.

Programs.—Although fibroid induration of the lung usually tends to increase, the immediate prospects of the child are not unfavourable so long as the disease is limited in extent and remains uncomplicated. The danger of these cases arises from the secondary disturbances, which are a common and unfortunate consequence of this condition of the lung. A catarrh cases great increase of bronchial secretion, and often leads to retention and decomposition of purulent matter in the dilated tubes. The irritation thus induced may be sufficient by itself to set up a catarrhal pneumonia. Fortunately in these attacks the type of the intercurrent disease is usually subscute; but its course is apt to be protracted, and if the fibroid consolitation is advanced, or the nutrition of the child impaired, the patient may account to the complication.

The continuance of healthy nutrition is very necessary to the favourable progress of these cases, and any derangement which tends to reduce the strength, such as digestive disturbance, vomiting, or diarrhoea, is distinctly injurious. The progress is more favourable when the disease is a table at the upper part of the lung than when it occupies the base. In the first case, on account of the downward direction of the air-tubes, retention of secretion is less liable to occur; in the second case the force

of gravity helps to favour accumulation in the tubes.

In the later stage of the illness, when amyloid disease of organs has course I, the prognosis is serious; but even at this period, if the patient be bung in a chinate which allows him to pass much of his time in the open as without risk of chill, nutrition may be carried on fairly well. Œdema *An or without amyloid change is an unfavourable sign, as it indicates a

a very unsatisfactory state of the blood.

Total neal. - In the treatment of this chronic disease we can do nothing we remedy the mischief in the lung so far as it is already completed. Wherever the fibroid change has advanced, the tissue affected is injured beton hope of repair, and no treatment can cause absorption of the moral material in the lung. Still, we can do much by careful attention to the conditions of life of the child to prevent further spread of the disease. On efforts must be directed to the removal of initation in the lung, so as to word the ten lency to active change, and to the promotion of healthy mention. The chief cause of the extension of the indurating process is to presence of bronchial secretion in the tubes. We must therefore do 10 m our power to avert the risk of chill, and if a catarrh attack the lung, " must be treated without delay. The child must be dressed from head to blis flund or woollen underclothing, and should never leave the house and or damp weather without suitable covering to his neck and chest. Despreaution is the more necessary as confinement to hot rooms is to be smited, and if the child be properly protected from cold, regular exerat .11 press the winter in a dry and bracing, but equable climate, where he is not liable to suffer from constant changes of temperature. His diet

should be nutritious, consisting of meat, eggs, milk, etc., avoiding excess of farinaceous food; and if he be weakly, half a glass of port wine, or of the St. Raphael tannin wine, diluted with an equal quantity of water, may be given him with his dinner. Iron and cod-liver oil are always indicated in these cases.

Directly signs of catarrh are noticed the child must be confined to his bed, and be subjected to the treatment recommended for such cases (see

Bronchitis).

In the more advanced stage of the disease much may be done by suitable medication to relieve the more distressing symptoms. One of our first objects should be to control the amount of secretion and destroy its fetor. Astringent remedies given by the mouth and inhaled into the lungs are very useful for this purpose. The child should take quinine (gr. j. ij), with tinet, ferri perchloridi (M.x. xx.) and a few drops of liq. morphiae several times in the day; and astringent and antiseptic solutions should be sprayed into the throat at suitable intervals. These solutions must not be too strong or they may excite so much cough that their use will have to be discontinued. Alum (gr. x. to the oz. of water) and tannin (half a grain to the oz.) are both very useful; or we may use carbolic acid or creasote (M.xx. to the pint of hot water) combined with a drachm of tinct, benzonnic, as an inhabition. Turpentine given internally is often a valuable remedy in diminishing the amount of secretion. It may be administered in doses of ten or twenty drops every three or four hours. Reducing the quantity of fluid allowed for drink will often considerably diminish the secretion; but children do not readily submit to this deprivation.

Vomiting is useful, as the act helps to effect the discharge of secretion from the tubes; but the paroxysms of cough are apt to be excited by taking food, and if the contents of the stomach are ejected shortly after a meal the loss of nourishment may cause serious interference with nutrition. In these cases it is advisable to give small doses of arsenic (M j. ij.) two or three times a day, or a drop or two of liq. strychniae, for both of these remedies tend to control the retching efforts at the end of a fit of coughing. But the vomiting should be excited at a more convenient time, as in the early morning, by a draught of warm water, mustard and water, or a

grain of sulphate of copper.

Cod-liver oil and tonics are of great service at all stages of the disease; and if amyloid degeneration of organs has occurred, and there be an emia, iron is especially indicated. Dropsy must be treated on a similar plan. Any complications which arise in the course of the disease must receive immediate attention; for it is indispensable to maintain the healthy working of the animal functions. Therefore indigestion, diarrhoea, etc., must be treated by diet and suitable remedies, as directed in the chapters treating of these subjects.

CHAPTER IX.

BRONCHITIS.

INFLORMATION of the mucous membrane lining the air-tubes is a common cause of death in infancy and childhood. The disease may be dangerous not only in itself but through its tendency to be accompanied by collapse of the lung or to pass into broncho-pneumonia. In young infants death, when it occurs in bronchitis, is seldom due to the uncomplicated disease. It is usually to be ascribed to one of the consequences which have been referred to. In older children a simple bronchitis may prove fatal, but up to the age of five or six years the untoward result is commonly due to extension of the inflammation to the finest tubes and terminal alveoli.

Bronchitis may be a mild complaint or an affection of the utmost gravity. When the disease attacks only the large tubes, it is usually of little consequence and can be readily cured by judicious treatment, although even in these cases, if the patient be a weakly infant, fatal collapse may occur very suddenly and unexpectedly. When the disease spreads to the smaller tubes (capillary bronchitis) the illness is a very

serious one, and many of these cases prove fatal.

Caeschum.—Bronchitis may arise from exposure to weather and to changes of temperature like other forms of catarrhal derangement. It may also be set up by irritants inhaled into the air-passages. Thus an escape of gas in the nursery is sometimes a cause of bronchial catarrh. During the pyrexia attendant upon deutition children are especially sensitive to the causes of pulmonary disorder, and very slight chills will give rise to bronchitis in such subjects. Some children are said always to "cut their teeth with a cough." In other words, their exceptional sensibility at this time to atmospheric influences makes them catch cold very readily.

Damp and cold combined, especially where great variations of temperature occur, are fruitful causes of catarrhal disorders; and if in a climate where such conditions prevail the child is insufficiently clothed, he usually becomes a frequent sufferer from bronchial derangements. Some mothers have a curious dislike to flannel worn next to the skin, and accustom their children in all seasons to depend solely upon the warmth of their frocks and wrappers for protection against the cold. The common result of such a practice is to increase the natural susceptibility to chill; and many a

child's life has been sacrificed to this senseless prejudice.

Besides the primary form of bronchitis which is induced by the above causes, the disease is frequently met with as a secondary affection. There are many forms of illness which are habitually complicated by pulmonary catarrh. Whooping-cough, measles, typhoid fever, and acute pulmonary tuberculosis are amongst the number. In others an intercurrent bronchitis is a frequent phenomenon. Thus in scarlatina, small-pox, diphtheria, certain special lung diseases, as croupous pneumonia and pleurisy, and

in diseases of the heart and kidneys, bronchitis is a frequent complica-

Morbid Anatomy.—The anatomical changes induced by the discussive primarily the mucous membrane, and may spread there to constructures. The membrane is congested and consequently red level at thekened. Sometimes it is softened. The secretion is at first discussive but afterwards becomes copious and watery, then thicker at large in pus. Under the microscope we find epithelial cells (many of the action bryonic), granular cells, and pus corpuscles.

When the bronchitis is capillary, the finer tubes are often found expletely occluded by this viscid muco-pus. This is especially the case to lower lobes, into which the secretion has probably penetrated by the lower and gravitation. More or less collapse is then usually found in the lower

with which the obstructed tubes are in connection.

The inflammatory process is at first limited to the nuccus menture but if the disease continues, may penetrate to the submucous tisserveren involve the whole thickness of the bronchial wall. In this case to tation of the channel may take place, and acute enlargement en process of the air-cells may be found. Often the two opposite conditions of the place and lobular emphysema may be found side by side.

Ulcerative excavations, described by Dr. Gairdner as "bronchal sheeseses," sometimes occur. These are found in the centre of collapse, challes, and consist of little collections of pus the size of a ben posse. larger. They communicate with the terminal tubes, and may be torreled dilatations of these tubes or of ulcerative destruction of the wills in joining air-cells. In the former case they are lined by a tine vill us are brane; in the latter they are minute cavities in the lung substance and their purulent contents lie in immediate contact with the hing takes. According to Dr. Gairdner, these purulent collections are the latter result of pus accumulated primarily in the extreme broughial tubes it the collapsed labules. The general appearance of these abscisses that of softening tubercles, for which, indeed, they have been often as taken.

In the majority of cases bronchitis is limited to the larger tabes, in even then the purulent secretion may be drawn inwards into the has been chi; and these are often found filled with viscid, yellow matter, ever a their lining membrane is not inflamed. In young infants, who can cough at will, this retention is very liable to occur, and, as is elsewhered planned, is one of the causes which render collapse of the lung so come a lesion in the beginning of life.

Besides the anatomical characters which have been described stood catarrhal pneumonia are very common. The appearances results: "
this form of disease and the mode of its production are described the state."

(see catarrhal pneumoma).

In chronic bronchitis the mucous membrane often appears to be the affected, although sometimes it is smooth and polished. The sometimes are considerably dilated; their transverse fibres are hypertrophed and the sub-mucous connective tissue is generally thickened. (Observed emphysema is usually met with, and collapse is an almost invariable feature of this form of the disease.

Symptoms.—When the inflammation is confined to the larger broads the symptoms are not severe unless the patient be a very young or walk subject. In a new-born child or a feeble, wasted infant a shirt decreed bronchial catarrh may be accompanied by very serious symptoms, and each

lead to death from the occurrence of pulmonary collapse. This form of

the disease is described elsewhere (see Collapse of the Lung).

In stronger infants and older children the occurrence of catarrh of the larger bronchi is indicated by coryza and cough. The child success and coughs at intervals. He complains of no pain, and if the cough is hard at the first it soon becomes loose, and ceases after a few days. In these mild cases the general symptoms are slight or wanting. There is no fever, the child is lively and cheerful, and his appetite is little impaired. The tongue is usually furred, and there is some costiveness; but an aperient powder soon remedies this inconvenience, and the child is quickly well. In such cases the only physical sign to be detected about the chest is the presence of a little sonoro sibilant rhonchus or an occasional large bubble in the inter-scapular region.

Although these cases are mild in themselves and easily cured, they may yet, by neglect, he so prolonged as to cause considerable interference with nutrition. If care be not taken to protect the patient from the ordinary causes of chill, he may pass through a succession of little colds, so that his cough continues for several weeks, and may be accompanied by a certain amount of catarrh of the stomach. Consequently, the child looks pale and gets flabby and languid. In such a state his condition may not only be considered an anxious one by his parents, who begin to entertain fears of consumption, but the resisting power of the child against changes of temperature being really lowered, he is very apt to alarm the practitioner by suddenly developing all the symptoms of acute bronche-pneumonia.

If the caturrh assume a severe form, it often begins with fever and soreness behind the sternum. The temperature rises to 100 or 101; the tengue is thickly furred; the pulse and respiration are both hurried, although their relation to one another is little altered; and the bowels are contined. The nares act with respiration. The cough is at first hard and frequent and increases the pain in the chest. The skin is most, the face flushed, and the child, if an infant, constantly requires to be in his nurse's arms. He is very thirsty, and on this account takes his bottle with eagerness. A certain amount of gastro intestinal catarrh often accompanies the bronchitis. The child may voint, and his bowels are often relaxed. Usually, after a day or two the temperature subsides, the cough becomes looser, and the soreness of the chest abutes. Under proper treatment, the child is usually well at the end of the week.

The physical signs in these cases are of trifling amount. They consist merely in more or less large bubbling at each base, with dry rhoughus and

occasional bubbling râles at various parts of the lungs.

When the inflammation penetrates into the smaller tubes (capillary bronchitis) the symptoms become alarming. The features look pinched, and the expression is one of extreme distress. The face is pale, with much lividity about the eyelids and mouth. The child is restless. His dyspmen is great, and his respiratory movements are laboured as well as hurried; but if the disease is uncomplicated with collapse or lobular pincumona, there is little disturbance of the normal proportion between the pulse and respiration. Often the child is subject to sufficiative spasms if had down, and has to be supported partially upright in his nurse's arms, or raised in his cot by pillows. At each inspiration considerable recession is noticed of the soft parts of the chest; and if the ribs are yielding from rickets, the retraction of the bases of the chest may be extreme. The temperature at first is raised to 101° or 102, but when accurtion of the blood is greatly interfered with the mercury usually sinks to 99°.

The pulse rises to 140 or 150, or even higher, and is small and often hard. The cough is hacking and house, and occurs in stiffing processing greatly increasing the difficulty of breathing and intensifying the higher of the face. The skin is moist and beads of sweat are often seen that ing upon the brows. The tongue is moist and thickly furred Appears is completely lost and the child is very thirsty. Still, on account of the dysphage an infant is quite unable to draw fluid from a bottle. To mouth is required as an air-passage, and the needs of respiration precodits being used for any other purpose. Vomiting sometimes follows a processing used for any other purpose. Vomiting sometimes follows a processing interferes with respiration, and he has no breath to space.

On examination of the chest percussion discovers no dulices. What the stethoscope the breath sounds are found to be more or less coppets covered by a copious sub-crepitant rhonchus which is heard over letters. In an uncomplicated case the breathing is nowhere bronchial or blank and the resonance of the voice is unaltered. These cases are, hower the often complicated with atelectasis or bronche-pneumona that the plank signs connected with these forms of disease are often to be detected at the

posterior bases.

Unless an amelioration in the symptoms occurs suddenly, the determined becomes more and more marked. The fits of dysphera are mere from an and alarming. The child, as long as his strength will allow, tosses a be bed, throwing his arms about restlessly. In an infant or rickety challes symptoms pass on to those which have been described as character-to-datelectasis or of catarrhal pneumonia. In older children, in whom the complications are less likely to occur, the face assumes a leaden his, a fingers and nails grow purple; the breathing is more hurried, and the telegets excessively rapid and small. As the weakness and asphysis have more marked the cough ceases; the restlessness diminishes; the clotter comes drowsy and intensely apathetic, and soon dies considered vulsed. The temperature often sinks to a normal level when the synd of asphysia become more pronounced, but often rises again before put to 102° or 103°.

If the case terminate favourably, the eyes grow brighter and the legity begins to clear; the cough is looser and less paroxysmal; the passlackens; the breathing is less laboured; and the child takes more acts.

seeming to be less absorbed in his own uneasy scusations.

The chronic form of bronchitis is not rare at the age of five converges and upwards. It usually occurs in children of scrotilous tensors who have been subject to repeated attacks of bronchial catairth, and in consequence from some permanent employeems of the lungs. Schildren are very sensitive to chills, and are apt to be troubled in the changeable sensons of the year with a distressing cough and shorters breath. Measles and pertussus in strumous subjects are often followed the same pulmonary susceptibility, so that during the colder mounts patients wheeze and cough, and present all the symptoms of chronic brochitis such as result from the same conditions in elderly persons

In the milder form of the disease the child merely suffers from chronic cough, which undergoes very noticeable exacerbations of a change of the weather, and on the occurrence of a chill is complicated a time by the symptoms of an acute attack of pulmonary catairs. The

cases often give much trouble and are very difficult of cure.

In a severer form, when the emphysems is marked, the chest become

harrel-shaped; the skin is habitually dry and the fingers are slightly claibled. These children are almost invariably short and thick-set, with coarse features, thick turgid lips, broad shoulders, and large bones. They often stoop as they walk. During the summer months they are fairly well, with a good appelite, and although they may pant after exertion, do not saffer from noticeable shortness of breath. In the winter they have a persistent cough, and cannot include in noisy games, as much movement produces instant dyspacea. The cough is loose and paroxysmal; sometimes they expectorate frothy, yellow phlegm. The face is usually livid and puffy-looking. The appetite is capricious, and vomiting is frequent after cough. The bowels are costive.

On examination of the chest we find general hyper-resonance; and the respiratory sounds are more or less concealed by a fine crackling rhonchus. It as often happens, there is dilutation of the bronchi, the respiration in the inter-scapular region may be bronchial or even cavernous. As a rule the

temperature is normal.

Chrome catarrh of the stomach or bowels, or both, often occurs in these cases. The appetite is poor, the bowels are loose and contain much much; and the loss of flesh is rapid. With great care the pulmonary enterth may be kept under, and if the child's strength be properly supported, life may be prolonged until the return of more genial weather, when the patient very quickly begins to improve. In too many cases, however, death ensues as a consequence of an intercurrent attack in which the temperature rises, and the symptoms which have been described as the consequence of capillary bronchitis are noticed.

A boy, aged thirteen years, both of whose parents were said to be "weak in the chest," was healthy up to the age of eight years, when he had an attack of measles followed by pertussus. From that time he suffered from cough which was always worse in the winter. He was admitted into the

Victoria Park Hospital in February for a severe bronchitis.

The boy was fairly nourshed and well built, although short for his age. His chest was full and expanded above, but at the lower part on each sale there was some infra-mammary depression. The spine was straight. The heart's apex was in the fifth interspace, three quarters of an inch to the inner side of the nipple line. Its impulse could be also felt in the epigastrium. The skin was dry and harsh; the fingers were slightly clubbed; the liver and spleen seemed pushed downwards. The face was congested, turgid, and more or less livid. The breathing was laboured, and the boy could not be down in his bed. The temperature was normal and the urine healthy.

On examination of the chest the percussion note generally was hyperresonant; and everywhere over the chest the breath sounds were concealed by a copious, fine, crackling rhonchus. This at the base was very superficial and ringing. The boy remained in the hospital until June, being sometimes better, sometimes worse; and the amount of rhonchus varied considerably from time to time. The temperature rarely rose above 99. On his discharge, although his breathing was much better and his general condition fairly good, much rhonchus remained at the bases of the lungs.

Diagnosis.—There is little difficulty about the diagnosis of bronchitis. In the milder form a mistake is hardly possible unless from teething or other cause there is a high degree of fever. With considerable pyrexis the derangement may be mistaken for measles or broncho-pueumonia. In the first case the occurrence of the characteristic rash on the fourth day will clear up the difficulty. In the second, the absence of distress in the

face, the normal pulse-respiration ratio, and the limited amount of theorems detected by the car will furnish a sufficient distinction.

In capillary bronchitis the laboured breathing, the thick and often paroxysmal cough, the copious mucous rales heard with the stether percombined with the absence of dulness on percussion and of broncian'r blowing breathing, are sufficiently distinctive. A point of great imperations the exclusion of atclectasis and of catarrial pneumonia. The new leasures introduced into the case by the occurrence of either of these completions are referred to elsewhere (see pages 467 and 436).

Prognosis.—As long as the catairh remains limited to the larger labor the prognosis depends upon the age and general strength of the patent. However slight the disorder may be, we can never feel sure that in a proborn, a weakly, or a rickety infant fatal collapse of the lung may not fellow unexpectedly. In all such cases, therefore, we should warn the parent of this possible danger, and caution them to watch carefully for half drowsmess, or other sign indicating insufficient aeration of the blood

In capillary bronchitis the danger is great, however healthy the dall may have previously been; and if the patient be weakly or the sulps of rickets, the peril is really urgent. Indeed, few such cases recover. The extremity of the danger is indicated by a high degree of interference with the acration of the blood. If the child become intensely apathetic of the sistibly drowsy, with blueness of finger-ends, an ashy-gray face, du. at lustreless eyes, and a normal or sub-normal temperature, death can seem be avoided. Other signs of unfavourable import are suppression of the cough, great rapidity of the pulse and respiration, smallness of pulse and fulness of superficial veins, with retraction of the base of the chest unspiration.

Signs indicative of collapse of the lung or of bronche-pneumonia was

ill for the child's chances of recovery,

Treatment.—A pulmonary catarrh in a child, especially if the patientle weakly or of a rickety constitution, should never be treated lightly. It is mildest case the patient should be kept in his room and be made to take saline mixture containing a few drops of ipecacuanha or antinonal wat in each dose. If there is any rise of temperature, he should be at our put to bed. This is essential. Perfect quiet is necessary for a feveral child; and even if pyrexia be absent, the repose and equable temperature of his cot will hasten the patient's recovery more certainly than the recovery energetic medication. Indeed, without this precaution treatment lows as rethan half its value. In the next place we must employ counter-rentate to There is, however, a right and a wrong way even of using a pontice Weak applications in these cases are better than strong irritants; for a fig. more effectual impression is made by acting slowly upon a large surface of the skin, than by producing a more violent irritation of a congenture limited area. One part of mustard should be diluted with five or sa un its bulk of finely ground linseed meal. The ingredients should be carfully mixed in the dry state and made into a poultice with hot but be boiling water. The application should be sufficiently large to cover to whole front of the chest, and should be allowed to remain in contact will the skin for six or eight hours, or even longer if the child can bear at 🔎 layer of cotton wool should be then applied in its place, and a fresh pale tice of similar strength should be made for the back and be kept on trans equal period of time. An infant will bear this strength well. For un older child a larger proportion of mustard may be used, but it is sell as wise to employ an application which cannot be borne for at least six lowThe effect of these measures is seen very quickly. In the milder forms of the disease the hard cough becomes soft and loose, the soreness of the chest subsides, and the pyrexis quickly disappears. Even in the more severe variety a sensible diminution in the distress and the labour of breathing is usually manifested when the skin becomes very red from the action of the irritant.

The diet should consist of milk and broth; and the child should be

allowed to drink freely of thin barley-water.

For medicine, a grain of calomel should be given in a little sugar, and be followed after a few hours by a dose of castor-oil or other mild aperient. A februing mixture can then be prescribed, such as citrate of potash or the solution of acetate of ammonia with a few drops of ipecacuanha or antimonial wine. A pleasant form in which these can be given is the following:—

B. Vini ipecacuanha	Щ	٧.
	η	
Glycerini	M	ST.
Aquam florse aurantiiad	3	j
M. Ft. haustus.		•
Sig. To be taken every four hours.		

The above is suitable to an infant. For older children the proportious

may be increased, or the draught can be given more frequently.

Unless the bronchitis be severe, the bronchial derangement quickly yields to this treatment and the patient is soon convalescent. If the cough continue after it has become loose, and the child's appetite has returned, a few drops of paregoric and tincture of squill added to the mixture will soon effect its removal. Stimulating expectorants are as useful at the later stage of the catarrh, after the cough has become loose and easy, as they are injurious at an earlier period when it is hard and painful.

In capillary bronchitis the child should wear a flannel night-dress, and the temperature of his room should be kept at 70° or 75°. It is also advisable to moisten the air round his cot by vapour from one of the many varieties of bronchitis kettle, or by Dr. R. J. Lee's "steam-draught inhaler." The poulticing of the chest should be carried out energetically; and when the skin can no longer bear the irritant, the chest should be wrapped in

cotton wool.

In this severe form of the disease stimulant expectorants are not only useless as remedial agents, but tend directly to increase the congestion and irritation of the mucous membrane. However feeble the child may be, if the cough is hard and the chest tight, ammonia, squill, tolu, and other remedies which exercise a stimulating effect upon the mucous membrane should be avoided. In such cases the distress of the patient is most certainly relieved and his strength improved by medicines, such as salines with ipecacuanha, which promote free secretion from the tubes. If necessary, this treatment can be supplemented by general stimulants, such as alcohol, and in weakly children it is very necessary to counteract any depressing effect of the remedies upon the system by the free administration of brandy and-egg. In young children whose strength is good it is often useful at the earlier periods of the disease, when the cough is hard and much soreness is complained of in the chest, to give two or three grains of providered mecacuanha in a teaspannful of muchage twice a day on an cu.pty stomach. The emetic in these small doses excites vomiting with

very little effort, and causes the expulsion of much mucus from the some and lungs. After a few doses of this remedy the character of the cart often undergoes a marked change for the better, and the distres of in patient is greatly relieved. So long, therefore, as there is fever will led cough, tightness behind the sternum, and lividity of the face, we should confine ourselves to ipecacuanha or antimonial wines (III v.-x.), curate d potash (gr. iij.-v.), solution of acetate of ammonia (" x.-xxx.), spans (natrous ether (M x -xxx.), and similar remedies.

Although the medicines recommended are all such as aid the free sertion of mucus, they are not given with any object of producing depressa On the contrary, we should watch the patient carefully for signs of protection tion, and hold ourselves in readiness to correct any undue sed thre industria by alcoholic stimulation. We must not, however, be in a hurry to give with or brandy. A small feeble pulse will be often found to become fuler ad stronger as secretion from the inflamed mucous membrane becomes non-

conious and the congestion of the pulmonary vessels declines.

In children of four or five years old and upwards a grain of calometrial two or three grains of jalapine at the beginning of the treatment is always useful. It is unnecessary to keep up a free action of the bowels, for these cases appear to be little benefited by purging; but a thorough unknown of the liver is very useful as a preliminary measure. Even in infants in a grain of calomel followed by a teaspoonful of castor oil often seem to render the after course of the disease milder and more tractable.

The above method of treatment will usually be found successful in case of primary capillary bronchitis, when the patient is seen before college ! the lung has occurred or the disease has passed into a chronic broader pneumonia. It is upportant that we should not allow ourselves to be tempted, by the apparent prostration of the patient, to preserve amount and other atimulating drugs. When the pulmonary vessels are coapstol and the obstruction to the circulation is extreme, the heart labour the face is livid, and the pulse is small and feeble; but these symptoms or stitute no real indication for ammonia. We shall best relieve the maple ment to the pulmonary circulation and promote the agration of the del by measures which relieve the congestion by producing free secretion in the overloaded vessels.

Opium should not be given unless the restlesaness is great, and conthen the remedy is hardly a judicious one; for anything which dids to sensibility of the bronchial mucous membrane hinders the expanded the phlegm and favours collapse of the air-cells. Acouste, veratrum von and other powerful cardiac sedatives are only admissible during the last forty-eight hours, and must on no account be given to young infants.

In capillary bronchitis, as in the case of the milder forms of the is ease, when the cough is quite loose and secretion free, small does d morphia or paregorie, with ammonia and infusion of senega or serpentant will soon bring the disease to a favourable ending. Profesences of sor tion at a late stage of the illness is an indication for small deses of the In infants, perhaps a few drops of sal volatile make the better rouse? but after this age the administration of four or five grains of the curate of iron with a drop or two of liq. morphie, and a few grains of the bi curtor ate of soda, is attended with great benefit. So, also, a grain of quant with a couple of drops of dilute nitric seid, and the same quantity of and anum or solution of morphia, given several times in the day, will are brace up the relaxed mucous membrane and diminish the frequency of the cough. These remedies must of course be confined to the later stage of be disease, after the pyrexia has subsided, and when secretion is copious

com want of tone.

in all forms of bronchial catarrh in weakly infants or rickety children be patient should be carefully watched for signs of collapse of the lung. I've active the child suddenly to become drowsy, and find that this change becauted with hydrig of the face, very rapid and shallow breathing, as fall of temperature to a sub-normal level, energetic measures should be taken to promote re-expansion of the collapsed lobules (see Atelectasis).

A secondary bronchitis, such as that which is apt to occur in the sub-

wer alcoholic stimulation is usually required early.

In bronc bronchitis the child should, if possible, be sent away for the micr to a mild climate where he can pass his time out of doors without his of chill. A sea voyage is very beneficial to these patients. As this min of the disease usually occurs in scrofulous children, the general treatment which has been recommended for that constitutional condition should be put in force.

The intercurrent acute attacks must be treated upon the principles much have been already indicated. Still, after the disease has returned to its return chronic course expectoration is often very difficult, and the breathing opposes of; and with the stethoscope we hear much large bubbling at the bases and for a considerable distance over both lungs. In these cases the erlinary expectorants seem to exercise little influence unless combined with bases. Quinine or quimne and mon, given with functure of squill, peaceants, and a drop or two of solution of morphia will often be found the expulsion of two politics. Cod-liver oil is also of great value not be to make in influence in checking secretion and problem the expulsion of phlegm. Tar taken internally has sometimes that influence in checking secretion and giving a more healthy tone to be taken membrane. A drop of liquid tar may be given on a small hand of sugar two or three times in the day; or for children who can take puls the remedy may be given as follows:

gr. ij.
gr. j.
gr. 88.
q a.

Sig. To be taken three or four times a day.

Inhalations are of service in these cases. The vapour of hot water imscatted with creasote, carbolic acid, or fincture of iodine (of either try drops to the pint), or of oil of turpentine (one drachin to the pint), he inhaled for half an hour several times in the day from Dr. R. J.

s "steam-draught inhaler."

The hypothermic injection of pilocarpine is often useful. In the case the key referred to above, one-fifteenth of a grain of the hydrochlorate fulocarpine was injected under the skin twice a day. The remedy expelled from the lungs. The effect of the drug was decided in minching for a time the amount of secretion, although it produced be permanent impression upon the disease.

Counter-irritation of the chest with the fincture or liniment of iodine

is often attended with great benefit; and warm woollen clothing worn next to the skin is essential to improvement. Still, in spite of all our efforts, although the child may appear better for the time, a cure is hardly possible in pronounced cases so long as the patient remains in a cold, damp climate. His only hope of throwing off the disease lies in his removal to a suitable air where he is not exposed to the constant risk of chill, and where no untoward conditions are present to interfere with his favourable progress.

CHAPTER X.

EMPHYSEMA.

Permonary emphysema is not uncommon in the child. As an acute lesion it is of frequent occurrence, arising in the course of various forms of pulmonary disease. It is then of little consequence, is accompanied by few symptoms, and usually subsides when the primary complaint has disappeared. As a chronic affection emphysema is met with much more rarely in early life; but a child so afflicted presents all the symptoms common to the adult sufferer, and may have his health permanently injured and his life considerably shortened by this condition of his lung. The lesion may be seen both in the vesicular and interlobular forms, and has been found at all periods of childhood, even in new born infants.

Causation. Pulmonary emphysema is always a secondary disease, and appears to be mainly due to forcible distention of the air-cells in the act of coughing. It is found in various forms of lung disease, especially in whooping-cough, bronchitis, and catarrhal pneumonia. Of these the violent cough of pertussis and catarrhal pneumonia produce the lesion with the greatest certainty, and emphysema is a constant complication of every

severe attack of these two diseases.

It seems probable that over-distention of the air cells in these cases may be effected both by inspiratory and expiratory mechanism. In whooping cough and bronchitis many air-resicles are rendered impervious by patches of disseminated collapse. In lobular pneumonia considerable portions of lung may be closed to the entrance of air. In all these cases the diminution in the respiratory surface necessitates increased energy of inspiratory movement, so that the air-vesicles which remain pervious are over-distended. Again, a serious strain upon the air cells is induced by strong expiratory efforts made when the glottis is closed, as when the patient is preparing to cough. Such efforts drive the air into the parts of the lungs which are the least supported, and dilute to excess the alveoli in these situations. In pertussis, especially, where the child strives with all his might to repress the cough, the strain is often very severe and long continued. Marked emphysema of the spices and auterior margins of the lungs may be excited by this means, and if the over-stretched walls of the air cells have been injured by the distention, the lesion may be a permment one. Usually the alveoli return to their normal size when their walls cease to be distended. It is only when the dilatation has been carried to an extreme degree, so as to impair the elasticity of the alveolar parietes, that the distention continues as a permanent condition.

Besides the diseases which have been mentioned, any complaint of which cough is a symptom may give rise to emphysems; as phthisis, where the alveoli at the bases often become distended; pleursy, where the air-vesicles of the sound lung are often temporarily over-dilated; also stridulous laryngitis, if prolonged, and membranous croup. In advanced

rickets, where there is marked grooving of the sides of the chest, the sternum is forced forwards at each inspiration, and the anterior borders of the lungs become over-distended with air. The mechanism of this form of emphysema is referred to elsewhere (see page 134). The tendency to perpetuation of the vesicular dilatation appears to be influenced by the scrofulous diathesis. It may be that in that constitutional condition the elasticity of the alveolar wails is more readily impaired; or it may be that the susceptibility to catarrh of the pulmonary membrane and other mucous tracts, inseparable from the strumous habit, induces a more frequent and persistent strain upon the air-cells. In any case the subjects of chrome emphysema in early life are usually found to be well-marked examples of the scrofulous diathesis.

Pulmonary emphysema may be found at all ages. It is not uncommon even in infants recently born. Thus, out of thirty-seven cases collected by Hervieux, nineteen occurred in infants under twenty days old, and of these one had lived no longer than two days. So, in a child who died of tetanus under my care in the East London Children's Hospital, aged fifty hours, the lungs after death were found to be emphysematous along the anterior margins, and also in spots over the surface. There were some

solid patches of unexpanded tissue in each lower lobe.

Morbid Austomy.—Pulmonary emphysema may be of the interlobular

or vesicular variety.

In interbolubar emphyseum the air occupies the connective tissue lying between the lobules and under the pleurs. When intiltrated into the tissue between the lobules, air collects in small bubbles like little beads. When in the sub-pleural tissue, it forms blebs of varying size—sometimes isolated, when they may reach the size of a small nut; sometimes arranged in lines, when they are rarely larger than an ear of wheat. Their shape is clongated or spherical. When thus extravasated into the pulmonary connective tissue, the air has been known to make its way into the anterior or posterior mediastinum and thence into the sub cutaneous tissue of the face and neck. Thus, in a case published in 1834 by Dr. Bird Herapatha child eighteen months old who had died of bronchitis secondary to whooping-cough-air was found to have escaped from one of the lobules seated at the root of the right lung into the anterior mediastinum. Starting from this point the air, without entering the pleura, had escaped along the sub-pleural connective tissue and formed numerous emphysematous swellings on the lung. It had distended the areolar tissue of the anterior mediastinum, and passing upwards had infiltrated into the cellular tissue of the neck, beneath the deeper cervical fascia and the subcutaneous tissue of the neck and chest. A similar case, in a child four months old, has been recorded by Dr. Pepper, of Philadelphia. In rare cases pneumothorax has been produced by rupture of the pleura and escape of air into the pleural cavity.

Interlobular emphysema is almost always produced by rupture of an air-vesicle during a violent fit of coughing. It may, however, be the result

of injury from without.

In cesseular emphysema the apices and anterior borders of the lungs are the parts commonly affected. These portions are dull white in colour, dry, and bloodless. They convey to the finger a peculiar soft sensation, which Hervieux has compared to that noticed when pressing a piece of wadding covered with satin. Close inspection in a good light shows a multitude of little, bright, transparent points the size of a pin's head. Sometimes rather larger projections are visible, and these are often angular.

When the chest is opened in these cases the lungs remain distended and their anterior borders are usually in contact so as to hale the greater porture of the cardine surface.

Symptoms — Intertebular emphysema, unless the air spread through the melisaturum to the sub-cutaneous tissue of the neck and chest, gives rise to symptoms. Its existence is only discovered on post-mortem examina-

um of the body.

Even in the waveler variety the limited amount of emphysems which soluted when the disease is acute, as in cases of catarrhal pneumonia, or state brunchitis with collapse, gives little evidence of its presence. Our the wedge of the morbid anatomy of such cases enables us to infer its existence, but the occurrence of abnormal dilatation of the air cells gives rise to be all litronal symptoms, and produces no characteristic modification of

the physical signs.

It is in the chronic form of the disease that we are able positively to determine the existence of over-distention of the pulmonary alveoli. In a procesured case of emphysema the symptoms and physical signs are those lander to us as a consequence of a similar condition in the adult. Such chilten, as has been already remarked, almost always present the chararterishe features of the strumous constitution. The patient is usually short for his age and of sturdy build. His head is rather large, his neck short with prominent jugular veins, and his face palled with a blueish tint round the mouth and eyes. The chest is flattened laterally at the base, and the lower part of the sternum is somewhat projecting. Consequently, to interesposterior diameter is increased. The intercostal spaces are ob tented, and in rare cases slight bulging may be noticed above the dineles. Sometimes the back is a little rounded, but I have never noticed the doop of the shoulders, which is such a marked feature in the adult, mess the employeema were combined with a persistent chronic bronchitis. The heart is pushed down so as to be felt beating in the epigastrium, and the liver and spleen are often appreciably displaced.

When a deep breath is taken the chest-walls rise and the shoulders are counted but there is little expansion of the upper part of the thorax, and the electric in at the base is exaggerated. On percussion, general hypermance is found in the front of the chest and the capillac area of dulness a lessened. With the stethoscope we find that the breath sounds are louded whereing above, weak although very harsh below, and more or less

to mentalant rhonehus is heard at various parts of the chest.

The symptoms vary according to the condition of the pulmonary mucous meanance: for, with such a state of lung, the child is excessively suscitude to fresh catarrh. At his best his breathing is hibitually short and offressed, but he coughs little and his appetite and spirits may be good, his when a new catarrh comes on that his troubles begin. When this accident happens, the breathing at once becomes difficult and wheezing, and he is subject to attacks of dyspinea which appear sometimes to be of the nature of asthmatic seizures. There is, however, another cause for these affects. In scrotulous subjects the breachial glands of the mediastina and hings are apt to enlarge as a result of pulmonary irritation; and these by their pressure upon the vagus, or directly upon the air-tubes, may produce their pressure upon the vagus, or directly upon the air-tubes, may produce their pressure upon the contract of air. The child's cough is husky and often occurs in paroxysms. He cannot lie down in his bed, and is much troubled at night by cough and dyspinea. If these symptoms continue, the patient passes into the condition which is described elsewhere as for the name of chronic bronchitis, and a case is there narrated in which

chronic pulmonary catarrh was associated with permanent emphysema of the lungs.

In cases where the attacks of catarrh are only occasional and pass completely away, the habitual state of the child is not unsatisfactory, but he is liable at any moment to be laid by under the influence of a fresh chill.

I may cite as a good example of chronic pulmonary emphysema the case of a little boy, aged three years, stout and thick-set, with large ends to his bones. The child only finished cutting his teeth at the age of two years and nine months, and was no doubt slightly rickety. He was said to have been wheeling off and on for eighteen months. Ten months previously he had been ill for a month with a severe attack of broughtts, and had since that time been a constant sufferer from wheeling and shortness of breath. In this boy the upper part of the chest was full and rounded, and there was some considerable constriction at the base. The heart's apex could be seen and felt in the epigastrium and between that point and the left nipple. The percussion note was drum-like all over the front of the chest, and much whistling and snoring rhonchus was heard

over both lungs. The heart-sounds were healthy.

Another little boy, aged two years and nine months, was said to have had a cough all his life, although it was better in the summer than the winter, and might even cease altogether for about six weeks in the warmest weather. The child was twelve months old before he cut his first tooth, and did not walk until the end of his second year. The ends of his long bones were full; but his limbs were straight, and he was not a marked specimen of rickets. The breathing was not much oppressed; the cough was hoarse, and the voice husky. He was not subject to attacks of distressing dyspinea, and was said never to have lost his voice. This little lad's chest was perceptibly retracted in the infra-mammary regions, and the lower part of the breast-bone projected. The spine was straight and the back rather flattened between the scapulæ. At each breath there was a slight sinking of the epigastrium. On percussion there was general hyper-resonance of the front of the chest, especially along the sternum. Some sibilant and large bubbling rhonchi were heard at each base behind.

In such cases as the above the emphysema is no doubt kept up by the repeated attacks of pulmonary caturrh. It is possible that if by residence in a suitable chimate such intercurrent attacks could be prevented, the emphysema might subside and the lungs return to a normal condition;

but upon this point I cannot speak with certainty.

It is not often in the child that serious secondary effects, such as passive congestion of the liver and kidneys, dilated hypertrophy of the right heart, ordems, etc., are noticed, although in some cases I have thought that the right ventricle was larger than natural. The danger of the disease consists principally in the repeated attacks of bronchitis from which these patients almost invariably suffer, and in the tendency of such attacks, if not immediately fatal, to run a chronic course. Usually, sooner or later, the life of the patient is brought prematurely to a close by this means.

Diagnose.— In the acute form of emphysems there are no symptoms sufficiently distinctive to indicate with certainty the presence of the lesson. This, however, is of little consequence, for no special treatment is required. In the large majority of cases the dilated air-cells return to their natural size when the cause or causes which have induced the distention are no longer in operation.

In chronic emphysems the chest distended in the upper regions and hyper-resonant on percussion, the diminished area of cardiac dulness, the pulsation at the epigastrium, the displacement of the liver and spleen (if present), and the wheezing breath-sounds are sufficiently characteristic of the lesion.

Promotis —In chronic emphysema the prognosis is not favourable; for although the disease in itself is little hurtful to life, the accompanying tendency to catarrh is a serious danger to the patient. If the child be found to suffer from repeated attacks of bronchitis, and in the intervals to be wheezy and scant of breath, we can never feel satisfied with his

condition or at ease with regard to his future prospects.

In cases of interlobular emphysema, where this has led to infiltration of air into the subcutaneous tissue of the neck and chest, the prognesis depends chiefly upon the disease, in the course of which the complication has arisen. The presence of subcutaneous emphysema is probably of little consequence, for the infiltrated air usually becomes absorbed very quickly.

Treatment.—In cases where acute emphysema is suspected no special treatment is required. So, also, in interlobular emphysema, where this has made itself evident by the passage of air into the subcutaneous tissue, no special measures are needed to hasten the absorption of the infiltrated

gases. They may safely be left to disperse at leisure.

In chronic emphysema any existing bronchitis should receive immediate attention, and the treatment must be conducted upon the principles described elsewhere (see Bronchitis). In the attacks of acute dyspines emeties are very useful; and ipecacuanha wine or the turpeth mineral, each of which produces free secretion of mucus, are to be preferred for this purpose. A teaspoonful of the former, or three or four grains of the latter in syrup, may be given every fifteen minutes until an effect is produced. If the attacks continue, the feet should be soaked in a hot mustard foot-bath, mustard poultices should be applied to the chest and back, and a draught containing ether and the tincture of lobelia may be given every hour. Children bear lobelia well. Ten drops of the ethereal tineture may be given to a child of two years old every hour or half hour without any danger. In very severe cases the fumes of Hinroid's powder may be inhaled. When the bronchitis has subsided iron should be given. A good form for its administration is the tartarate of iron with iedide of potassium. The combination makes a perfectly clear mixture with distilled water. It may be sweetened with glycerine.

The food of the child should be nutritious and digestible. The diet should be regulated upon the principles already laid down for the treatment of scrofula. In fact, emphysematous subjects, who, as has been said, are very often of the strumous habit, require in all points such general treatment as is recommended elsewhere for children suffering from the scrofulous cachexia. The most important point in the treatment of pulmonary emphysema lies in the adoption of means for the prevention of catarrh. With this object we should urge upon the child's parents the necessity of removing the patient to an equable chimate where he can live an out-door life without danger of chill. It is only by keeping the lungs free from catarrh that we can hope to promote a return of the air-cells to

their normal condition.

CHAPTER XI.

GANGRENE OF THE LUNG.

GANGREER of the lung is not a common disease of childhood. If the relative frequency of the relative frequency of the lesion, this form of illness would appear to be much more often net with in adult life than at an earlier age. A contrary opinion has, however, covailed, chiefly on the authority of E. Boudet, who in the space of the months met with five cases of pulmonary gangrene in the child. The experience is, however, too exceptional to furnish a satisfactory base in statistical calculation.

The extent of tissue which undergoes the gangrenous change is wrate. The lesion may occupy only a limited patch in one of the lobes our scribed gangrene), or may involve the whole of the lobe, or even of as

lung (diffused gangrene).

Causation. - Pulmonary gangrene may be the consequence of a gentle condition affecting the whole body, or may arise in constitutionally heads subjects from some local cause which interferes with the circulation of the

blood in the lung.

In the first case, a disposition to spontaneous mortification of the property manifested as a result of the cruptive fevers, especially measles, and said depressing diseases which cause great prostration of nervous power malower the nutrition of the whole body. The gaugiene is usually of the diffused variety, and the lung is often not the only organ which safe from the morbid tendency. There may be also gaugiene of the gains to checks, the pharynx, and in female children of the vagina, and these commonly precede in point of time any mainfestation of a similar affector of

the pulmonary or rans.

Of the local causes which interfere with the circulation through the lungs the most common in children is probably the presence of a force body in the air passages. The irritation of the intruding substance at up a form of pneumonia which may run rapidly into gangrene. Of the & examples of the lesion which have come under my own care one was a see of this kind. It is narrated shortly in another chapter (see page 523) cases where lobar pneumonia ends in mortification of the lung the .. grenous lesion cannot be looked upon as a natural consequence of the monary inflammation. Indeed, the inflammatory disease is often with true croupous pneumonia, but an acute heratisation of the lung read to from the presence in the organ of some local irritant. Thus a variety pulmonary inflammation with which gangrene is often associated is all due to emboli swept into the pulmonary circulation from an ante-more clot formed in the right side of the heart. The irritation of these ends causes complete stasis in neighbouring vessels, and sets up patroli ... and gangrone in the lung tissue around. Bouillard states that the cident may happen in cases of true croupous pneumonia and determine 🐸

agrenous change; indeed, according to this observer, a peculiar tensity to the formation of such congula is a common feature of the pneumonic disease. But even if this be the case, the mortification of tissue is clusted by something superadded to the original lesion, and is not to be exacted as an ordinary incident of the croupous form of pulmonary disamination.

The retention of decomposing secretions in dilated bronchi and cavities in the lung is another local cause of the gangrenous lesion in the child. It may receib the course of phthias, or at the end of an attack of acute catarrhal measurements. So, also, extensive hemorrhage into the lung, if it undergo pure faction, is said to be a cause of gangrenous changes in the surrounding tissue. No doubt in all these cases a debilitated or cachectic state of the lung may arise in children of sound constitution who are well lourished, and whose sanitary surroundings have been to all appearance

Mulactory.

Martial Anatomy.—The commonest form in which gangrene of the lung met with in the child is that of a patch of mortification situated in the entre of a lobe and surrounded by gray hepatised tissue. The gandramus patch consists of a pulpy detritus, yellowish-grey, dark green, or the grey in colour, and intolerably offensive in its smell. It gradually costs down and leaves a cavity with disintegrated gangrenous shreds adents to its walls. This is the circumscribed variety in which the number of sphacelated masses may be one or more. In some cases the diseased was in very small, and the lesion consists merely in greenish streaks of catarrhal and the lesion consistence in the centre of a bronchomonic nodule. In other instances we find patches of catarrhal mannonia enclosing small gangrenous abscesses of variable number, com-

In the diffused variety the gangrenous change involves more or less of the whole lobe. Thus, in a case recorded by Dr. Hayes, after the death of the patient—a boy of seven years of age—the lower half of the inferior lobe of the right lung was in a state of grey hepatisation. Its tissue was try frable, and drops of pus exuded from it on pressure. The remainder of the lung was of a dark purphish colour. Its tissue broke down on the largest pressure and gave forth an unbearable stench. The centre of the mobile lobe was occupied by an irregular cavity, about the size of a

arge walnut, filled with putrid matter.

In the circumscribed form the seat of the lesion is usually the lower to be or the periphery of the organ. In the latter case the pleura may be inflamed or may participate in the sphacelating process. In my was case, related elsewhere, not only was the whole of the left lung in a late of gangrene, but adhesions had formed between the adjacent layers of the pleura at the posterior surface. Moreover, the chest-wall had been afformed in the eighth intercostal space, and a communication had formed atment the disintegrated lung and an extensive abscess which lay outside wall of the chest.

If adhesion of the pleurs does not occur, pneumothorax may arise from

poture of the lung into the pleural cavity.

In many cases the bronchial glands are enlarged and cheesy. In two

Rilbet and Barthez' cases they were gangrenous.

Supplant. The symptoms of the disease are often very indefinite.

her may consist only of general drooping, disinchination to exertion,

ther and wasting, with alight cough and obscure pains about the chest.

CHAPTER XL

GANGRENE OF THE LUNG.

GANGRERE of the lung is not a common disease of childhood. If the prober of recorded cases be a fair measure of the relative frequency of the lesion, this form of illness would appear to be much more often that with in adult life than at an earlier age. A contrary opinion has, however provailed, chiefly on the authority of E. Boudet, who in the space of months met with five cases of pulmonary gaugrene in the child. The experience is, however, too exceptional to furnish a satisfactory like for statistical calculation.

The extent of tissue which undergoes the gaugeenous change is range. The lesion may occupy only a limited patch in one of the lobes or as seribed gaugeenes, or may involve the whole of the lobe, or even of the

lung (diffused gangrene).

Causation.—Pulmonary gangrene may be the consequence of a promcondition affecting the whole body, or may arise in constitutionally leads subjects from some local cause which interferes with the circulation of the

blood in the lung.

In the first case, a disposition to spontaneous mortification of these manifested as a result of the cruptive fevers, especially measure, and the depressing diseases which cause great prostration of nervous powers lower the nutrition of the whole body. The gaugiene is usually it diffused variety, and the lung is often not the only organ which safe from the morbid tendency. There may be also gaugiene of the gauss to cheeks, the pharynx, and in female children of the vagina, and these comonly precede in point of time any manifestation of a similar affector of

the pulmonary organs.

Of the local causes which interfere with the circulation through the lungs the most common in children is probably the presence of a form body in the air passages. The irritation of the intruding substance set up a form of pueumonia which may run rapidly into gangrene. Of the for examples of the lesion which have come under my own care one was a comof this kind. It is nacrated shortly in another chapter (see page 52%, h cases where lobar pneumonia ends in mortification of the lung the co grenous lesion cannot be looked upon as a natural consequence of us promonary inflammation. Indeed, the inflammatory disease is often mass true croupous pneumonia, but an acute hepatisation of the lung result as from the presence in the organ of some local arritant. Thus, a vacce of pulmonary inflammation with which gangrene is often associated is the due to emboli swept into the pulmonary circulation from an ante-mental clot formed in the right side of the heart. The irritation of these cales causes complete stasis in neighbouring vessels, and sets up putrels in and gangrene in the lung tissue around. Bouilland states that the erdent may happen in cases of true croupous pneumonia and determine the congrenous change; indeed, according to this observer, a peculiar tendency to the formation of such coagula is a common feature of the pneumonic disease. But even if this be the case, the mortification of tissue is in luced by something superadded to the original lesion, and is not to be regarded as an ordinary incident of the croupous form of pulmonary uniformation.

The retention of decomposing secretions in dilated bronchi and cavities in the lung is another local cause of the gangrenous lesion in the child. It may arise in the course of phthisis, or at the end of an attack of acute catarrhal postmonia. So, also, extensive hemorrhage into the lung, if it undergo patrofaction, is said to be a cause of gangrenous changes in the surrounding tissue. No doubt in all these cases a debilitated or cachectic state of the system favours the occurrence of pulmonary gangrene; but mortification of the lung may arise in children of sound constitution who are well posturated, and whose sanitary surroundings have been to all appearance

satulactory.

Merbid Anatomy.—The commonest form in which gangrene of the lung is met with in the child is that of a patch of mortification situated in the centre of a lobe and surrounded by gray bepatised tissue. The gangrenous patch consists of a pulpy detritus, vellowish-grey, dark green, or date grey in colour, and intolerably offensive in its smell. It gradually brake down and leaves a cavity with disintegrated gangrenous shreds adhering to its walls. This is the circumscribed variety in which the number of sphacelated masses may be one or more. In some cases the diseased are is very small, and the lesion consists merely in greenish streaks of cangrenous odour and semi-liquid consistence in the centre of a bronchopseumonic nodule. In other instances we find patches of catarrhal pseumonia enclosing small gangrenous abscesses of variable number, communicating here and there with a bronchus.

In the diffused variety the gangrenous change involves more or less of the whole lobe. Thus, in a case recorded by Dr. Hayes, after the death of the patient—a boy of seven years of age—the lower half of the inferior observed the right lung was in a state of grey hepatisation. Its tissue was not triable, and drops of pus exuded from it on pressure. The remainder of the lung was of a dark purplish colour. Its tissue broke down on the subtest pressure and gave forth an unbearable stench. The centre of the middle lobe was occupied by an irregular cavity, about the size of a

lurge walnut, filled with putrid matter.

In the circumscribed form the seat of the lesion is usually the lower libe or the periphery of the organ. In the latter case the pleura may be inflamed or may participate in the sphacelating process. In my manesse, related cisewhere, not only was the whole of the left lung in a tate of gangrene, but adhesions had formed between the adjacent layers of the pleura at the posterior surface. Moreover, the chest-wall had been perforated in the eighth intercostal space, and a communication had formed between the disintegrated lung and an extensive abscess which lay outside the wall of the chest.

If a the non of the pleura does not occur, pneumothorax may arise from

rupture of the lung into the pleural cavity.

In many cases the bronchial glands are enlarged and cheesy. In two

of Rilbet and Barthez' cases they were gangrepous.

Symptoms.—The symptoms of the disease are often very indefinite. They may consist only of general drooping, disinclination to exertion, pallor and wasting, with slight cough and obscure pains about the chest.

The physical signs may be also indefinite, consisting merely of slight diness at a certain part of the chest, with feebleness of breath-sound. After a time the child dies without any more characteristic symptoms having been developed, and the autopsy discovers a patch of gangrene in the large In almost all the cases observed by Rilliet and Barthez, these expensed physicians failed to detect the nature of the illness during the life of the nature.

In more pronounced cases the disease may begin gradually or saddenly. In the first case the child is noticed to be failing. His appute is poor, he looks pale, and his flesh feels flabby. Soon he complained pains in the chest, coughs occasionally, and sits by the fire if the weather is chilly, refusing to play, and objecting to any exertion. He is therety and sleeps restlessly at night, being often disturbed in his sleep by

cough.

The sudden onset may be announced by headache and sickness a feeling of chilliness, or even a rigor. The child is feverush, with a dry that is very restless and anxious, and the pulse is quickened. Perhaps there

may be pain in the side and a dry cough.

When the symptoms are fully developed the patient is pale and weakly looking, with a haggard expression of countenance, and dull, sunker ever The tongue is foul, and appetite is almost completely lost. The hours are seldom relaxed; sometimes there is marked constipation. There s often great restlessness, so that the child is in constant uneasy movement in his bed. The pulse is feeble and frequent, 130-150; the respectives 30-40. The temperature is high, and may reach 103° or 104' in the secing, usually falling in the morning to 100° or 101°. The cough is fee, and and loose. It is often excited by movement and may be accompanied by pains in the back or side. Usually there is expectoration even in the children, for the sputum is too offensive to be swallowed. It exhaust sickening odour, and is frothy and reddish-brown in colour. On standar it deposits a reddish-brown, shreddy sediment, containing greath participated granules, in which Leyden and Jaffe have discovered bacteria and a specific fungus—the leptothrix pulmonaris. In quantity the expectoration cans from time to time, being sometimes copious, sometimes scanty and por tenacious. Occasionally the fetid odour ceases to be noticed, but it was quickly returns. A similar odour is perceived in the breath of the joint! especially during cough. As in the case of the expectoration, its offense ness occasionally ceases for a time. The cough may be so harasem: frequent as almost entirely to prevent sleep; and the consequent established tion, combined with the unwillingness of the child to take admust nourishment, adds greatly to his weakness.

In most published cases great variation has been noticed in the stensity of the symptoms. Sometimes the pulse is excessively frequently and feeble, the eyes sunken and lustreless, the restlessness extreme the cough distressing, and the face earthy or lead-coloured. The breakers also may be laboured and difficult. Thus, in a case recorded by last Sturges there were attacks of violent dyspinons in which the face looks pinched and blue, the expression was terrified, the body was count with a clammy sweat, and no pulse could be felt at the wrist. At other times the symptoms are less distressing, the face looks brighter the course quieter, the pulse fuller, and the manner more composed. The pulse for cases sinks after a further period of suffering. Sometimes death a preceded by one or more attacks of hemoptysis. In a case reported is

Dr. Hayes, the child, on the afternoon before his death, after a fit of coughing, spat up half a pint of red, frothy blood; and the hamoptysis was repeated in the evening shortly before he died.

In some cases gangrene of the gums or cheek has been observed; and if the signs from the lungs are not marked, the fetor of breath may

be attributed to the presence of these lesions.

The duration of the illness in cases which terminate in death is never very prolonged. Dr. L. Atkıns, who has collected thirty-one cases of the affection, states that it varies between two days and twenty. The child usually dies from asthenia. The complexion grows more and more livid, the pulse weaker and more rapid, and death may be preceded by a gush of blood from the mouth or by rupture of the lung and the formation of pneumo-thorax.

In the rare cases in which recovery has been recorded, the fetor of the breath disappeared at the end of a fortnight or three weeks; but con-

valescence was very slow.

The physical signs in cases of pulmonary gangrene are not distinctive of the lesion. At first the signs are usually those of bronchitis. Percussion of the chest discovers no dulness, and with the stethoscope we find merely large bubbling rhonchus pervading the lung on both sides. After a few days a limited area of dulness is detected at some part of the chest—usually the posterior base; the breath-sound becomes brouchual, and the rides are drier and more crepitating in character. The dulness usually extends its area and may pass to the front of the chest. If eventually a cavity form, it may give no evidence of its presence unless its situation be near the periphery. In that case the breathing may become bronchial, blowing, or cavernous, and the rhonchus larger and more distinctly gurgling. In the case of a large cavity amphoric respiration with metallic

tinkle may be discovered at some point in the dull area.

In a case which was under the care of my colleague Dr. Donkin, in the East London Children's Hospital—a microcephalic idiot, between two and three years old, who was admitted for rigidity and paralysis of joints, with partial loss of consciousness—the breath a few days before death was noticed to have an insupportably offensive odour. The child began to cough slightly, and the pulse and respiration were greatly hurried. On examination of the chest dulness was discovered at the left base, passing round from the back to the front, being most intense beneath the left axilla. Much large bubbling rhonchus was heard all over both sides, especially the left. The child grew rapidly worse, the face became much pinched, and petechase appeared upon the abdomen. The temperature, which had been always high, rose to 108° shortly before death. An autopsy revealed two small embolic infarctions in the left lung. The lower lobe was completely solidified, and contained a cavity the size of a hen's egg. This excavation was partially lined with a membrane, and held much stinking fluid and detritus. The right lung was merely congested with patches of collapse.

In this case the high temperature noted before death was probably due more to the condition of the brain than to that of the lung. The cavity seems to have been the consequence of breaking down of an inflammatory consoliciation set up by a metastatic infarction, the gangrenous nature of the process being determined by the low agreeous power of the

patient

Diagnosis.—On account of the uncertain character of the symptoms and physical signs which present no definite features by which the disease

can be recognised, we are forced to rely solely upon a gangrenous udor from the breath and expectoration for evidence of the nature of the lesion. Without this symptom there is really nothing in the condition of the child to suggest that the inflammatory process has gone on to mortification of tissue; for a cachectic appearance, great feebleness, a laggard look, constant restlessness, and varying intensity of symptoms are common to many forms of illness. If the characteristic fetor of break be present alone, it may be the consequence of other conditions. It gangrenous atomatitis and gangrene of the pharynx the same phenomenon may be observed; and in many cases of cirrhosis of the lang when secretion is retained and becomes decomposed in the dilated toler. the odour of the breath may be exceedingly offensive. In the latter isease, although the breath and expectoration may be very offensive without obvious gangrene being present, shreds of sphacelated usue are, no doubt, present in the matters discharged from the lung. If gangrene of the haz coincide with the same condition of the mouth the unpleasant odour > usually attributed to the lesion which is within reach of the eye, and the pulmonary gangrene may not improbably pass unrecognised. pearance of offunsive expectoration, however, at once directs attention to the lung, and if hemoptysis occur, the blood giving out the same unlessable odour, doubt is no longer possible.

In infants and the youngest children expectoration is sometimes abset, but a gangrenous odour from the breath is seldom wanting. Fetor of the breath in such cases is the more characteristic, as fibroid induration of the lung is very rare below the age of six years, and gangrene of the most

is not often met with during the first two years of life.

Prognosis.—Recovery is so exceptional a termination of the disease that in any particular case the patient's chance of escape is very small. Vinitions in the severity of the symptoms are a common feature of the illness and we must not allow our hopes to rise too high merely because we to the child looking brighter and more composed, and notice that the fell odour from the breath is no longer to be perceived. Such a favorable change is too often only a temporary improvement, to be followed, perhaps a few hours, by a return of all the worst symptoms. If, however, the dar acteristic odour is not reproduced, and we find that the pulse because fuller and stronger, and the cough less distressing; that the tongue legal to clean and the appetite to return, we may centure to hope that the factor able change may be maintained. According to Kohts, when the grants results from the presence of a foreign body in the lung the present less desperate than in other cases, but this can only be if the intake substance is expelled.

Treatment.—In the treatment of this distressing disease we must do our best to support the strength of the child and make energetic entire.

ment of disinfecting and stimulating inhalations.

The chamber should, if possible, be large, and must be kept theregiventilated. It should be continually disinfected by spraying with called acid or Condy's fluid, and pans of either disinfectant should stand and the room.

The child should be made frequently to inhale vapours or spray in pregnated with oil of turpentine (ii) xx. -xxx.) to the pint of boiling war or with creasote or carbolic acid (iii) xx -xxx. to the pint). Glycenter of carbolic acid may be also given internally, in one or two drop does, are ing to the age of the child; and Traube recommends the salicylate of with or the acetate of lead. The sulpho-carbolates are said to be of service.

removing fetor, if given freely. The sulpho-carbolate of soda may be given to a child of four years old in doses of four grains every six hours. Buc quoy recommends the tincture of encalyptus for the same purpose, and states that the remedy not only reduces the offensive odour of the breath and sputum, but relieves the violence of the cough. A child of four years

old may take five or six drops three times a day.

Quinine and the mineral acids are preferred by some; and it is important that the former, if employed, should be given in full doses. For each dose the quantity may be calculated at one grain and a half for each year of the child's age; and this may be given three or four times in the twenty-four hours. Ammonia and bark have also their advocates. The bowels must be kept regular. If they are confined a dose of castor-oil will usually relieve the constipation.

Alcoholic stimulants are always required. For an infant white wine whey, for an older child the brandy-and-egg mixture should be given at

frequent intervals.

With regard to diet: an infant should be restricted to milk diluted with barley-water and guarded with a few drops of the sucharated solution of time (twenty drops to the teacupful). An older child can take milk, strong beef-tea, pounded meat, eggs, etc., in quantities regulated according to his age and powers of digestion. In this, as in all other cases where the debility is great, we must remember that the digestion shares in the general weakness; and must be careful not to overload the stomach or fill the blood with unassimilable nutriment in our anxiety to sustain the strength and obviate death from asthenia.

CHAPTER XII.

PULMONARY PHTHISIS.

PULMONARY phthisis is a common disease in the child. The term sensite ulceration of the pulmonary tissue. The affection is therefore practic distinct from acute tuberculosis. The latter is a general disease in what the lungs, if they are involved at all, are affected in common with most other organs of the body, and if they undergo disintegration break domas a consequence of inflammatory changes due only indirectly to the presence of the grey granulation. Pulmonary phthisis, even when the consequence of a general dyscrasia, is especially a lung disease, which if it rules course unchecked passes on necessarily to softening and excavation.

Phthisis may be acute or chronic. The acute form is not uncommon a young subjects, and consists in rapid hepatisation and caseous untitabes of the lungs, with equally rapid softening and disintegration. The form of the disease is to be distinguished from acute pulmonary tuberculoss.

although it may be combined with it.

Chronic phthisis is seen in two principal forms, viz, chronic tubercular phthisis and catarrhal or pneumonic phthisis. These varieties differ markedly in their mode of origin, their course, and often in their termination and are, no doubt, the consequence of very distinct pathological conditions.

Causation.—Most cases of pulmonary phthisis are dependent upon a general predisposition, which may be hereditary or acquired. The end may be born into a consumptive family and thus inherit a constitution delicacy which renders him especially sensitive to morbific influences. On the other hand, although without any family tendency to this form of the ness, the patient may yet, through the agency of special disease, add prhaps by insanitary surroundings, acquire a pulmonary weakness when sooner or later, under suitable conditions, developes phthisical changes in

the lung.

The inherited disease may consist of either form of phthisis and either variety may be acquired by a child in whose family no tendent to consumption can be discovered. Even chrome tubercular phthist of though in the majority of cases no doubt the consequence of an inherital predisposition, may be excited by infective agency through the presence softening cheesy matter at some part of the body. A special pulmound delicacy is often the consequence of whooping-cough and measles. The diseases are very liable to be complicated by catarrhal pneumona and often happens that after convalescence the absorption of the consumitate material is incomplete. Consequently a caseous lump is left at some part of the lung, which after remaining inactive for a shorter or longer parts begins at length to soften and set up irritation in its neighbourhood. Because if perfect absorption of the consolidating material take place, a consequential take place, a consequence of the inflammation, as taken the child becomes attacked again and again by obstinate catarrha. These

catarrhs in favourable subjects are apt to lead to cellular infiltration of the bronchiad walls and gradual invasion of the alveoli. In this way a catarrhal

or pneumome phthisis is eventually developed.

In children of scrofulous tendencies there is very commonly a pulmonary weakness. The child is very subject to catarrhs, and he has also the proneness inseparable from his strumous constitution to rapid proliferation and caseation of cellular elements. In such a subject a catarrhal phthisis is readily set up. So, also, in subjects especially prone to tubercular formation the lung irritation may induce this variety of pathological change. In the present day, owing to the discovery by Koch of the tubercle bacillus, there is a tendency to look upon all forms of phthisis as due to infective agency. According to this view, the various pathological conditions would be all tubercular, as the bacillus appears in most cases to be discoverable either in the sputum or the pulmonary tissue of the part affected. The question, however, is as yet far from settled; and looking at the wide differences in the climical characters of the several forms of pulmonary phthisis, it seems desirable to consider these diseases from a climical rather than from an anatomical point of view.

The causes which tend to originate a pulmonary weakness or encourage a natural deheacy of lung are all those which in any way help to lower nutrition and depress the natural vigour of the body. In childhood—a period of life in which nutrition is only maintained at a healthy standard by the continual influx of nutritive material—any interference with the digestive or assimilative processes has an exceptional influence in diminishing resisting power. It is for thus reason, probably, that in unwholesome conditions of living slight febrile attacks, such as are incidental to many of the less serious ailments of early life, may start an enfeebling process which ultimately determines phthisical changes. In this way unsuitable food and close rooms, a damp residence, mental depression from unkind treatment, over-exercise of the immature brain, and any other like agency

may have an influence in exciting the mischief in the lung.

Certain diseases have an undoubted tendency to be followed by phthese. On this account measles and whooping-cough are justly dreaded for the injurious influence they are known to exercise upon scrofulous and weakly subjects. These affections not only encourage a special lung weakness, but also by promoting enlargement and caseation of the lymphatic glands, may set up a focus of infection by which, through the medium of the blood-vessels or lymphatics, secondary inflammatory processes of a more or less acute character may be excited in the lung Scarlatina, too, is sometimes a cause of phthisis, acting by similar means; empyema may induce the pulmonary muschief through absorption of infective material from the pleura; and the disease not uncommonly arises in children who suffer from scrofulous joints and old-standing caries of bone. The influence of catarrhal pneumonia in inducing the disease has been already referred to.

Since the discovery of the bacillus the question of the infectiveness of phthusis from person to person has again assumed considerable prominence. The presence of bacilli has been discovered in the air expired by consumptive principles; and if this microphyto be indeed the agent by which the infection is conveyed, it would seem to follow as a logical conclusion that the disease must be continually communicated by this means. Whether, however, it be that a predisposition of rare intensity is required for the ready reception and development of the bacillus, or that the importance of this organism as an infecting agent has been overestimated,

the fact remains that the disease is practically not communicable by an

Morbid Anatomy.—In all cases of pulmonary phthisis the lungs after death are found to be more or less consolidated by a cheesy-looking mastance which is in various stages of softening and disorganization. Whether the disease has begun by a chronic process of tuberculastic, or has originated in a catarrhal pneumonia and epithelial accumulates a the alveoli, the degeneration of the morbid material gives rise to cases solidification of very similar character. Even when the primary pathlogical change consists in a chronic formation of grey tubercle in the lung tissue, a secondary catarrhal pneumonia is usually set up sooper or later; and the resulting caseous infiltration materially contributes to the enlargement of the area of solidification. Again, when the form of phthisis is originally catarrhal, softening of the cheesy material which infiltrates the lung may be a source of infection. By this means a secondary formation of miliary tubercle is excited, at first in the immediate neighbourhood of the affected region, afterwards more generally over but the lungs. Consequently, in most cases, the pathological changes are not simple, but tend to complicate one another, so that the lung is at the same time the seat of different morbid processes. We often find grey or relies granulations combined with masses of yellow infiltration of various extent In these masses the tissue is soft and friable, and on section is found to be dryish, of a straw or grey colour, and streaked or spotted with black pigment. The surface is commonly marked with intersecting hies which indicate the position of the interlobular septa. At the borders of the nasolidated region is usually a zone of reddish-grey glutinous intiltrance Often many of these caseous masses are seen scattered over the lang. the pulmonary tissue between them being cedematous or congested, and partially collapsed.

If the phthisis has reached an advanced stage, cavities from breskes down of the consolidating material are usually found. Cavities are not uncommon in the young subject, and are probably met with less frequerity in the child than in the adult, only because the disease in early life the proves fatal from a secondary tuberculosis or other exhausting completion before the stage of excavation has been arrived at. When selfeting begins, it always occurs first in the centre of the caseous mass. The deal shrunken cells and molecular debris lying around them are loosened by the imbibition of watery fluid, and the cheesy material is converted by the imbibition of watery fluid, and the cheesy material is converted by the nodule, then becomes perfornted, and the cheesy matter is converted up, leaving a ragged accavation. The softening may attack the disease generally through the long, as happens in the more acute formed the disease; or may begin in those situated in the upper part of the long, and thus pass gradually from apex to base. The expectorated matter is these cases contains particles of elastic tissue and shrunken cells, and

often under the microscope exhibits bacilli in large quantities.

In cases where the disease consists principally of the grey and selection miliary nodules, these bodies are seen grouped in clusters and more the less closely aggregated. They are more numerous towards the application and in some parts, in addition, there may be softening characteristic more or less disintegrated. In most cases the lungs are also found to the seat of increased fibrosis, and some dilatation of the smaller arctules can be perceived.

The real tubercular phthisis attacks both lungs simultaneously. The catarrhal form begins in one lung, and it is not until signs of softening are noticed that the opposite lung becomes affected. This softening of the cheesy matter in the affected lung is often a signal for a more general diffusion of the disease. The apex of the opposite lung is attacked, and cascation and softening occur in the glands of Peyer's patches and in the solitary follicles in the neighbourhood of the illo-caecal valve, giving rise

eventually to ulceration of the bowels.

On microscopical examination of the lungs, the seat of pulmonary phthisis, various histological changes are discovered. According to Dr. T. Henry Green, these are mainly of four kinds: 1st, a filling of the pulmonary vesicles with fibrinous exudation and leucocytes; 2d, an accumulation of large epithelial cells within the alveoli; 3d, an infiltration and thickening of the walls of the air-vesicles, and often also of the terminal bronch with small cells; 4th, an increase of the interlobular connective tissue. These various changes occur in varying degrees in different cases, but all of them are said to be present in the majority of instances, although in very different proportions.

In a practical treatise it is unnecessary to enter minutely into the various pathological changes which combine to make up a case of pulmonary phthisis; and the reader is referred to the standard works on pathological anatomy for fuller information upon this subject. The preceding sketch is necessarily brief and imperfect; but some reference to the conditions which give rise to the signs and symptoms about to be

enumerated was indespensable.

The acute and chronic forms of pulmonary phthisis will be described separately.

ACUTE PHTHISIS.

Acute phthisis, or "galloping consumption," is not uncommon in early life. The term is sometimes used to include cases of acute pulmonary tuberculosis. It is, however, more properly restricted to cases of rapid catarrhal pneumonia where, as a result of an acute inflammatory process, the air-cells become stuffed with epithelial elements which undergo rapid casestion, and the solidified tissue quickly breaks down into cavities. The consolidation is at first lobular and is generally diffused over the lungs. Softening takes place pretty equally in all parts at the same time, so that the lung becomes destroyed by sinuous and burrowing cavities separated by reddened and esdematous tissue; much purulent matter is formed, and the lining membrane of the air-passages is excessively red. In this form unhary tubercle may occur as a complication, but its appearance is comparatively rare, for the disease is essentially pneumonic in its nature.

Acute phthisis generally occurs in a child who has been reduced in health by previous illness or bad hygienic conditions, and is sometimes seen to attack one already the subject of a chronic consolidation which had given rise to but few symptoms. The age of patients so affected is usually

five or six years and upwards.

Symptoms.—The general features of the illness are those of an acute attack of pneumonia combined with very great severity of the general symptoms. At first the child usually complains of a pain in the side. Thus may come on quite suddenly during some slight muscular exercise. Thus, in a little girl under my care, the child first complained while she was helping her mother to make a bed. The pain may subside after a time, or be complained of occasionally all through the illness. Cough comes on at

the same time with the pain, and the child is noticed to be very levered a night. In older children the cough is usually accompanied by expect a tion. The sputum is at first whitish and attated, but as the lungs beta to break down it becomes yellow or greenish and numinulated and a found to contain large quantities of yellow elastic tissue. The number bacilli found in the sputum is not, however, always very great. In succases under my care these organisms were found in much less quantities in cases of phthisis which ran a more chronic course.

Dyspuces is always an early symptom; the appetite is very poor, they is great, the tongue is furred, the bowels are relaxed or confined and the child wastes with extreme rapidity. In some cases swelling of the abdate is noticed, and the liver may be found to be enlarged from fatty infiltration.

The fever is often very high. It is not uncommon to find that the temperature rises to 104° or 105° at night, sinking to 100° or 101 as the morning. It soon begins to be accompanied by copious sweats, and the night-clothes may be drenched by the profuseness of the secretion

Examination of the chest discovers principally the signs of burshopneumonia. Dulness is noticed, usually beginning at the upper part of the lung. At the onset this may be limited to one side of the chest, but the opposite lung becomes very quickly affected. That first attacked he ever, generally maintains its precedence and keeps in advance of its fed a throughout the course of the disease. The diminution of resonance revolves more and more of the area of the lung, and is accompanied by bronchial or blowing breathing which may be more or less covered by a copious, course, subcrepitant rhonchus. This râle is usually heard and the whole extent of both inspiration and expiration, and is very large and metallic in quality. In spots here and there cavernous respiration may be heard after a time; and the rhonchus in such places is larger and in we ringing than elsewhere. If a cavity of some size form, the breath-some may be amphoric. Vocal resonance is usually stronger than natural and may be bronchophonic in places.

The above are the physical signs in a typical case of the disease but must be confessed that in many cases, especially in the younger children cavities may form in the lung without any sign of their existence been noticed on examination of the chest. In such cases the signs are class those of catairbal pneumonia; but the dulness begins at the upper partition chest instead of the lower, and the rhonchus is usually larger and a ringing and metallic than in an ordinary case of broncho-pneumonia. Be child in all cases looks excessively haggard and ill. The wasting is prapid; in a surprisingly short time the temples and cheeks get hell must the flesh seems to fall away from the body. Often more or less getting cadema is noticed, although an examination of the urine may discover to

trace of albumen.

A little girl, aged thirteen years, was said to have been healthy until age of six years when she had an attack of measles followed very state by scarlatina. Enlarged glands formed in her neck soon afterwards to some of these suppurated. Since that time the girl had been delicate, had never coughed until ten months before coming under observation for four months her cough had been very distressing, and she had suffered much from pain in the side. She had been very feverish, had successively at night, and had wasted rapidly.

The girl was much emaciated and very weak. She had a district haggard expression. The cervical glands were enlarged, and her neck has many sears resulting from former suppurations. On examination of the contraction of the

chest the clavicles were seen to be very prominent from retraction of the apices of the lungs. There was much diminution of resonance over the whole of the right side and at the upper third on the left; and much coarse, metallic, bubbling rhonehus was heard over the whole of both sides. The respiration was cavernous towards each apex, and bronchial below. The liver was enlarged, reaching nearly to the navel.

The girl complained greatly of dysphoea and sweated freely at night. Her cough was troublesome, and she expectorated nummular sputa. She atous, and her urine contained albumen. There was no diarrheen.

During the first few days the gurl's temperature was 101' at night, sinking to the normal level in the morning. It then became subnormal both morning and evening, and the patient died on the twelfth day after admission into the hospital. On inspection of the body cavities were found at the upper part of each lung, and other small collections of purulent matter were scattered over both organs. The pulmonary tissue generally was red, and easily broke down under the finger. At the base of the right lung a marked increase in the fibrous tissue was noticed, and the bronchial tubes in that situation were somewhat dilated. No grey or yellow tubercles were to be seen. The pleural surfaces were firmly adherent. The kidneys appeared to be healthy.

Death is preceded in these cases by great prostration, restlessness, and inability to sleep, complete anorexia, a glossy eroded tongue, and sordes upon the teeth and lips. The duration of the illness is comparatively short, and death usually takes place at the end of five or six months.

Diagnosis. - The disease with which acute phthisis is most liable to be confounded is acute pulmonary tuberculosis. In the beginning, however, the affection may be mistaken for croupous pneumonia. The sudden onset, accompanied by pain in the side, cough, and high fever, presents sometimes a close resemblance to an ordinary case of inflammation of the lung. Still, the temperature does not maintain the same little varying clevation in acute phthisis as in croupous pacumonia, and the course of the illness in the two cases is very different. Instead of the sudden crisis which occurs in pneumonia about the end of the first week, the symptoms persist and grow more and more severe, the signs of consolidation continue to extend themselves, the opposite lung is quickly affected, and very soon clastic tissue, and perhaps bacilli, can be discovered in the spulum.

From acute pulmonary tuberculosis the disease is distinguished by its more abrupt onset, the early signs of pulmonary consolidation, and the absence of indications pointing to the implication of other cavities of the body. Comparatively few cases of pulmonary tuberculosis in the child terminate without some signs of intracranial mischief; but when acute phthisis is uncomplicated by tuberculosis these are absent. The two diseases are, however, sometimes present together. The existence of the tubercular malady is then made evident sooner or later by the onset of convulsions, squinting, rigidity of joints, and other symptoms pointing to

Prognosis.—Acute phthisis is a very fatal disease, and the prognosis is consequently very unfavourable. The patients do not invariably die, but instances of recovery are exceptionally rare. In any case the best we can hope for is a remission in the acuteness of the symptoms. Sometimes the discuse, its first force expended, loses a part of its energy and becomes unite measured and tranquil in its course. It may even settle down into

an ordinary case of chronic phthisis. It is impossible in any indicate instance to anticipate such a result; but a dimension in the pyrous of combined with an improvement in the appetite and a brighter expression the face of the child, is a sign of good omen. A decrease in the face if unaccompanied by other signs of improvement, so far from but; of avourable symptom, is one to be regarded with great anxiety, and under such circumstances, the temperature fall to a subnormal level 2 may be an indication that the end is not far off.

The treatment of these cases will be considered afterwards.

CHRONIC PULMONARY PHTHISIS.

The two principal forms in which chronic pulmonary phthisis usually presents itself in the child have well-marked and very distinctive this acters. Chronic catarrhal or pneumonic phthisis, which begins as a slowly forming consolidation of one lung, or succeeds to an attack of acute cat. rhal pneumonia from imperfect absorption of the solidifying material in at first the characters of a local disease. It is accompanied by certain again and symptoms which indicate the existence of irritation within the haz. but as a rule the general health is comparatively little interfered with nutrition is fairly performed, and the appearance of the child gives hillevidence of serious pulmonary mischief. It is only when softening is set up at the seat of consolidation, and infection of the system follows with secondary deposits in the opposite lung and other parts of the body that signs occur indicating that the patient is suffering from a general decar. Even when these general symptoms arise, they remain for a long time insignificant as compared with the signs of extensive disease discovered m examination of the chest. On the other hand, chronic tubercular plants has completely different characters. From the first indeed, before any signs of pulmonary irritation have been noticed-there is some fever and wasting, showing general distress of the system; and throughout its whole course of the illness the general symptoms continue severe out of all proportion to the actual extent of lung mischief discoverable by the stethoscope. Therefore, whatever opinions may be held with regard to the pathology of these two varieties, they still remain two distinct charal types marked out from one another by very separate and distinctive features.

Symptoms.—The peculiarities in the size and shape of the chest strained with in children of consumptive tendencies are elsewhere referred to (see page 399). It may, however, be remarked that although small but and a carrow elongated chest are often found associated with an inheated pulmonary weakness, phthis is is not confined to such subjects. We stall never be justified in excluding pulmonary phthis is because the child shoulders are broad and his chest well proportioned. In the productor form of phthis the eye often detects nothing to raise a suspicion of pulmonary mischief. It is the tubercular variety which is most constantly combined with narrow sloping shoulders and flattened ribs

In both varieties of phthisis we find local symptoms against ant of pulmonary distress, and general symptoms arising from irritation of the system and impaired nutrition. The severity of the case is usually my fairly indicated by the degree in which the latter predominate over the former.

.In chronic pneumonic phthisis the first sign of the disease is usualy

cough. The patient may have lately passed through an attack of acute catarrhal pneumonia, or may have suffered from neglected pulmonary catarrh with gradual implication of the alveoli at one apex. In the first case the child recovers his strength but slowly. He continues to cough, often violently; and is more or less feverish at night. After a time, however, the fever subsides, and the child regains flesh and a certain proportion of his strength; but he still looks pale and has a frequent lacking cough. In the second case the disease creeps on insensibly, and at last it is noticed that the child coughs, and is pale and easily tired. However the disease may have originated, the symptoms are insignificant as long as the unabsorbed deposit in the lung is undergoing no active change. A child with an unabsorbed mass of caseous matter in his lung may be plump, active, and cheerful; but he is usually rather pale, may complain of pains in the lumbs, and is apt to cough a little in the morning or in the day after exertion. On examination of the chest at this period we find slight dulness with some little increase of resistance at the apex or any other part of the chest on one side. If at the apex, the dulness is best detected at the supra-spinous fossa. The breathing is bronchial and some coarse clicks are heard with inspiration. The resonance of the voice is also increased. Children with the lung in this condition are very susceptible to chills; and if tirst seen when the lungs are the sent of a fresh catarrh, general bubbling may be heard all over the diseased side; and also, but to a less extent, over the opposite lung. When this happens it is difficult to form a correct opinion as to the actual amount of disease present in the chest; and it is well to correct our first impressions by the results of a subsequent examination.

At this stage of the illness, before softening has begun, absorption is still possible, and sometimes occurs in young subjects many months after

the first symptoms have been noticed.

When softening begins the general symptoms become more pronounced. There is fever, the evening temperature rising to 102 or 103"; there is marked pallor, although the checks become flushed towards night; and the expression is distressed. Often the child sweats towards the morning. These symptoms indicate an infection of the system by absorption from the softening area. The disease from being local is becoming general; and the consequences are quickly seen in the interference with nutrition which never fails to ensue. The child begins to lose flesh and strength; his spirits fail; his appetite and digestion become poor, and he shows all the symptoms of suffering. The course of the disease is almost always unequal. Every now and again an improvement is seen to take place. By careful nursing and treatment the fever diminishes or subsides; the nutrition improves; and deah and strength are regained. It is not uncommon to see a child fairly plump and to all appearance in tolerable health, who yet has a cavity in one lung and signs of consolidation at the opposite oper.

During this stage pains are often complained of in the shoulder of the affected side. They come and go, and seldom continue for long together. The respirations are usually more hurned than in health, but when the child is quiet are not necessarily much exaggerated. The increased frequency of breathing is a cause of no inconvenience to the patient, and unless after exertion does not give rise to a feeling of dyspinea. The cough is frequent and fairly loose. If expectoration occur, the sputum consists of yellowish or greenish muco-purulent matter which under the microscope is found to contain fragments of yellow elastic tissue and

often bacilli, the latter perhaps in large quantities. Harmoptysis is resulted does occur in exceptional cases. Children accustomed to a sufficient of good food seldom have much appetite, and often show a complete degust for food. In hospital patients, however, the appetite may reaskeen; and a child with cavities in his lungs and a high temperature are be seen to enjoy his meals almost as if he were well. The digestics is usually impaired, and, probably from the quantity of acrid muchs whell is swallowed, vointing is not uncommon. Diarrhos, too, is a familiar expetion. In cases where the appetite is preserved nutrition may seen for time to go on fairly well in spite of the pyrexia. Hospital petients of gain weight after admission, although the evening temperature may stable

every night at 102 or 103°.

The physical signs in the stage of softening consist of an increase the dulness, for the irritation set up by the changes occurring at the decod spot induces an extension of the catarrhal process; and an alteration is the quality of the breathing, which becomes blowing or even essential It is accompanied by a moist crackling rhonchus which, as a cavity form becomes very metallic and ringing. At this time the apex of the opposite lung should always be carefully examined. In many cases slight loss if resonance with high-pitched or faintly bronchial breathing will be found at the supra-spinous fossa, and a chek or dry crackle can be heard at the col of inspiration. It is at this period of the illness that diarrheen is experient frequent; and if caseation and softening occur in the solitary followed the intestine and the glands of Peyer's patches, the stools may soon began to present the characters peculiar to ulceration of the mucous mentione (see page 662). If this complication occur, the child wastes rapidly and becomes haggard and hollow-eyed. He sweats profusely at night; is restless; refuses food; and quickly dies with all the symptoms of prostration The temperature in these cases seldom reaches a high elevation. It a

usually between 101° and 102 in the evening.

Children who are the subjects of a chronic caseous consolidation of the lung often suffer from attacks of secondary catarrhal pneumonia. In the attacks the boundaries of the original mischief are not always extend-It is common to find the chief force of the complication expended upon different part of the lung. Thus, a child with signs of consolidated at the apex of the right lung is attacked with catarrhal pneumonia. A loud corp itating rhonchus is heard all over both sides of the chest, and at the nest posterior base there is some dulness with tubular breathing and a metale quality of the rhonchus. The basic dulness becomes gradually more prenounced, and at this spot the respiration gets to be cavernous or crease phoric, and the rhonchus to be excessively metallic and ringing. The occresonance is broughophonic. The temperature rises to 103 or 101 m the evening. After two or three weeks the temperature begins to fall and the dulness to diminish; the hard metallic rhonchus becomes looser and aste bubbling; the cavernous breathing is less intense at the base, and the gling is less large and metallic. The child begins to regain firsh, and about lost sight of, although looking plump and well, has still the old manual at the apex, and the signs of consolidation with cavernous breathing still jet sist at the base of the lung. In such a case, which is no imaginary occ. child recovers from his intercurrent attack with two consolidations intest of one. The catarrhal pneumonia has given rise to a cheesy deposit at the base of the lung and dilatation of the bronchi. This of course if the patient be placed under favourable conditions, may possibly be recovered from; but the probable consequence of such a condition, if time be allowed

for the change, is the development of a fibroid overgrowth at the spot and permanent brouchectasis.

An attack of broncho pneumonia is often a cause of death, or the patient dies worn out with fever, diarrhous, cough, and want of sleep. In not a few cases a secondary tuberculosis supervenes, or the case may be complicated by a more chronic and less general formation of miliary tubercule confined to the lungs. These are called cases of tuberculo-pneumonic pithusis.

CHRONIC TUBERCULAR PHTHISIS.

In this form of the disease the illness begins in a very gradual manner, and the special symptoms arising from the lungs are preceded by others showing the existence of general disorder of health. The child is noticed to be languid and hatless. He looks pallid; has little appetite; complains of pains in his legs, and is disinchined for his usual cames. He is often found to flush at night and his hands are noticed to be hot. After these symptoms have continued for several weeks the patient begins to have a slight cough. This at first is merely a short occasional back which excites little attention; but after a time it becomes more frequent and annoying. The course of the illness in this variety is less irregular than in that previously described; but still the downward progress is more rapid at some times than at others. The temperature, although it undergoes considerable variations, rarely stands at a normal level in the evening; but unless the disease be complicated with catarrhal pneumonia the pyrexia is not high and seldom reaches 102'. Wasting is usually persistent; but if the patient has been exposed to privation, the comforts of a hospital may induce a temporary improvement in nutrition, although the pyrexia continues and the other symptoms remain unaltered. Cough for a long time may be a very insignificant symptom and, even with signs of extensive discuse of the lungs, may be almost absent. The breathing is often rapid, rising to thirty or forty in the minute. Increased hurry of breathing, according to Niemeyer, may be one of the earliest local symptoms, occurring before any physical signs of the disease can be discovered in the chest. The digestive organs are weak and irritable. Vomiting is common and is often excited by cough. Purging is also a frequent symptom. In many cases examination of the belly discovers fatty enlargement of the liver, and ordema is often noticed in the limbs. Death may occur from general weakness, from catarrhal pneumonia, or from the extension of the tubercular formation to other parts.

The physical signs of tubercular phthisis appear late, and at first are curiously insignificant when compared with the severity of the general symptoms. We find a child pale and thin, with a depressed, saddened look. The borders of his mouth have a faint blue tint; he pants after evertion, and coughs occasionally a short hard back. We are told that he has been failing for several months; that he cats scarcely anything; has lost all his spirits, and gets flushed and feverish at night. On examination of his chest we discover merely some slight want of resonance at the apices of the lungs with weak, harsh brouthing. A faint dry crackle of rhouchus is caught at the end of inspiration, and is brought out more clearly by a cough. The chest is elongated, with a narrow antero-posterior diameter, but the lungs, although naturally small, appear healthy except for the

signs which have been mentioned.

As the disease progresses the physical phenomena become more pro-

nounced. They are always discoverable at both apices, although more marked on one side than on the other. Usually the area of dumes a perceased by a pneumonic process set up in the lung; and marked duless with blowing breathing and the ordinary signs of consolidation are decovered. The disease then after a time presents much the same character to physical examination as those referred to in describing the catural variety of phthisis. In exceptional cases disorganisation gots on without the aid of a pneumonic process. We then find the feeble breath-sound to become gradually blowing, and eventually cavernous sounds are discovered at the apex.

Tubercular and tuberculo-pneumonic forms of phthisis are often met with in scrofulous children who suffer from long-standing disease of the joints. In such cases the articular affection has probably been the engical cause of the pulmonary mischief; and by the continual irritation to what it gives rise may influence the condition of the patient very unfavourable. In these cases it is often advisable to remove the diseased joint, even though the amount of disease in the lung is too extensive to allow of lating improvement. Life may be considerably prolonged and the combined

of the patient greatly promoted by this step.

A little girl, aged eight years, was a patient in the East London (1-1) dren's Hospital under the care of my colleague, Mr. R. W. Parker The girl's father had died of consumption, and she herself had been suffered from strumous disease of the right astragalus for aix months. The was much emaciated and very anomic and feeble. Her skin was hard un dry, her eyelids were swollen; and the cervical and inguinal glands it each side could be felt to be enlarged. The finger ends were somewhat thickened. There was no slbumen in the urine. The temperature was usually normal in the morning, but would rise towards night to between 101° and 103°. At Mr. Parker's request I examined the child's chest, and found the signs of a cavity at the upper part of the right lung, with co-dence of considerable consolidation over the lower lobes. The left lung was also diseased, although to a less extent. A moist crackling rhadwas heard over both sides of the chest. Although this child was exacute suffering from tuberculo-pneumonic phthisis, and the pulmonary nascad was very extensive, the system was obviously so greatly distressed by the irritation and pain of the diseased ankle, that Mr. Parker decided upon amputating the foot. After the operation the temperature, which on the previous evening had been 101.6', fell to 98° at 6.30 P. M., and remarks for the most part at a normal level while the clubd remained in the level tal. The clicking rhonchus also ceased to be heard in the chest; the face lost its distressed look; and nutrition improved in a surprising matter the patient gaming between six and seven pounds in three weeks. Untrtunately, after the child left the hospital and returned to her own por home, the improvement was not maintained, and in a few months no band that she was dead. Still the remarkably good results which followed the removal of the diseased joint are very instructive, and fully justified in operation.

The majority of cases of pulmonary phthisis are seen in children of discover years and upwards; but younger children and even infants as subject to the disease. In very young patients ulceration of the long is not always easy to recognise. Serious disease may be present without ring rise to any very characteristic symptoms. The child is no doubt feel and wasted, but loss of flesh and strongth are common in very young children with almost any form of illness. Cough may be trifling and the organic

ing not obviously interfered with. Even a physical examination of the chest may yield us little information, for over the site of a cavity the percussion note may be merely tubular (tympaniae) and the breathing bronchial with moist clicking sounds. Moreover, the occurrence of softening in a cheesy pulmonary deposit is usually a signal for the occurrence of secon lary deposits clsewhere; and cheesy and ulcerating intestinal glands with the consequent diarrhaes may completely draw away the attention from the large. When pulmonary phthisis occurs in the young child, it runs a comparatively rapid course. It is in the large majority of cases primarily of the catarrhal form, and is most commonly the consequence of an attack of sub-scute broncho-pneumonia succeeding to measles or whooping-cough.

Diagnosis.—In the diagnosis of pulmonary phthisis in the child an accurate account of the beginning and course of the illness is very important. At the same time it is necessary to remember that a history of cough with persistent loss of flesh is no sufficient proof that the child is suffering from pulmonary consumption. Scrofulous children and others with a like susceptibility to chills, are very subject to attacks of pulmonary and intestinal caturrh. Such patients may be troubled with continual cough, and lose flesh steadily without any organic muschief being set up in the lung. They may even be feverish at the onset of every new chill without this additional symptom being evidence of phthisis. No doubt the condition of such children is one of danger, for they often eventually develop pulmonary disease; but until this has actually taken place, ordinary precautions for the avoidance of chills will quickly cause the symptoms to disappear.

Even if examination of the chest discovers slight dulness at the supraspinous fossa of one side with a high-pitched or faintly bronchial quality of breathing, these signs are not necessarily due to phthisical consolidation. Weakly children are very liable to temporary collapse at the apices of the lungs from insufficient expansion. In such cases the morbid signs are limited strictly to one aspect of the chest—the back or the front—and can often be made to disappear if the child is instructed to take two or

three full inspirations in rapid succession.

In young subjects consolidation, as a result of catarrhal pnoumonia, may be met with at all parts of the lung. It is seen as often at the base as at the apex, both in front and behind. In all cases, therefore, it should be made a rule to search the chest completely before we allow ourselves to exclude the existence of a cheesy deposit. If this be done quietly and gently, as directed elsewhere (see page 13), the examination can usually be carried to a successful issue. In infants, as has been already remarked, pathwas may be present although but few symptoms of the disease have been noticed. The cough may be insignificant, the breathing quiet, and a looseness of the bowels of some standing may seem to explain sufficiently the pallor and wasting of the body and the distressed expression of the child's face. If, however, at the same time the evening temperature is higher than natural, the symptom is a suspicious one; and if the state of the stools indicates the existence of ulceration of mucous membrane (see page 662), we must remember that this condition is often dependent upon chromic pulmonary mischief. In every case the physician, if he do his duty, will take nothing for granted, but will make systematic examination of all the organs of the body.

A distinction between the catarrhal and tubercular forms of phthisis is readily made by comparing in each case the local signs with the general symptoms of the disease. Catarrhal phthisis, even when it begins at the apex by slow extension of the catarrhal process to the pulmonary alveoli,

produces comparatively little impairment of the general nutrition of the body. The patient coughs and is a little feverish at might; but his appetite is usually good; his strength is little impaired; and he retains a kramount of flesh. Even when the progress of the disease has led to retain a few consolidation of the lung, the marked contrast between the neither of the general symptoms and the severity of the local signs discovered to physical examination, is sufficient to reveal the nature of the parameter mischief. In chromic tubercular phthisis the general symptoms are seen from the first. The child is pale and thin, feverish and langual, for sectime before he is noticed to cough; and it is still some time longer before examination of the chest discovers any positive indication that the landare the seat of pathological change. Moreover in catarrial phthisis and softening begins in the deposit, the disease is confined to one ling. In tubercular phthisis the physical signs, when they do present themselves.

are discovered at both apices.

On account of the frequency with which secondary attacks of sub-acce catarrhal pneumonia complicate cases of old consolidation, chlatel I made are often present. These give rise to all the signs characteristic of example. tion; and it is very important to satisfy ourselves as to the nature of to pathological condition. Dilated bronchi are most common in the clad & the base of the lung, while cavities are more frequently scated pears to the apex. Therefore the situation of the signs at the base, although by the means conclusive evidence, points rather to bronchectesis than to a views Again, the general symptoms are of great importance. Dilated break unless occurring as a chronic condition in a case of fibroid industria if the lung, are met with towards the end of an attack of broncho-purous so If then we find that, with the physical signs of a pulmounty carry ve general condition of the child is improving; that the temperature about signs of falling; the appetite improves, and the flesh and strength begs to return, the evidence is strong that the signs are not the consequence of ulcerative destruction of lung. Moreover, much assistance is to be derived from a microscopical examination of the sputum, where this can be obtained. In pulmonary ulceration arcolar fibres of yellow cluster basic will be seen in the muco-pus vomited or expectorated; in cases of bat chiectasis these will be absent. Lastly the progress of the signs and famous corroborative evidence. Cavities tend to grow larger, diluted browns a contract. If, therefore, while the general symptoms remain status with area over which the cavernous signs are heard is found to extend itself as cannot but conclude that disorganisation of lung is advancing, where with general improvement, the local signs diminish in intensity, our operation that these are due to dilutation of brouchi receives additional confirmation

The distinction between pulmonary phthisis and fibroid indurated

the lung is considered elsewhere (see page 478).

Empyema is often confounded with phtheses; and there is no delite that the general appearance of a child the subject of old-standing parameters are been as very like that of a consumptive patient. There may be same hearing, the same emaciation, and the same weakness. In case we the child is irritable and restless with a backing cough, some stortest breath, a poor appetite, and a feeble digestion. On examination of exchest in each case we find dulness, often extensive, with perhaps the cavernous breathing. But the history of the illness is very different in the two diseases. In pleurisy it begins with pain in the side followed that an interval by cough; the dulness is complete with extreme sense of resistance, it occupies both the front and back of the chest, unas the

empyema be loculated; and reaches down to the extreme base. Moreover, the disease is strictly himted to one lung, the other being healthy; and aghs of pressure are noticed, the affected side is expanded, the interceptal spaces are less hollowed; and the heart's apex is displaced. On the other hand, in a case of pulmonary phthisis sufficiently extensive to unrulate a pleuritic effusion, the opposite lung will certainly show signs of hisease. There will be no displacement of the heart or bulging of the side; the dulness will not be complete; the resistance to percussion will not be greatly exaggerated, if no great excess of fibroid tissue is present; and the breath-sounds will be accompanied by a large-sized metallic garging rhonchus. In either case the vocal resonance will probably be bronchophome; but in empyema it often has an agophonic quality.

Catarrial phthiss in the young subject is very lable to be complicated by tuberculous as a result of infection of the system by softening cheesy matter. The occurrence of tuberculosis is sometimes indicated by a rise of temperature and an increase in the rapidity of the breathing without any extension of the physical signs. Great irritability of the stomach and bowels is often induced; the child vomits repeatedly, and the bowels are relaxed. Usually in these cases signs of intracranial irritation become quickly manifested; and convulsions occur followed by squarting, ptosis, rigidity of joints, and other well-known signs of tubercular meninguis.

Prognosis. - The gravity of the case in the two forms of pulmonary phthiais is very different. In an early stage of catarrhal phthiais we may reasonably hope, by putting the patient into the best sanitary conditions, to effect removal of the caseous consolidation. Absorption of a chronic solubification left after an attack of catarrhal pneumonia may be effected in the young subject after the lapse of many months; and I have often seen cases in which signs of pneumonic phthisis occurring at the apex, from slow extension of a catarrh to the alveoh, have disappeared when the child has been sent to winter in a suitable chinate. Indeed, if we can protect the patient from fresh chills, and secure for him an adequate supply of purfectly pure air-such conditions with good and sufficient freel will do much to help him on his way to recovery. It is difficult to eav at what period of time it becomes hopeless to expect absorption of a cheer deposit. I believe that so long as no active change has taken place at the affected spot this fortunate termination to the case is still possible if the patient be a child.

When a secondary catarrhal pneumonia occurs in a case of pneumonic phthisis the child will not necessarily die; indeed, the acute attack usually runs a sub-acute course and is eventually recovered from. Still, the future prospects of the child are sensibly darkened by the addition usually made to the amount of previously existing disease by the passage of the com-

phention.

Curse of chronic tubercular phthisis always go on from bad to worse; for although by a suitable climate and the careful avoidance of chills, attacks of catarrhal pneumona may be prevented, the normal course of the

tula roular disease is little affected by the treatment.

In all cases, signs of very unfavourable import are:—Great rapidity of breathing, and signs of lividity; a high evening temperature; a red glazed torigue, with or without great disturbance of the stomach, diarrhea. The accordious constitution or a strong hereditary predisposition to phthis is an element in the case of the utmost gravity. As far as is at present known, the quantity of the bacilli discovered in the sputa furnishes little information of majortance in prognosis; for these organisms are not found to be

necessarily most numerous in cases where the diseased processes are notive.

Treatment.—Children born into families in which there is a consumptive tendency require special care in their bringing up; and ever miable means should be adopted to counteract their unfortunate premases tion. Infants should, if possible, be suckled by a healthy wet-rurs, and every precaution should be taken to ensure the purity of the air tag breathe. As they grow, they should be accustomed to warm clother perfect cleanliness, and regularity of meals. Their food should be page and well selected, avoiding excess of sweets and farinaceous matters, what are so apt to excite and maintain an acid condition of the alimentary outsi Their residence should be, if possible, on a dry soil and in a bracing an If this be not practicable, they should at any rate be sent away to a more suitable habitation during the spring and fall of the year-times when the changeable season is so prejudicial to delicate children. They should be trained regularly to strengthen their muscles by out-door games, std if the lungs are small, and the chest consequently narrow, every messas should be resorted to to invigorate the pectoral muscles and expend the cavity of the chest. All forms of catarrh should be attended to with peculiar care, and the parents should be warned that neglect of such derangements may entail the most serious consequences. By such means child naturally delicate may, as he grows up, appear to cast off many of the external signs of his constitutional tendency; and although, no doubt still exceptionally sensitive to unhealthy influences, may preserve his vigour under conditions which would quickly prove injurious to another less carefully nurtured. A cold douche in the morning on rising from bed and great service in these cases; and if the shock is too great under order conditions, the bath will be readily borne when given with the proceedings recommended in a previous chapter (see page 17).

If a child with such a tendency be attacked by measles or whospiccough, the parents should be warned, as the disease subsides, of the imger of neglecting the catarrhal complications which are so liable to cover in the later stages of these specific maladies. In every case where u is possible the patient should be sent for his convalencence to a good service air. If catarrhal pneumonia have occurred, the clearing up of the considdation must be carefully watched. Good ventilation and careful decay are more than ever necessary; and if absorption appear to that, invasing should be taken at once to after the conditions under which the patient is living, and a change of air should be insisted upon. Alkalies and alianne sprays are very useful in these cases, and the citrate of tron and quantumary be given with the citrate of potash with great advantage.

In cases of acute phthosis energetic measures must be adopted. We should at once take steps to reduce the pyrexis, which is considerable and to maintain the strength of the patient. Dr. McCall Anderson recommends the application of cold, either by iced cloths, Letter's temperature regalitors, or, if these means fail, by cold baths. He has found the applicated to the abdomen of cloths wrung out of re-cold water and frequently renewed, very useful in lowering the temperature, and speaks highly allow meyer's combination of digitalis, quinine, and opium. I cannot my all set that I have seen much benefit result from this form of medication, but of thought desirable, half a grain each of the two former drugs may be a with an eighth or tenth of a grain of opium every four hours to a child ten years old. Of other drugs, large doses of quinne seem to have the a temporary effect, and the salicylates in my hands have proved worse than

useless as anti-pyretica. They seem to exert little influence upon the temperature, while they irritate the stomach and cause nausca. Our chief resource for reducing the temperature in this as in other forms of febrile disease, consists in the application of cold.

In order to maintain the strength Dr. Anderson recommends hourly feeding, both day and night, with simple food, such as milk, broths, etc., and gives brandy or other stimulant as seems to be required. The profuse awests must be controlled by the subcutaneous injection of atropine (gr. 187). According to this author the most striking results may be sometimes obtained, and a complete cure occasionally effected by the above means.

In the chronic forms of phthisis it is also of the utmost importance to improve the nutrition of the body. The absorption of recent deposits and the obsolescence of more chronic consolidations are best promoted by plenty of fresh air, the avoidance of chills, and a liberal supply of good food In order, however that the child may profit by an abundant dietary, it is essential that his digestive organs should be maintained in a high state of efficiency. The subjects of pulmonary phthisis resemble in one respect hand-feet infants. Lake them they are liable to repeated attacks of gastrointestinal catarrh, which gives rise to indigestion and flatulence. These attacks, by the influence they exercise upon general nutrition, may produce very serious cousequences. If a child with disordered stomach be fed continually with food which he has no means of digesting, not only is the gastric derangement protracted, but his system is kept in a state of fever which often culminates in a fresh attack of pneumonia. In any case, such a condition of the body is not calculated to encourage the healthy removal of morbil products. In all these attacks the diet should be at once altered. The child should take for food little but milk alkalinised with lime drops and diluted with barley water, weak broth, and dry toast. For medicane he may have an alkali with nux vomica to act as an antacid and stomachie By this means the gastric derangement will be quickly overcome.

In all cases where the parents are in a position to afford the expense, a change of climate is of great service. A child who is the subject of an unabsorbed pneumonic deposit, whether this succeed to an attack of bronchopneumonia, or have occurred more slowly from neglected catarrh, should change the conditions under which he has been living. If he reside at the sea-side, he should be sent inland; if inland, he should be sent to the sea-side. A good sea voyage often brings about a complete cure in these cases. The body should be warmly clothed, the bed-room should be large, any, and well ventilated, and the child should pass a large part of the day out of doors whenever the weather permits. Cod-liver oil is useful as a help to the treatment, but not as a substitute for it; and iron and quinine with

an alkali should be prescribed as already recommended.

When softening begins at the seat of mischief and evident constitutional symptoms are observed, the child should be carefully protected from chills, and at the same time be insured a plentiful supply of fresh air. Mild counter-irritants should be applied to the chest over the diseased spot, such as painting with fineture of iodine or rubbing in a weak croton-oil liniument. The hypophosphite of lime (gr. iij. v.) is of sensible value in these cases, and will often, when debility and weariness are complained of, cause an immediate improvement in the strength. In other cases arsenic is of great service, and may be given with quinine in doses of three to five immins of the arsenical solution three times a day. Lately iodoform has been recommended with the object of reducing secretion, moderating fever and cough, and arresting the progress of cascution. I have seen benefit

result from half-grain doses of the remedy given three times a day reextract of gentian. If the pyrexia is high, it may be reduced by specially the surface with tepid water; and night-sweats are usually readily or trolled by one or two drops of the liq atropic at bedtime given in a is-

spoonful of water.

For some years, and especially since the discovery by Koch of the "tubercle bacillus," antisoptic inhalations have come greatly into favor At night the sur of the bed-room may be impregnated with the funes of tar or creasote by Dr. J. R. Lee's "steam-draught inhaler ' or some sinds instrument. In the day-time, by means of a perforated metal response such as that devised by Dr. Coghill, of Ventner, various antisephotole stances may be inhaled for an hour at a time more or less frequently deing the day. At the Victoria Park Hospital we have been in the tabut of using for this purpose a preparation composed of two drachus each of the etherial tincture of rodine and carbolic acid, one drachm of creasete, as one ounce of rectified spirit. Of this ten drops are poured upon a just of cotton wool and used in the respirator several times in the day is many cases it is well to use the antiseptic frequently; and if the child wil submit to the inconvenience he may be made to wear the respirator to day long. In such a case the antiseptic drops can be renewed every two or three hours. Very good results are often obtained by the help of the method of medication. The violence of the cough is often duminal of after the respirator has been worn for a short time, and the sputter v there readily brought away from the lungs. Expectorant mixtures was often have to be given in addition. The disadvantage of all these down however, is their unfortunate tendency to cause derangement of the etomach. When made use of it is advisable, if possible, to combine to expectorant with an alkali or a mineral acid. If the cough is hard and beta few drops of mecacuanha wine should be given, with five or six grains (brearbonate of sods, in a draught sweetened with giveering. Afterwar a when secretion is more copious, four or five drops of sal volatile may be combined with a drop or two of liq. morphie, or five to lifteen or paregorie, in glycerine and water. These may be followed by an analysis. line and from mixture, or a draught containing permitrate of from and asset nitric acid. Cod-liver oil should always be given if it can be borne. Was this does not agree, maltine often proves a good substitute, and is usually taken readily by a child.

In all cases the state of the digestive organs must be watched with the greatest vigilance, and any sign of acidity or flatulence must be a same for a prompt reconsideration of the dictary. Pepsin is often useful as with dilute hydrochloric acid and strychnia, as recommended character (see page 641). If a difficulty is found in digesting starches the appetitus (Benger) given with an alkali about an hour after measure service. In such cases, also, the measures recommended for the transment of chrome diarrhea may be adopted with advantage (see page 66).

If the cough excite vomiting, this symptom can be generally above of the administration of one drop of Fowher's solution of arsence before med; or half a drop of high stryching often has an equally be nefected at a life amopty sis occur, the child should be kept perfectly quiet in bed the should be given to him in small quantities at a time, and he may take a term to twenty drops of the liquid extract of ergot with mildly approximately of Epsom salts three times a day. If, however, the bowels are the rate the saline laxative must be omitted. Diarrhage dependent upon the settinal lesion must be treated as recommended elsewhere (see page 66).

CHAPTER XIII.

PAROXYSMAL DYSPNCEA.

Dispose is a symptom frequently met with in early life. The term does not denote merely increased rapidity of breathing. The respiratory increaseds may be hurried without the patient's being sensible of any unusual effort in the act of breathing or of suffering from imperfect acration of the blood. To constitute dyspines there must be perceptible distress; and the term may be defined as a conscious embarrassment in the performance of

the respiratory function.

Dyspiner is by no means confined to cases of pulmonary mischief; indeed, in the child, extreme difficulty and labour of breathing, with great lividity of face, although possibly produced by disease of the lung, is yet more commonly the consequence of some other cause. The most urgent and alarming form of dyspiner is seen in cases of impediment to the passage of air through the glottis. We find it carried to its highest point in strelulous and membranous larringitis, in obstruction of the windpipe by a foreign boly, in extra larryngeal pressure from an abscess in the pharynx, and in pressure upon the trachea or a large bronchus by a mass of enlarged glands. Again, intense dyspiner may be found in a case where air penetrates freely into the lungs. If the circulation through the pulmonary vessels is obstructed, as when a clot is slowly forming in the pulmonary artery, the suffering from deficient aeration of blood may amount to an agony. So, also, in serious disease of the heart dyspiner is a common symptom, for the passage of blood through the lungs is impeded by the valgular lesion.

Again, external pressure upon the lung will excite a very pronounced feeling of dyspuces. When one lung is entirely compressed, and the heart disjocated by a copious liquid effusion into the pleura, dyspuces may be argent and threaten actual suffocation. When the ribs are greatly softened, as in a case of advanced rickets, the pressure of the atmosphere upon the yielding chest-walls may cause such impedament to the expansion of the lungs that serious dyspaces may be induced. If at the same time the deseent of the driphragm is impeded by accumulation of flatus in the belly, the danger is really imminent. On the other hand, in cases of actual pulmonary muschief dyspines is not always present. We find it, indeed, in catarrhal pneumonia and bronchitis, especially if the latter disease is accompanied by any occlusion of the tubes; but in other cases of interference with the pulmonary function it is exceptional to see signs of suffering from constions want of air carried to an extreme degree. Even in advanced phthisis distress from this cause is rarely great; and in croupous pneumoma and collapse of the lung the respirations, although greatly quickened, are accompanied by little or no exaggeration of movement, and dyspiners in the sense of an active feeling of oppression of the chest cannot be said to exist.

In every case of dyspaces we have, therefore, to examine very carefully in order to discover the cause to which the impediment to respirate an be correctly attributed. As a rule, perhaps, dyspaces is are ular as severity. It is subject to temporary increase and diminution, so that a patient from a condition of great distress may pass into a state of asparative case. The term "paroxysmal dyspacen" is, however, contains cases where the difficulty of breathing occurs in attacks of variable subject, which last a longer or shorter time and then pass completely and

There are certain rare causes of remittent dyspines in the child be may be mentioned. These are—paralysis of the respiratory inuscles and the displicagm, such as may occur as a sequel of diplitheria (see page 100 interstitial ordema of the lung from acute Bright's disease (see page 100 and clotting of blood in the pulmonary artery (see page 100). These was are, however, exceptional, and the dyspines they induce is not provided in the correct sense of the word; for although the feeling of sufficient moderates, it does not entirely subside.

As commonly met with in the child, paroxysmal dyspaces, i.e., dyspace occurring in paroxysms with intervals of complete internassion, is a resize of the following causes:

Stridulous laryngitis.

Pressure upon the traches or a large bronchus by swollen broached glands.

Obstruction of a bronchus by a foreign body.

True bronchial asthma, occurring often in the course of chronic bro-

chitis and emphysema.

Of these the first-named disease is fully considered elsewhere. It requires no further notice in this place, as the severity of the laryngeal symptoms at once indicates the seat of the impedient to respiration. The etce forms of paroxysmal dyspinea are often confounded together union to common name of "asthmatic attacks." Dyspinea arising from the presure of enlarged bronchial glands and the difficulty of breathing model by the presence of a foreign body in the air-tubes are described in other parts of this treatise. They will, however, be again referred to in discount the diagnosis of asthma.

Bronchard ashima is comparatively seldom met with in the child. We it occurs at this period of life, it appears to be almost invariable the consequence of wheoping-cough or catarrhal pneumonia. The seizure active assume the "catarrhal form;" indeed, the subjects of the disease to usually sufferers from emphysema of the lungs, and the attack of despets occurs as a consequence of a fresh caturrh. In many cases the child come of a gouty family, and sometimes the pulmonary disease appears to be hereditary. The tendency to asthma is occasionally associated with a tendency to general eczematous emption; and Dr. West states that be been ever known eczema to be very extensive and very long continued without a marked liability to asthma being associated with it. The two affections may alternate—the one subsiding when the other appears—as in the confidence of a boy of six years old referred to by Caillaut; but they may be also of a boy of six years old referred to by Caillaut; but they may be also existent, and the cure of the one is often followed by the disapparation.

of the other.

The exciting causes of the attack appear to be in most cases the inlabtion of some irritating matters, either in fine dust or vapour, directly the air-tubes. A paroxysm sometimes follows an indigestible meat a induced by food imperfectly masticated and hurriedly awallowed. It is been consequently suggested that irritation of the gastric filaments of the

penmogastric may be reflected to the pulmonary branches of the nerve, but through them set up spasm of the tubes. But the theory of reflex

ction is surely exposed to a severe strain by such an explanation.

Without expressing any opinion upon the vexed question of the nature of the asthmatic seizure—whether it be a pure neurosis (as is commonly left or not—I may observe that it is at least curious that in children, where tendency to nervous spasm of every kind is one of the physiological permarities of early life, pure asthma should be an affection so rurely met with, that while general convulsions may be induced by peripheral irritation of various degrees of severity, while spasmodic contraction of the cletts may be set up by a triffing laryngeal catarrh, an attack of paroxysmal dysphose from spasmodic occlusion of the smaller air-tubes should be a phenomenon of such infrequent occurrence. That it is extremely rare there can be no doubt. Of the recorded cases of asthma in young children there are very few in which direct pressure upon the bifurcation of the tracker or a main bronchus by enlarged bronchial glands can be excluded. I have seen many cases of so-called authum in the child, but have rarely fined to find evidence of swelling—often of considerable swelling—of these giands.

Asthmatic children, as has been said, are usually the subjects of emphysems. This condition often gives little evidence of its presence until the lungs are attacked by a fresh catairh. The breathing then becomes excessively oppressed, so that the child is unable to lie down in labeled. The face is pale, with a dusky tint round the mouth and eyes; the treams staring and congested; the mouth is open; the hips are purple; the asside work violently, and the forehead is covered with beads of sweat. The child is very restless, throwing about his arms, and his face expresses great suffering. His heart acts violently and irregularly, but the pulse is still and weak. When the chest is uncovered, all the respiratory muscles are to be in action, but the chest remains fully distended and move but slightly at each breath. There is little hurry of breathing on account of the increased length of expiration, and the temperature is not elevated

The cough is usually short and dry, but not at all paroxysmal.

On examination of the chest during an attack we find general hyperresonance of the percussion note; the vesicular murmur is either very feeble or completely suppressed, and is often quite covered by large somorowhilm rhonchus. At the base copious subcrepitant rales may be heard.

The attack lasts for a variable time. It usually continues more or less seems for two or three days, and then gradually subsides. As a rule, the more severe the dyspaces, the shorter its duration; but for days or even wells after the attack is over the child may wake up wheezing in the morning and his breath may be short for some hours after rising from his bed

Sometimes the onset of the attack is heraided by severe coryza, with repeated successing, and this is quickly followed by distressing dyspacea. The
"Porcession of breathing seems sometimes to threaten actual suffocation and
it all cases the severity of the suffering from want of air is out of all proportion to the insignificant character of the physical signs. The science,
lowever, invariably ends in recovery. After a time the breathing becomes
asier, and eventually all distress is at an end; but before the termination
of the attack is reached there may be many alternations in the intensity of
the dyspacea, and even after the days have become peaceful the nights
any still be disturbed by a return of the paroxysms.

Daymons. — In cases of paroxysmal dyspnea it is important with regard

both to prognosis and treatment to ascertain the exact cause of the datressing symptom.

When the dysphona is due to occlusion of the larvax from spass, for impaction of a foreign body, or from the pressure of a retro-planter, a abscess, the difficulty lies cluefly in inspiration. As each breath is describe soft parts of the chest sink in and the engastrium is deeply retracted. The inspiration is excessively long and laborious, the expiration short and comparatively easy. At the same time crowing sounds are produced in the

glottis and point unmistakably to the seat of the impediment.

In cases where the hindrance to respiration is scated at a lower level as when a main bronchus is obstructed by a foreign body, or the traces at its bifurcation is compressed by a mass of swollen glands, and also a cases of bronchual asthma, the distress is cluefly seen in expiration, what is prolonged, laborious, and ineffectual. Attacks of dyspinor from the causes require to be very carefully discriminated, as they are all commany spoken of as "asthmatic attacks." The most frequent of these in crustical beyond all comparison, is enlargement of the bronchual glands; and make cases of "asthma" in early life are due to direct pressure by swolch, jame upon the air-tubes. Scrofulous cluddren are very sensitive to challe air readily take cold. They are consequently frequent sufferers from paintary catairch. In these attacks the glands unitergo a rapid temporary acrosse in size, and their enlargement may set up serious pressure upon the windpipe at its bifurcation.

Dysphora from this cause is often intense, and comes on in violent paroxysms which usually occur at night. The character of these services has been clsewhere described (see page 182). In such cases there is not dways dulness at the upper part of the sternum, or between the sample for alteration of the percussion-note can only be noticed in cases when the swollen glands are in contact with some part of the chest-wall. The case collection of bronching glands lies in the bifurcation of the tracken, but others are distributed along the course of the bronchin as far as the third fourth subdivisions. Enlarged glands, therefore, may be found after death deep in the substance of the lung, as described by Cruveiliner. The effect of enlargement of these bodies is to press upon and flatten the air-passence and if the calibre of the tube be at the same time lessenced by vising servtion, the channel for the time may be completely occluded. By such means

the most serious dyspines may be produced.

A little girl, between three and four years old, was said to be subject to feverish attacks which lasted from a few days to a week. In these the cost first showed symptoms of catarrh and then began to suffer from weeks dysphora. In the last of these attacks, as described to me, the breaks ness began quite suddenly at night and woke the child up from Ler - 🤏 She was said to have started up gasping in the utmost chistress, and of voice was hourse. After about an hour the paroxysm substituted and the child had a violent attack of spasmodic cough, retching up much price. The seizures were repeated for six nights in succession, becoming the ever, less severe towards the end of this period. In the daytom the in tient seemed fairly well, although towards evening ber breathing wand or a little short. Her nose also bled a great deal. This little girl was be a set to me some time after the last attack had subsided, who is she had returned to her usual health. The jugular veins on each side of the neck were been noticed to be full, and the venous radicles on the front of the chest ! ... unnaturally visible. There was a suspicion of dulness on the ware week of the sternum, and when the child bent her head backwards a ver our -==

was heard at that spot, ceasing when the chin was again depressed. The lungs did not appear to be emphysematous, nor was there any dulness at other apex; but the breath-sounds were very loud and hollow at the su-

pra-spinous fossæ, especially in expiration.

There can be little doubt that this child was suffering from enlargement of the bronchad glands. The character of the attacks, accompanied by hoarseness of the voice, the bleeding from the nose, the fulness of the jugular in the neck and of the superficial veins of the chest, the hollow breathing at the apiecs without sign of disease of lung, and the renous hum heard at the upper part of the sternum when the head was retracted—indicating some pressure set up in that position upon the left innominate vein all these signs were very suggestive of glandular enlargement. The child had a scrofulous appearance and was living in a cold, damp situation. She was treated with roduce of iron and cod-liver oil, and has sent to pass the winter at Bournemouth, whence she returned greatly improved.

This subject of glandular enlargement in the mediastinum has been already considered in another place. The reader is therefore referred to the chapter on scrofula for fuller details with regard to the phenomena produced by the lesion and the signs by which its presence may be ascer-

tained (see pages 182 and 183).

The intrusion of a foreign substance into the bronchus is sometimes a cause of paroxysmal dyspacea. This accident may be suspected if a first attack come on quite suddenly at or shortly after a meal, or under circumstances which justify the assumption, as when a child is playing with small objects which might readily shp into the larynx. In such a case, if the object be a small one, the breathing is not always affected at once; and if some cough and discomfort are excited at the first, these symptoms almost invariably subside, to return after a longer or shorter interval. Professor Henoch has reported the case of a girl, aged nine years, who went to bed apparently in good health, but was restless, complaining of discomfort during the night. Towards the morning she was seized with extreme dyspnea and cyanosis The child was taken to the hospital, where no signs of pulmonary disease could be detected. Shortly after her return home she began to vomit large quantities of undigested food, amongst which were found pieces of a hard-hoiled egg which she had hurriedly swallowed or the previous evening. When the vomiting had subsided the gul had a good night's rest and the dyspines did not return. In this case Dr. Henoch attributed the dyspnæa to irritation of the gastric filaments of the vagus; but it seems more probable, as Dr. Birkart has suggested, that the symptoms were due to actual bronchial obstruction by a portion of the imperfeetly masticated food. The ordinary symptoms produced by the presence in the air-tubes of a foreign substance, and the means by which the cause of the dyspaces may be recognised, are treated of more fully in another chapter see page 5271.

The diagnosis of bronchial asthma has usually to be made by exclusion, no other cause being found to which the access of dysphora can be attributed. When called to a child who is said to be suffering from attacks of severe dysphora, unaccompanied by laryngeal stridor, we should first of all suspect the presence of enlarged bronchial glands. If the most careful examination fails to detect the existence of any such lesion; if we find that in the interval of such attacks the child is well and hearty, without alluminum or sign of disease of the heart; that the seizures came on ander the induced of a pulmonary catarrh; and that the only physical

signs discoverable consist in a certain hyper-resonance of the percussionnote with an occasional click or coo of rhonchus, we may conclude that we have to do with a case of bronchial asthma.

Prognoss.—If the child be in such a position in life that proper measures can be taken for his relief, his prospects are not unfavourable. If he can be sent away to a proper climate, be warmly dressed and carefully attended to, dysphora from cularged bronchial glands or from bronchial asthma is usually recovered from. The most serious forms of paroxysmal dysphora are those which result from the presence of a foreign body in the air-passages; from interstitual pulmonary ordenia in Bright's disease; and from clotting in the pulmonary artery. In the last of these, few cases recover. In the case of Bright's disease when the illness is of the acute form, we may have hopes that if the immediate danger can be tided over, the child may eventually recover. If the renal mischnef be chronic, the prognosis is very unfavourable. When the dysphora is due to the entrance of a foreign body into the air-passages, the prognosis is given elsewhere (see reace 523)

(see page 533).

Treatment.—If the child be first seen during an attack we are forced to treat the dyspnose without reference to its cause. Strong mustard poultice should be applied to the chest and moved about from one place to another over the front and back of the thorax. Secretion should be promoted by giving hot liquids to drink; and a very useful form is that

composed of a dessert-spoonful of liq ammoniae acetatis, diluted with three or four times its bulk of hot water. Trousseau recommends the burning of stramonium leaves in the room; but this is a very uncertain remedy and has lately fallen out of favour in the case of the adult. The fumes of intre paper are preferred by some. Enough should be used to make the atmosphere thick with the introus vapour. If we can discover that the child has lately swallowed some indigestible food or notice any undue distention of the abdomen, it will be well to relieve the stomach by an

emetic dose of iperacuanha wine.

When the attack of dyspacea has subsided or the respiration has become easier, we shall be probably able to examine the patient sufficiently to form an opinion as to the cause of the distress in breathing. When the dyspacea is due to enlargement of the bronchial glands, or to any of the less common causes which have been mentioned, the general treatment

to be pursued is described in other parts of this treatise.

If the case be one of bronchial asthma the child is almost invariably the subject of pulmonary emphysema, and the treatment recommended for that condition of the lung should be scrupulously carried out. All means which invigorate the general health are useful, and cod-liver of with iron, especially the iodide of iron, should be prescribed. Fowler's solution of arsenic is also often of service, especially in cases where the asthmatic symptoms are associated with eczema of the scalp or other part of the body. Dr. Thorowgood advocates the use of a tonic during the day, and recommends a sedative at night, such as a dose of the extract of stramonium or tincture of belladonna. Thus, a child of six years old may take three or four drops of the liq. arsenicalis with ten of the tincture of perchloride of iron freely diluted after each meal, and on going to bed twenty to thirty drops of the tincture of belladonna.

The hypodermic injection of pilocarpine may be used in these cases, as directed by Dr. Berkart. Children bear this remedy well. For a child of five years old, gr. ¹/₁₀ to gr. ¹/₁ may be injected under the skin when the child is put to bed. In the daytime the arsenic and iron can be continued.

When the attacks of dyspnosa come on chiefly at night, the child should be forbidden to eat heartily in the latter part of the day, and should by no means be permitted to go to bed shortly after a full meal. Indeed, care should be taken at every meal that the stomach is not overloaded, and Dr. Thorowgood's caution that moderation should be exercised in the use of farinaceous and saccharine articles is especially wise in the case of a child. The whole secret of the treatment of these cases consists in employing

The whole secret of the treatment of these cases consists in employing all available measures for improving the general strength and in guarding the patient carefully from chills. Exercise, gymnastics, and games which further the development of the muscles and promote the action of the skin are all very useful.

CHAPTER XIV.

FOREIGN BODIES IN THE AIR-TUBES.

The passage of solid substances into the air-tubes is a far from uncertaaccident and one to which children, for obvious reasons, are pecualliable. Articles of the most varied description have been inside the drawn into the traches, and their retention in the bronchi may set a produce the most serious distress but set up profound disorganization.

the affected lung.

Fruit-stones, as might be expected, are perhaps the commonest than to make their way into the trachea; also peas, beans, grains of corn acous seeds, bits of solid food, fish-bones, portions of nut-shell, and assmall articles which lie about in a room or can be picked up from the for such as little coins, tin tacks, dress-hooks, buttons—all of these object and many others, have been known to pass between the vocal constant level as ubstance as large as a plum- or date-stone can pass through the name aperture formed by the vocal cords in a young child. It must be reasoned, however, that when the chest-walls are expanded in the act of a perform the external atmosphere forces it onwards, while resistance is from the external atmosphere forces it onwards, while resistance is driven through the opening with colour able force.

Mertud Anatomy.—The morbid changes which result from the position of a foreign substance in the air-passages are often very extensive. It immediate consequences are congestion and irritation of the muccus to brane hing the trachea, and if the substance is small enough to permit into them, of the bronch. Secretion then takes place of a thir the fluid which soon becomes purulent, and may be so profuse that after the air-tubes are found filled with yellow puriform matter. Thick with may be also thrown out so as partly to coat the obstruction. In a consequence of a line of the minimum and almost closed the upper portion of the windpipe. The natories of thick and ropy and in long-standing cases may be inexpressably feed.

A substance capable of passing into the larger bronchi score inflammation in the lung. The inflammation may be limited to consider or may spread to the entire organ. Sometimes both lungs are after simultaneously, owing to the oftending substance being dislodged the repeated cough and falling back into one or the other bronchis in hard instelly. The affected part becomes consolidated, and if the unital types sist, soon disinfegrates and breaks down. Cavities are thus possible which are filled with offensive and even gangrenous debus and most in lent matter. If there be no sufficient communication with an array extensions.

with the bronchus and much fetid matter is expectorated. In scrofulous or tubercular subjects gray granulations may be developed in the hepatized tissue around the cavity, and it has happened that the child has died from greneral tuberculosis. The bronchial glands also become enlarged and

chesy

Best-les pneumonia, other pulmonary lesions may be present. More or less emphysema is usually produced, and collapse of portions of the lung may occur. The inflammatory action may not be confined to the lung. Emptema is a common consequence of the presence of the irritant; and charmons quantities of purulent fluid have been found distending the pleand cavity. Percearchtis has also been known to occur, and in a case resided by Mr. Solly a large abscess had formed in the mediastinum as a consequence of the pericardual inflammation. Sometimes the abscess of the lung becomes adherent to the chest-wall and points in an intercostal space or elsewhere. Dr. Wilks has referred to a case in which an ear of corn escaped in this manner from an abscess which had formed in the supra-ampular region; and other cases of a similar kind are on record.

Symptoms.—The irritation produced by the entrance of a foreign body into the trachea and bronchi varies greatly in different patients. Although in the majority of cases the suffering is extreme, in a few instances curiously little discomfort appears to be excited. It is important to be aware that valent dyspines is not an unfailing symptom of this accident. In some recorded cases a little cough has been the only inconvenience complained of. Dr. Goodheart has stated that on two occasions in his experience in which dissection revealed gangrene of the lung set up by a spicula of bone in one of the bronchi no symptoms had been noted during life pointing to the entrance of a foreign substance into the air-tubes; and thence concludes that pulmonary disease is more often excited by this mischance than

is commonly supposed.

Still, although in exceptional cases the suffering may be slight, as a rule the intrusion of any adventitious matter into the wind-pipe is a cause of immediate and extreme distress. If the substance be of large size it may completely occlude the glottis and cause sudden death. Many cases are on record in which the entrance of the wind-pipe has been blocked up by a lump of food with immediately fatal results. Smaller bodies which can pass reachly into the nir-tubes, if not arrested at the bifurcation of the tracas, full as a rule into the right bronchus. Mr. Goodall of Dublin pointed on many years ago that the septum of the division of the windpipe is placed considerably to the left of the mesial line, and that this position to be acceptable.

The first consequence of the accident is usually a fit of severe dyspaces with sense of impending suffocation. The child shows all the symptoms of the most extreme distress. His eyes look wild; his face is hvid; his tares work; his chest heaves convulsively; he tears with his hand at his tand, and bur its into a paroxysm of spasmodic cough. As a rule expection seems more difficult than inspiration, and the effort to discharge at from the lungs is laborious and painful. In some cases foam tinged with blood appears at the lips. The early symptoms are more severe if the object he light sufficiently near to the giottis to keep up irritation of the voral cords. The attacks of spasmodic cough are then almost incessint and the difficulty of breathing extreme. In ordinary cases after some minutes the more urgent symptoms abate and may entirely subside, so that the child who a short time before had seemed on the very point of

suffocation returns to his play as if nothing had happened, but the period of calm the paroxysms usually return with more or less usually variable duration. It may last from a few minutes to several hours at cases have been published in which no return of the distress was uppended for many months. The degree of suffering in these cases are ing to Dr. Stokes, is dependent to a considerable extent upon the applicances with which the intruding body interferes with the passage of a through the tube. He states that in all cases which have come usually a own observation the distress was great in proportion to the feebleme of respiratory murmur in the affected lung. A smooth body, there for so as a bean, by completely occluding the tube causes greater suffering the a more irregular substance will do; for the latter, although it observed

the passage, does not render it absolutely impermeable.

Often in addition to recurring attacks of dyspucen and spession cough there is a fixed pain or soreness referred to the throat or war pat of the chest, back, or side. This sensation is probably dependent open the impaction of the intruding substance in some particular part et : bronchus, for it has been known suddenly to shift its place, passing ince the throat to the chest or to the region of the nipple. In some cases the pain is accompanied by a sense of constriction. Often, also, there .. 2. bility to lie on one or the other side, such a position increasing the unserfeeling and impeding the respiration. Sometimes the child can also breathe with case in the sitting position, and has to be proposed up as bei with pillows. The fits of coughing are of a peculiar clamacter. The exusually excessively spasmodic and often resemble the cough of pertana They are accompanied by much congestion and lividity of the face to are not followed by attempts to vomit. Sometimes the paroxysms are a violent as to lead to a convulsive seizure. If the object introduced as fruit-stone or similar solid substance, and is free to move in the at 1> sages, the cough may be accompanied by a peculiar clicking or fist; g noise heard in the direction of the larynx, and produced apparent. the impact of the object driven upwards against the glottis by the course of air. In many cases the unpact may be felt as well as heard if the I we and thumb be applied during the cough to opposite sides of the largest

The voice may be unaltered unless the object be arrested in the toolbourhood of the glottis, as in one of the ventricles of the larying is such case there may be any degree of houseness even to complete aphoria.

On inspection of the chest considerable recession of the soft period usually to be noticed in inspiration, and there may be a swelling of the neck and upper part of the chest from surgical emphysema. Often apprecial examination at an early period detects little or no deviation has be healthy state. There may be perfect resonance; the respiration may be normal, and nothing may be heard but a little sonorous or sibilant reschoes over the lung in connection with the occluded brenches. If the foreign substance be impacted and immovable in the air-tube size of collapse may be noticed at some part of the lung a few days after the scient; or there may be absolute suppression of the respiratory murant over the whole of the affected side.

Whenever irritation is excited in the air-passages there is fiver at the general health of the child necessarily suffers from the constant trees and interference with sleep. Food can, however, be taken without

difficulty.

In some cases after a few hours or a day or two a spontaneous cred-

sion of the offending substance takes place during a fit of coughing and the patient is instantly relieved. If, however, the child is less fortunate and the foreign body remains in the tubes, its presence being unknown or efforts to produce its removal having proved fruitless, serious consequences ensue. The object may become impacted in the larynx, causing death by suffocation; it may set up a violent catarrhal pneumonia and the patient may quickly die; it may give rise to suppuration and gangrene; or it may lead to chronic phthisis which ends fatally after a more or less lingering allness.

Spontaneous expulsion usually takes place, as has been said, during a violent fit of coughing. It may occur after a short or a long interval; and in some cases a period of years has elapsed before the offending substance has been ejected. The completeness of recovery in such cases depends upon the degree to which the lung has suffered from the presence of the intruder. If the foreign body have only given rise to irritation in the lung, its removal is followed by instant and permanent relief. If, however, pneumonia have been set up, or an abscess have formed, or chronic phthisical changes have been induced, the patient may die, although the original cause of his suffering has disappeared.

In cases where the foreign body remains in the tubes, a constant source of irritation and of interference with the function of the affected organ, the physical signs depend upon the form of lesion which is produced. In some cases profound disorganization of the lung follows, and extra-costal suppuration may be set up leading to the formation of a large superficial ab-

KCPNN.

A little boy, aged seven years, whose family history showed no tendency to phthisis, was in his usual health when, on March 28th, he returned from school saying he had swallowed a date-stone. He complained of difficulty of breathing and pain in the side, and coughed a great deal. The symptoms apparently were not very severe, for the child was only brought to the hospital on April 8th. On his admission it was noted: "Much recession of the lower parts of the chest on inspiration; intercostal spaces move equally on the two sides. Resonance good over both sides, but on the left the inspiration is everywhere high-pitched and bronchial, and is as loud below as above. No rhonchus or friction. Heart's apex between the fifth and sixth ribs just outside the nipple line. A faint double friction-sound at the base of the heart and a soft systolic murmur at the apex."

At this time nothing was known of the accident; and as there was but little oppression of breathing and the cough soon after whoission was found to be spasmodic, the boy was thought to be developing whooping-cough

and was sent out by the House Surgeon.

On April 22d, the child was brought back to the hospital with a full account of the origin of the illness. It was stated that after his discharge he had continued to cough in a spasmodic manner and to whoop occasionally. He had often complained of pain in his stomach and left side and his breathing had been oppressed. He had little appetite. His skin had been hot with occasional perspirations. Shortly before his return to the hospital the aspirator had been used to the chest by a practitioner of the neighbourhood, but no flut I had escaped.

The boy appeared to be excessively ill. He complained much of pain in the abdomain and lay with his knees drawn up. The abdomaind parietes were somewhat retracted. Over the left back reaching from the posterior axillary line nearly to the spine, and from a little above the lower angle of the scapula to the tenth rib, was a large superficial collection of

matter. This on being opened was found to consist of very officer particle abscess evidently communicated with the plental carity for at the nucled in through the wound at each inspiration. The boy's bracked was laboured and his voice whispering. An examination of the desired difficult on account of the tenderness of the side. It was however satisficult on account of the tenderness of the side. It was however satisfied that resonance of the left back, although impured, was lost, and that the respiratory sounds were concealed by houd creake, as gurgling rhonchus.

The boy remained very prostrate and in great distress. He was considerly restless and occasionally screamed in a very hears too. It discharge from the wound was inexpressibly fetid. He died of the 25th. His temperature after readmission varied between 100 ar. 102 cm.

On examination of the body, seventeen hours after death, the specificial abscess eavity was found to extend from the middle line of the recolaricle across the chest and round the left side to the spice. The over it was sodden and seemed almost decomposed. The body was not emaciated. On opening the chest the right lung was generally often to the chest-wall, although not very firmly. Its substance was sense congested but otherwise normal. The bronchi were injected at least

mucous lining adematous,

The left lung, firmly adherent on its posterior surface, was attered disorganized. Its substance tore easily and the small was almost uportable. The surface of the disphragm had the appearance of in also in the eighth interspace, about one unch behind the posterior arrives was a large ulcerated depression rather more that an unch in determine the hottom of which was a perforation communicating the substant and in the left bronchus was a date-stone impacted about an inch an half from the bifurcation. The lining membrane of the bronchus was a half from the bifurcation. The lining membrane of the bronchus was a final ordernatous, but the air-passages contained no excess of final the account of the disorganized state of the lung it was impossible to whether an abscess had originally formed in the neighbourhood of the disorganized state of the lung it was impossible to date-stone. There was no peritorities. The left ventrally of the was hypertrophied, and the edges of the united valve were much that ened.

This case is peculiar on account of the situation of the fore, a best which had passed into the left bronchus instead of the right. When we child was first brought to the hospital no mention was more of 18 and nothing in his symptoms suggested the presence of a substance in his lung. There was no great distress of breather, which is the left lung that is the of the chest being healthy.

The foreign body after passing the rima glottidis may be cally one of the ventricles of the larynx; it may become fixed in the first or may pass further down and lodge in one of the princary division air-tube. There are, therefore, certain varieties in the symptoms are

to the position of the obstruction.

If the solid substance remain in the larynx, the voice is supposed the dysphera is continuous; the courh is generally violent at the child feels as if he should choke, and there is often pain a feed the situation of the cricoid eartilage. It may, however, be reposed aphonia is not limited to these cases, and that a hourse with part to those not necessarily indicate that the obstacle is fixed in the larval be the case just narrated, although the fruit-stone was impacted in the

bronchus and the larynx was free, the voice was hourse and almost suppressed.

If the substance lodge in the trachea below the larynx, the suffering produced is not very great, as a rule, so long as the passage remains pervious. In the often-quoted case related by Mr. McNumara of Dublin, in which a boy who had constructed a whistle out of a plum-stone, inadvertently drew the toy by a strong inspiration through the glottis, the object remained fixed transversely in the lower part of the larynx, and gave rise to a whistling sound as the air passed through it in expiration. The only inconvenience produced by the accident while the obstacle remained in this situation was an occasional sufficiently cough; but this did

not prevent the boy from running about and playing as usual.

In the bronchus the symptoms produced by the presence of a foreign body vary according as this is fixed or is free to move. If a smooth substance, such as a fruit-stone, become fixed in the bronchus, it causes great distress by plugging the air-tube and arresting the function of the corresponding lung. The air-tube and arresting the function of the corresponding lung. The air-tube and arresting the function of the corresponding lung. The air-tube and arresting the function of the corresponding lung. The air-tube and arresting the function of the corresponding lung. The air-tube and enter or escape. Consequently the patient experiences great dyspines from sudden loss of haif his breathing surface. He has attacks of spasmoche cough from the irritation in lunced at the seat of obstruction, and on the affected side the vescular murmur is weakened or suppressed. Catarrhal pneumonia in this case follows very quickly. If the impacted body be irregular in shape, so as still to allow the passage of air through the tube, there is less oppression of breathing, and in many cases less irritation in the lung; also, the pathological results are more chronic in their course.

If the intro ling substance be free to move, as is sometimes the case with a rounded body which does not so readily become impacted in the air-tube, very curious consequences follow. When the object is carried against or into the larynx, it produces spasmodic cough and an agonizing feeling of suffication. As it descends again into the lower tube there succeeds a period of comparative culm; and the physical signs which have been described as indicating impaction of the substance in the bronchus may perhaps be noticed. This alternation of sufficiency with intervals of more or less complete repose are very characteristic. It is in these cases that the presence of the foreign body can sometimes be detected by the ear and the touch. In the case of a little girl, aged two years, who was under my care in the East London Children's Hospital suffering from the presence of a haricot bean in the air-tubes, the physical signs noted by the House Surgeon, Mr. Scott Battams, on the evening of the day on which the accident happened were: "Air enters fairly well into both si les of the chest. At the apices expiration is prolonged and wheezing, On listening at the middle of the right back a sound is heard as if a solid boly were drawn down in inspiration and carried away again in a forced expiration." The child, although not much troubled by dyspinea, suffered greatly from cough; and when this was violent the finger and thumb placed on either side of the upper part of the traches could feel a distinct impact as of some solid body striking this part of the tube with each impulse of cough. Afterwards with the stethoscope placed upon the same part a dull thud-like sound was distinctly andible as the object was forced apwards by the current of air.

Interests.—Whenever a foreign body has passed into the windpipe it is of the utmost importance to the patient that there should be no mystery as to the cause of his symptoms, for recovery will probably depend upon to by measures being taken for the expulsion of the oftending substance.

The diagnosis rests upon the history of the accident and the sudden correspond to the symptoms in a child previously healthy; also, upon the automatic situation of the physical signs to be discovered on examination of the chest.

The history is not always to be obtained. Thus, in the case of a late unless the child have been seen to play with some small object immediate before the suffocative attack occurred, the likelihood of a foreign being ing passed into the traches may not even be entertained Again, the Latory may be misleading. Attacks of spasmodic laryngitis may occur as young child while at play; and if any small objects likely to preduce to symptoms are found within his reach, the inference that a similar and has been introduced into the air-passage is sufficiently obvious. It is attack of laryngitis occurred first under such circumstances, the inferent would be almost unavoidable. Still, although not necessarily concluse, a history of the probable introduction of a solul substance into the was pape is of great value. If a child while in his usual health has been exact stoned fruit, or playing with small articles such as peas, barrent bears of grains of corn, and is seized all at once with violent oppression of boniing and spasmodic cough, we should consider very carefully the entire to be obtained from a physical examination of the cliest. It must be amembered that the first distress is only temporary, and is succeeded by a period of calm, of variable duration. When called to such a case tagfore, we must not conclude because the child's suffering has subsided 22 all danger is at an end.

The physical signs in these cases may be indicative of pulmonars mattion or of more or less complete obstruction of a bronchus. The units set up in the air-tube leads quickly to increased secretion, so that more less sibilant or sonorous rhonchus and bubbling rules are usually bad with the stethoscope. If in a case where the symptoms occurred sadic under circumstances suggesting the introduction of a solid substance me the windpipe, the above signs of irritation are discovered on one sale of and that side the right side, the evidence must be looked upon as input

Signs of plugging of a bronchus are, however, of the greater who Complete absence of breath-sound and of respiratory movement over the whole of the affected side without alteration in the normal resonance—as signs occurring suddenly in a child in whom suffocative cough be, at the once in the midst of perfect health, would be strong evidence of the precise of a foreign body in the air-tubes, even in the absence of any beauting to such an accident. If in such a case violent suffocative curb breaks out again, and at the same time the morbid phenomena dapper from the chest, the vesicular murmur returning with natural larises the side previously silent, the phenomenon is very characteristic. The alternations of comparative calm and absence of breath-sound with the appendix of cough and perfectly normal physical signs move be taked at as pathognomonic. If the impact of the imprisoned body can be felted beared in the trachea during the cough, the evidence thus furnished to presence of a solid substance in the air-passages is practically compared.

If the tube, instead of being perfectly closed is partially permains a preciable weakness of the vesicular murnur may be noticed on the star side. Such a sign occurring alone may have little importance attacked it; but if with weak breathing over the right lung we notice were contained and rhouchus or bubbling rules over the upper part of the same sature other lung being healthy, the combination is of some value.

When the foreign body remains in the larynx caught in one of the ventricles, the resulting symptoms—aphonia, dyspnon, violent croupy cough, and sense of choking—may suggest stridulous laryngitis or membranous croup. In such a case the history of the seizure, especially the sudden occurrence of the distress in a child previously in a state of perfect health, is of great importance. In stridulous laryngitis, although the complaint often begins with much violence and quite suddenly, the spasm almost invariably occurs at night, the child starting from his sleep with urgent dyspnora; and the symptoms subside completely after a short time. In the case of a solid substance in the larynx the access occurs while the child is awake and at play; the dyspnora is more continuous; and the remission, if it occur while the foreign body remains in the neighbourhood of the larynx, is fur has complete.

In membranous croup the attacks of dyspuces come on gradually, and slowly increase in severity; the voice is not whispering at the first; and in

many cases patches of false membrane may be seen in the fauces.

Prognosis —If expulsion of the imprisoned body cannot be effected, the prognosis is very gloomy; for although cases have been recorded in which the patient has continued for years to suffer little from the presence of the solel substance in his air-passages, such cases are very exceptional. Most commonly ill effects are not slow in making themselves evident. The prognosis is more favourable if the impacted object is of irregular shape, so as to allow air to pass and repass it in the tube. In such cases the patient may escape rapid death. In almost all the instances in which chronic phthisical changes have been developed as a consequence of the accident the substance has been of an irregular shape.

If expulsion is effected, the prognosis accessarily depends upon the changes which have been set up by the irritation of the substance during its retention. Chronic phthicael symptoms often subside in a surprising manner after the ejection of the offending body, and in such cases, unless disorganization have proceeded too far, recovery may be hoped for. If absense or gangrene have been set up in the lung, death generally ensues.

Treatment.- When we are satisfied that a foreign body is retained in the air-tubes treatment must be energetic. Emetics have been found of little value and may therefore be dispensed with; but if we are certain that the solid substance is of small size, the child should be at once turned head downwards and shaken in the hope of dislodging the imprisoned body and aiding its escape from the tubes. Often violent cough comes on during the operation, and sometimes so much spasm is excited in the glottis by the solid body pressing against it, that our efforts have to be promptly discontinued. This proceeding is more likely to be attended by good results if the substance is small. A shot, a seed, or object of similar size, would be able to pass without difficulty between the vocal cords, while a larger one might become impacted in the glottis and cause speedy death by suffocation. Whenever, therefore, the foreign body is known to be of some size, it is wiser to postpone all violent measures, such as eversion and succussion, until an artificial opening has been established in the traches. This procedure is equally important whether the imprisoned body be fixed or be free to move. If it be fixed, the air-tube can be directly searched by a long forceps, and the object may sometimes be seized and withdrawn in this mountr. If it be free to move, an artificial opening in the trachea is a great aid to its escape, as under these altered conditions the glottis relaxes readily and there is no risk of dangerous spasm.

After the operation the imprisoned body may be ejected through the

wound or may pass through the relaxed glottis. In the latter case it is apt to be swallowed. If, therefore, it be not found after the signs of suffering

have subsided, the stools must be carefully examined.

If the early measures for promoting the escape of the solid body do not succeed, or if on account of the size of the substance we fear to employ them, it is seldom judicious to delay the operation of tracheotomy. It must be remembered that it is only in exceptional cases that the continued presence of a foreign substance in the air-tubes has been borne without dangerous injury to the lung. As long as it remains in the respirators passages there is constant danger of suffocation from the lodging of the object in the larvnx, and of serious disorganization of the lungs from the irritation set up in the tubes. Therefore, if we are satisfied that a solid body is impresoned in the procages, the fact that the resulting symptoms are not urgent should not induce us to postpone the operation. As Mr. Barwell has observed, "If a body be impacted in the larvax or traches, urgent symptoms will mean merely increased arritability and spasm of the glottis, and on removal of the foreign body this will naturally cease. If the body be in the bronchus and do not more, urgent symptoms will mean the establishment of serious disease in the lung," and this may not disappear when the foreign substance is removed.

The operation is equally necessary whatever be the nature of the substance in the traches. Soft matters, such as gristle, etc., will not become disintegrated in the air-tubes; and small vegetable substances, such as seeds and grains of corn, may swell up to a much larger size through

absorption of moisture.

Part 7.

DISEASES OF THE HEART.

CHAPTER I.

CONGENITAL HEART DISEASE.

LIKE other parts of the body the heart is subject to malformations from arrest of development. These vary in importance according to the period of intra-uterine life in which they occur; but all, since they affect the centre of the circulatory system, materially hamper the distribution of the blood-current and therefore interfere with the due discharge of all the

nutritive functions of the body.

In its progress from the simplicity of its rudimentary state to the complex machinery of the fully developed organ, the heart passes through a variety of changes. At first a mere tube doubled upon itself, it soon becomes divided into three cavities—a simple auricle, a simple ventricle, and the arterial bulb. At this stage the organ resembles a horse-shoe in shape, the ventricle occupying the position of the curve. This cavity then begins to bulge out more conspicuously at its lower part so as to suggest by its appearance the later form of the heart; and at the same time the auricle and the bulb approach more closely together. Next, the suricle and ventricle become each divided into two parts by a septum; and the bulbus arteriosus is also divided into two channels which are the future sorts and pulmonary artery. The auricular and ventricular septa are each at first incomplete, so that the cavities severally communicate; and the opening in the auricular septum—the foramen ovalo—remains open until birth.

Just before the completion of intra-uterine existence the course of the blood-current is as follows: Starting from the placenta, in which it has been to a certain extent purified and recharged with oxygen, the blood enters the body of the fictus through the umbilical vein and is conveyed to the under service of the liver. At this point a portion passes directly into the inferior vena cava by the ductus renowns; the remainder joins the blood in the portal vein and circulates through the liver before it reaches the inferior vena cava and is conveyed with the first portion to the right annule. Here it meets with the blood returning from the head and neck by the superior vena cava. The two currents do not, however, mix. That

coming from the head passes, as it would do in the adult, through the auriculo-ventricular ordice to the right ventricle. From this points and quantity reaches the lungs through the pulmonary artery; but the large portion is directed through the ductas arteriosus into the sorts belonge origin of the great vessels, and passes to the lower part of the habit of the placenta. The blood reaching the right suricle by the inferior on casa, instead of entering the right ventricle, is directed by the lasts are valve through the forumen ovale into the left suricle. Consequents this portion of the blood also escapes the passage through the lung sales distributed by the left ventricle to the head and body generally that is distributed by the left ventricle to the head and body generally that is

At both, the lungs, which had been previously inactive, come into part and blood as drawn into them through the pulmonary arters in a necessary consequence, the foramen ovale and ductus arterosas to channels by means of which the passage through the lungs had been avoided, become useless. The arterial duct contracts and covers to pervious; while the foramen ovale also closes and the separation of the

suricles is henceforth complete.

The arrest of development of the heart, which is the cause of the segenital malformation, may occur at any of the stages which have but referred to. The heart may retain its nearly primitive form of a court cavity with only rudimentary divisions between the two sides and so acres and pulmonary artery may be still undeveloped from the court arterial trunk. This form is not common, but examples have been ticed. In the earliest of these, placed on record by Mr. Wilson is 120.

the infant survived its birth seven days.

If the arrest take place at a later period, the septa dividing the court are more nearly complete, and the sorta and pulmonary artery are decast vessels. This condition is far more common than the preceding in prominent feature, in addition to the still imperfect state of the partures is a displacement or even a transposition of the great vessels. The adis displaced to the right, arising in part from the right ventrale as springs completely from that cavity and the pulmonary artery takes a origin from the left ventricle. When the sorta is merely displaced to 3 right, without malposition of the pulmonary artery, we usually had see obstruction to the pussage of blood from the right ventricle through the ter vessel. The actory is too small, or its valves are incomplete, or its blood is prevented from passing freely into it by some constriction of the ventricle near the outlet, or its channel may be even entirely obligate. In all such cases the foramen ovale must remain open or the circulated could no longer be carried on. The blood being unable to find to any a sufficient quantity to the left side of the heart through the lung or tinues to follow its original course through the opening in the aun septum, and the forumen ovale is prevented from closing. If, however such a case the north arise sufficiently to the right to allow of the case of blood through it from the right ventricle, the foramen ovale and design arteriosus may cense to be pervious.

Construction of the pulmonary artery with deficiency in the septem of the ventrales, so that the north communicates with the right verticals cavity, is the commonest form of congenital malformation of the last. Whether in such a case the foramen ovale and ductus arterious are don't

¹ Under normal conditions the foramen evals should be closed by the end of the third month after both

or not depends, as has been said, upon the freedom with which the blood can escape from the right side of the heart through the displaced aorta. If the right ventrule is not unduly distended, and the pulmonary artery allows enough blood to get away, both these channels may become closed. In the other case, where the aorta and pulmonary artery are transposed, the septum of the ventricles is usually imperfect, and the foramen ovale and ductus arteriosus still remain open.

Sometimes the descending aorta is found to arise from the pulmonary artery, being apparently a continuation of the ductus arteriosus. In this case a small ascending aorta springs from the left ventricle to supply the head and neck by the usual vessels. The pulmonary artery communicates through an opening in the ventricular septum with the left ventricle. The

foramen ovale is usually closed.

In contradistinction to the class of cases where the feetal openings remain pervious after birth is another class in which these orifices close too early, before uterine life has reached its term. If the foramen ovale is obliterated prematurely, the whole quantity of blood has to pass through the pulmonary artery and ductus arteriosus. Consequently, the right side of the heart is enormously hypertrophied while the left side is smaller than natural. In cases where the ductus arteriosus has undergone early obliteration, the aerta usually springs from the right ventricle, and this vessel commonly gives branches to the lungs, the pulmonary artery being

very small and rudimentary.

Besides the varieties which have been mentioned, the congenital disease may also consist in defects in the valves, or in narrowing of the ordices of the large vessels which spring from the heart. Sometimes, as in the preceding cases, the defect may arise from malformation, as when the number of the valves is deficient or otherwise abnormal; but it may also be due to intra-uterine endocarditis. Inflammation, when it attacks the feetal heart, almost invariably affects the right side, which at this period of life is more active than the left. The tricuspid valve may be beaded, or the pulmonary semi-lunar valves may be more or less adherent. In many cases the three pulmonary valves are found united into a funnel-shaped dome with a small ordice at the apex, through which the blood is propelled with difficulty. A similar attests of the aortic ordice is much less frequently met with. When the latter malformation exists, the arteries of the head and upper limbs are probably filled through the pulmonary artery by the ductus arteriosus

It is possible that these inflammatory lesions may be occasionally excited, as Dr. Von Hoffman suggests, by extravasation into the placenta, from which hasmorrhagic foci, pathological products, may be introduced

through villous absorption into the fostal circulation.

Mortad Anatomy.—In addition to the maiformations which have been described, the heart is always found to be greatly enlarged, especially on the right side. Moreover, morbid conditions are usually seen in other organs. There is often more or less atelectusis of the lungs, and the expanded portions have a dark, congested appearance. The liver and spleen are not unfrequently swellen and congested; and effusions may be found in the pleura and peritoneum. Also, morbid conditions of the brain are common. There may be congestion or inflammation or effusion; or an abscess may be formed in its substance.

The congenital imperfections of the heart may be complicated by inflammation in or around the organ, for the original malformation, far from guarding the patient from subsequent inflammation, appears rather to prepare the way for it. We may therefore find the anatomical chara-

ters of endocarditis or inflammation of the pericardium.

Symptoms.-In cases of congenital heart disease the most street symptom is the purplish or livid tint of the skin which, if the class see vive its birth many months, rarely fails to be developed. It has been this peculiarity of colour such cases are often spoken of as cases of man sis or "morbus coruleus." The depth of the purple tint varies grad. is different subjects. In some it merely gives a dusky or swarthy has to be skin. In others the discolouration may reach a deep purple or even used a black colour. It is distinguishable in all parts of the body; but is took noticeable in the cheeks, hips, and evelids, and also in the enti- fits fingers and toes. Even in the same subject the symptom is him: variation. While the child is completely at rest the fint most next as proaches the normal colouring; but movement, especially fretfaloss t anger, makes the skin darker at once. The cause of the evanetic tall be been the subject of discussion. By Morgagni it was attributed to gate general congestion, and by Hunter to great contamination of the setend current with unoxygenized blood. The latter view has been shown ! / untenable. Cyanosis may exist without any admixture of venous at 12 rial blood; and in many cases where such admixture occurs the dept tint is not in proportion to the amount of venous blood which is preinto the aorta. Dr. Peacock gives his support to the theory of Metal and attributes the discolouration to stasis of blood in capillaries blace. long-standing congestion, aided by imperfect acration of the whole and of the circulating third.

The evanotic tint is not always an early symptom. We often incite the child at birth presented no peculiarity of colour, and that it was after an interval of weeks or months that anything was noticed to it suspicions of disease. In less common cases the tint of the skin is to the

throughout.

Dysphora and pulpitation of the heart are common symptoms. It case of an infant the mother often remarks upon the beating of her debeat when the patient is washed or otherwise disturbed, and color dren may complain spontaneously of the throbbing when they are run. At these times there is usually shortness of breath, and color be present. In some cases when the cyanosis is extreme, the control be accompanied by the expectoration of blood. The pulse is often an

ular and intermittent, but its strength is fair.

Sometimes dropsical symptoms come on. There may be admit

the legs, or ascites; but serous effusions are less common than might be supposed, for, as Dr. Chevers has pointed out, the venous system seems to adapt itself to the overloading. The right auricle, cava, and systemic veins are often of unusual capacity from the first; and the veins of the liver are capable of containing a vast quantity of delayed blood. The superficial veins of the chest or limbs are rarely more visible than natural, but the skin is habitually dry and may be harsh. The liver and spleen can often be felt to be enlarged; and on account of the congestion of the kidneys the uruse is habitually scanty and high coloured. On account, too, of the congestion of the alimentary canal, the tongue is generally foul, the breath offensive, and the digestion feeble. The appetite is poor or capitalous; and the bowels costive or irregular, with clay-coloured pasty stoots. The guins are often dark-coloured and spongy-looking, and may be ulcerated

at their edges. Sometimes they bleed.

Cyanotic children are generally irritable and easily disturbed. Consequently at a first examination it is often impossible to come to a satisfactory conclusion even as to the physical signs present in the case. These are hable to vary according to the character of the congenital lesion, and may possibly be absent altogether; for if the malformation consist in a mere transposition of the aorta and pulmonary artery, without narrowing of the channels or persistence of the foetal openings, no murmur will be heard, and careful examination will detect no sign of cardiac enlargement, The most common mulformation, as has been said, is that in which the pulmonary artery is greatly constructed, and the septum between the ventrueles is deficient, so that the aorta appears to arise in part from the right ventricle. In such a case there is great hypertrophy of the right ventricle; we find a very strong pulsation all over the pracordial region, and a forcible impulse between the left nipple and the cusiform cartilage. The impact may be accompanied by a systolic thrill. On listening to the clied we hear a loud systolic marmur in the course of the pulmonary In the case of a boy who died at the age of nearly six years in the East London Caildren's Hospital with this condition, the apex beat of the heart was in the fifth interspace in the nipple line. The impulse was felt very strongly over the whole precordial region, in the epigastrium, and even to the right of the lower part of the sternum. The arteries in the neck also pulsated strongly. A loud systohe murmur was heard all over the front and back of the thorax. It was rather louder at the base of the heart than at the apex, and became much fainter towards the armpits. The point of greatest intensity was over the site of the pulmonary valves. In this child there was no discolouration of the skin.

Even a patent foramen ovale without constriction of orifices or other abnormal condition will give rise to a murmur. In a case published by Dr Buthazar Foster—in a little girl of two years old—a faint murmur was heard with the latter part of the first sound at the level of the lower edge of the third rib at its junction with the sternum. It did not, however, extend over a wide area, and was audible neither at the base of the heart

nor the apex.

Infants who suffer from congenital malformation of the heart are usually thin. If, however, the patient survive the period of infancy, he may not be wasted and may even have a sturdy appearance. He is usually lethargic and dull of intellect, and is cautious in his movements, as experience has taught him that exertion is apt to be followed by pulpitation and dyspicea. In most cases where serious multormation of the heart exists the patient is subject to attacks of syncope, and often symp-

toms occur referable to disorder of the nervous system. In the case nferred to above, the patient died of cerebritis. Another cyanotic and under my care in the East London Children's Hospital-a little gai acidy two years old-suffered, while she remained under observation, from general loss of power, with ptosis of the right evelid and contraction with newly of the muscles of the left forcarm. The child had all the signs of an ed disease of the right petrous bone. Disease of this part of the skull seem to be a not uncommon lesion in children who suffer from congenied reformation of the heart. Dr. Lawrence Humphry has kindly communicated to me the notes of a case which occurred during his period of Early Resident Physician in the Victoria Park Hospital. The patient a current boy between five and six years old-had suffered from long-or mal otorrheen. A fortnight before his death the discharge ceased. The call then began to complain of headache, which became very severe. This symptom was soon followed by attacks of violent convulsions, without and of consciousness in the intervals, and the boy died in a few days. And death, in addition to the ordinary form of congenital malformation istrated of the pulmonary artery, deficiency in the ventricular septum, and some if the aorta from both ventricles) an abscess was found in the moddle ale of the left cerebral hemisphere, and the petrous bone on that side was less

Convulsions are very common, especially in infants; and startuces and twitchings during sleep are seldom absent whatever be the age of the patient. Another curious symptom is great heaviness and some determinant children attacks of uncontrollable sleepiness form a pasternent feature in the case. Those attacks are apt to come on after a mean. The child shows symptoms of great drowsiness; the face becomes purple, 44 the breathing slow and heavy. In extreme cases the sleep because a profound that it resembles come and the child cannot be roased. After some hours, however, the patient revives, his heaviness passes off, sailte

is restored to his normal condition.

The duration of life is very variable. It is dependent chiefly upon the degree of obstruction to the circulation. Nearly one-half of the case is before they have completed the first year, and two-thirds before they are two years old. Death often occurs in a convulsive fit; and infants assure die in or directly after such a seizure. Moreover, attacks of synope is common, and the failure of the heart's action is sometimes not recommon. In some cases the patient falls a victim to pneumonia or ofter it tercurrent disease; indeed, on account of the impaired state of nutrice usually prevailing, the resisting power of the child is feeble, and demanded by symptoms provered and which a stronger subject would have little unbeauted as has been said, in not a few cases death is preceded by symptoms pairing to cerebral mischief.

Diagnosis.—A child, cyanotic from malformation of the heart, pressure is very characteristic appearance. His dusky tint, his purple type at the lids, his livid and clubbed finger-tips—these symptoms, together with the physical signs and the history of the patient, can leave little doubt at the existence of a congenital lesion of the heart. If, however, evances are sent, the nature of the case is less immediately recognisable; but by some full review of the physical signs we can usually arrive at a correct of some. If we are able to localize the murmur at the pulmonary or a subcan discover signs of hypertrophy of the right ventruele (increase discovers) duliness to the right with pulsation in the epigastrum, these series of the pulsation in the epigastrum, these series of the right with pulsation in the epigastrum, these series of the pulsation in the epigastrum, these series of the pulsation in the epigastrum.

te almost pathognomonic of congenital disease, for endocarditis affecting e night side of the heart is rare after birth. Sometimes, on account of be small size of the chest in young subjects, it is impossible, especially in unfant, to discover the point of greatest intensity of the murmur. In sch a case, signs of hypertrophy of the right heart are doubly important; ad if we notice clubbing of the finger ends, and find that after movement he child's face becomes livid or his lips blue, the existence of congenital bart disease, in the absence of any affection of the lungs, may be safely asmed. According to some observers, attacks of dyspaces alone, occurring ham trithing causes, are very suspicious of this form of lesion. Louis was of pamon that "sufficative attacks brought on by the slightest cause, then periodic, always very frequent, and accompanied or followed by syntire in I with or without blue discolouration of the body, generally "formed reflecent grounds for the diagnosis of an abnormal communication between the night and left cavities of the heart. Again, the occurrence of tuberculoss in a child the subject of old-standing heart disease, although not conclose evidence, points very decidedly to a congenital origin for the cardiscurschief.

Even in cases where all necessary symptoms are present, and the congental origin of the heart-lesion is unmistakable, the exact variety of mal-form on must often remain a mystery. The difficulties in ascertaining the form in which the arrest of development has occurred are very great. In the case of a fully developed heart we are dealing with an organ the structure of which is known. We are acquainted with the number and mind on of its openings, the number and mechanism of the valves which class them, and the direction normally taken by the current of blood. In such a heart any morbid alteration of the physical signs has a definite morning; and in ordinary cases there is little uncertainty as to the cause when has given rise to it. In the case of a heart the seat of a congenital multimation, the conditions are very different. The number of openings is unlitermined; their position is doubtful, and even the direction in which the blood is flowing can only be conjectured. In such cases, therefor an exact charmosis is often impossible. Still, there are certain general rubs which should not be forgotten. Thus, some forms of malformation powerery quickly fatal. An infant whose heart remains in a primitive state, consisting merely of two cavities, will probably be dead within a Therefore at a more advanced age this variety may be excluded. An eier form of congenital disease which usually has an early termination 15 to sposition of the sorta and pulmonary artery. Children in whom this form of mulformation occurs rarely live longer than two or at the most thre years. One little boy under my care with this form of lesion surmal to the age of eighteen months; but the majority of the recorded tranceles have died within the first twelve months. So, also, the variety what masists in the origin of the north from the pulmonary artery is not likely to be present in a child who has survived the first year.

In the liren who have reached the age of three years the above conditions may be excluded with a high degree of probability. At this age we should search for signs indicative of atresia of the pulmonary artery. If we can localize the murmur over the pulmonary valves, and can ascertain the sustence of hypertrophy of the right side of the heart, we may safely infer the presence of contraction of the orifice of the pulmonary artery. It such a case there is probably also deficiency of the ventricular septum, will a communication between the aorta and the right ventricle, and perhaps patency of the arterial duct. This, it may be repeated, is the

commonest form of congenital malformation. Still, other morbid tions of which we know nothing may also be present. Patent foramen ovale is seldom the only abnormality, but, if in a child years old or upwards we find the symptoms of congental be the without cardiac nurmur, or with a very faint brunt hunted strictly level of the third interspace towards the middle line, and without hypertrophy of the right ventricle, this condition may be suspect no case, probably, can a positive diagnosis be arrived at; at least, never say that the condition diagnosticated is the only cardin

present.

Prognosis.—The prospects of a child, the subject of congent formation of the heart, are necessarily very unfavourable. On according the difficulties under which his circulation is carried on, and the per congestion of his whole venous system, the child's nutrition is faid his vitality low. He has therefore little power to throw off even derangements, and is peculiarly sensitive to disturbing influences. dition, then, to the dangers directly attendant upon his corgonital he is exposed to constant risk from the serious consequences, in feebled state, of the ordinary adments of childhood. Every change growth and development of the infant is a new period of trul. The establishment of the respiratory function at birth, the occurrence of tion, the time of weaning, and all the innumerable causes of distri to which infant life is liable, are distinct sources of peril. To another of such dangers a large proportion of these pattents such and, as has already been stated, hardly one-third of the whole number cases survives to the age of two years.

On account of the difficulty of ascertaining the exact variety and of the cardiac defect, the prognosis during the first few months of especially serious. Later, as the child grows and arrives at a pariod the more fatal forms of malformation may be excluded, his prospec prove; but they can rarely be said to be otherwise than unfor our a comparatively small proportion of these petients live to attac. solul

Of special symptoms, some should be regarded with anxiety attacks of syncope are dangerous; great drowsness is of unfare omen; and convulsions or other sign of cerebral irritation have a reister meaning. According to Dr. Chevers, failure of the renal seems the occurrence of albuminuria, as indicating the probable beginn structural changes in organs which have always been hompered in f charge of their functions, is to be viewed with much apprehension.

Treatment.—The treatment of these cases consists in the adopts at rules for the diet and general management of the princit, and in early tion to any intercurrent disorder by which he may be attacked. On a of the general sensitiveness to chills, and the tendency to lowering temperature, the child must be warmly dressed with a flannel band belly, and should be clothed in some woollen material from head t His diet should be carefully arrange I so as to awad excess of ferror matters, such as starches and sweets; and he should be taken out of whenever the weather is not too unfavourable, in his nurse's arm suitable carriage. If a perambulator be use I, a hot bottle to the feet is a necessity unless the weather be warm. The patient's boack be kept regular, and an occasional mercured purge is useful to attack relief to his congested liver. It pulpitations are violent, small the infusion of digitalis may be given; and Dr. Peacock speaks har if beneficial effects of Dover's powder. It is important to excite the

n of the skin, which in these patients is habitually dry. Tepid baths id be given twice a day, and should be always followed by careful one over the whole body with the hand. Small quantities of alcohol also of service, and may be given in the form of brandy or the St. seel tannin wine. The attacks of dyspnæa are best treated by stimuand small doses of digitalis and ammonia.

my catarrh, whether of the lungs or bowels, must be attended to withlelay; and if albuminuria be detected in the urine, or the renal secrebecome scanty, gentle aperients and diuretics should be at once reed to. In cases of extreme discolouration, the peroxide of hydrogen been recommended; and Dr. Balthazar Foster states that given three saday in eight-minim doses the beneficial effects of the remedy are

decided

CHAPTER IL

CHRONIC VALVULAR DISEASE OF THE HEART.

Curronic disease of the heart is very common in childhood; and there are few forms of valvular lesion found in the adult which may not be also met with in the young subject. The signs and symptoms to which such faulty conditions give rise are much the same at all ages. A child, like an adult, may have valvular disease without himself being conscious of discomfort or betraying to others any sign of inconvenience; or he may suffer from breathlessness, palpitation, general cedema, and all the other symptoms which are liable to arise in an older person similarly affected. The physical signs of valvular lesion, and of consequent alteration in size of the organ, also resemble very closely those met with in adult life. It is not, therefore, necessary to enter into these subjects at great length. It will be sufficient to point out any peculiarities of feature conferred upon the cardiac disease

in the child by the youthful age of the patient.

Causation. - Amongst the causes of valvular defect of the heart, rheumatism takes by far the most important place. To this disease, indeed, most of the cases of heart disease occurring in early life are to be attributed. The manifestations of rheumatism in the child, as is stated elsewhere, are often very trifling; and in infancy, on account of the difficulty of referring signs of distress to their true source, the disease no doubt often escapes detection altogether. Next to rheumatism, scarlatina is perhaps the most common cause of endocardial inflammation. This disease is often followed by joint pams and other symptoms industinguishable from the quatism, and chronic valvular disease of the heart appears in not a few cases to owe its origin to this exanthem. According to Bouilland, measles is also an occasional precursor of endocarditis; and Dr. Samson has recorded a case in which both pericarditis and endocarditis occurred a fortnight after convalescence from measles had begun. This fever, however, is no doubt a much less common cause of the valvular disease than the other maladies which have been mentioned. In certain cases, chorea appears to be a starting point for valvular mischief. Sometimes, without any evidence of rheamatism, we find a murmur become developed in the course of the chorac attack; and it may happen that the morbid sound continues after the cessation of the nervous derangement, and is accompanied after a time by displacement of the heart's apex and other signs of hypertrophy. Still, in these and other cases where no history of rheumatism is to be obtained, it is possible that the endocardial lesion may still have a rheumatic origin. The tendency of this disease is to attack the fibrous tassues of the body generally; but all need not suffer at the same time. The selection, even, of the joints to be affected by the disease is apparently capricious. Some are

Acute peri- and endo-carditis and their consequences are considered in the chapter on scute rheumatism

tacked while others are passed over. It is surely, therefore, not unreasonable to suppose that the fibrous tissues of the heart may be implicated thile those of the joints are left unharmed. In addition to the preceding, yellulis may be an occasional cause of the heart lesion, for valvular imperation is sometimes found in very young infants, the subjects of inherited

philis

Ameromatous degenerations, which are so common a cause of valvular sion in the adult, rarely occur in early life. It once, however, happened to me to meet with a small calcareous mass on one of the aortic valves in thitle girl three years old. The mass had given rise during life to a systolic murmur which was most intense at the base of the heart, but total be heard distinctly at all parts of the chest. This child had never had recurred, but had suffered from

measles nearly two years previously.

the test has been said to be a cause of hypertrophy of the heart; but I senot say that I have ever myself met with a case of cardiac enlargement with I was able to attribute to the chest distortion produced by this discusse. When the framework of the thorax is much deformed, the heart is, and oubt, forced more forwards towards the wall of the chest, and a larger test of impulse is consequently perceptible. It is common in such cases to be able to feel the contractions of the right ventricle in the epigastrium; but this sign alone is insufficient proof of enlargement of the right side of the leart in the absence of extension of dulness to the right of the sternum, and other necessary signs of that condition.

In some cases valvatar lesions are probably congenital in their origin, using from endocurdate occurring during intra-uterine life. In most of bese cases the valves on the right side of the heart only are attacked. I must valvalur disease, according to some authors, is more common in hors than in girls; but my own experience would point to a directly op-

poste conclusion.

Mortal Anatomy. - In most cases of chronic valvular disease in the young subject the lesion consists in a beading or puckering of valves or May cause of insufficiency, or in a narrowing of the valvular opening. It walve most commonly affected is the mitral; the next, that closing the Bealing of the tricuspid valve is mirely seen. This lesion, howoccurred in a case under my care in the East London Children's H qital A girl aged thirteen was admitted, suffering from general venous corposition, cyanosis, and anasarea. The child's fingers were clubbed, and ber breathing was hurried with some degree of orthopnica. The patient was sail never to have had rheumatism, but had suffered from measles and whiting, and seven years previously had had an attack of chores, from wird all her trouble was dated. On examination there was evidence of great hypertrophy of the left ventricle, and a strong pre-systolic thrill and but pre-systolic murmur were discovered at the apex. There was also a abort liastolic thrill at the base to the left of the sternum, and a diastolic purmur was heard at this spot. There were, in addition, signs of double bidochorax. On examination of the body after death, the heart was hand to be very large, especially transversely, and to weigh twelve and a half onness. The right auricle and ventricle were much distended with dirt post-mortem clot : and were both dilated, the ventricle being much pertrophied. The tricuspid valve seemed to be competent, and measured have and a half inches in circumference. Its edges on the auricular surwere fringed with papille which measured about one-eighth of an inch a length The left auricle was dilated and hypertrophied to a less degree

than the left ventricle. The mitral orifice was contracted to a mere with a circumference of one inch. The pulmonary arrary was very but the valves were competent. The aortic ordice leaked very a big the water test, but had probably been competent during life. The anal other organs showed the usual signs of prolonge t venous a gratage.

The heart was shown at a meeting of the Pathological South the colleague, Dr. Radeliffe Crocker. In his comments upon the last be Crocker suggested that the basic systohe murmur had been probable to a temporary incompetence of the pulmonary valves, owing to dilute of the artery from extreme congestion of the lungs. Such a case for pulmonary regurgitation is supported by the authority of Hope and the tening or other lesion, it almost always seems to be affected accident being usually found, as in the above case, in connection with a supported of the mitral orifice.

Adhesion of the layers of the pericardium is found in not a few case. The adhesions are often very thick and strong; and the lymph appears that penetrated between the muscular fibres of the heart, for the content torn in the attempt to separate the firmly attached scrong as a layer Great hypertrophy and dilatation of the organ usually accompanies has

condition.

It is important not to mistake for pathological bealing of value a condition to which Parrot has drawn attention. According to the server, in a large proportion of infants who die during the first :-after birth, hamatomata and fibrous nodules are found on the auniventricular valves. The hamatomata are little spherical or corneal ton arof a dark purple or nearly black colour. In size they may be so was be scarcely to be visible to the unaded sight, or may re, ch the un 11 millet-seed. They are placed singly or are arranged in groups. It little projections are seated exclusively on the mitral and tricosyclosics. at the part where the tendinous cords are inserted. They he close these free edge of the valve, and are covered by the most superficial layer (19endocardium. In a short time they lose their colour, and sink dows the little flattened prominences before they finally disappear. They cons w be visible shortly after the end of the first mouth of life. Parpot attracts their origin to rupture of intravalvular vessels. The manner and any cupy the same situation as the preceding, and are seen as little thread projections widened towards the base. They are composed of a box fibro-elastic tissue. These nodules, especially the former, occur to the quently, and are too harmless in their character, to be ranked as ; so " gical lesions, for no ill results appear to follow their presence on the last Strictly speaking, no doubt, they are not healthy productions, but is scarcely merit the name of disease.

The effect upon the heart's substance of the morbid changes is valves is much the same in the child as in the adult. Hypertrapical dilatation follow, and in severe cases may reach an extreme degree the young subject there is great power of compensation; and we find that the vigour of the heart becomes rapidly increased so as to up for the valvular deficiency, and the health of the child is seen impaired. In examining the heart in early life we must not a mistake of attributing all murmurs to valvular imperfection that any, to a degree of imperfection imprious to health. It is now in the child than in the adult to find a systolic murmur at the special beart, without any other sign of regurgitation through the auxiliary.

icular opening. Such a murmur may persist for years, and finally disappar without having led to any alteration in the site of the apex beat, or ther indication of ventricular hypertrophy. In such cases there is probably some roughening of the surface of the valve, which, however, still re-

pains perfectly competent to perform its functions.

Nymptoms.—A valvular lesion of the heart does not necessarily give to symptoms of discomfort; and it seems that in some children years in pass without any sign of distress being manifested on account of the ariac muschief. It is common to find signs of valvular insufficiency in a child who has been brought for advice on account of some casual derangement quite unconnected with the condition of the heart; and even in the charter breathlessness has been noticed, it is often a recent symptom, while the enlargement of the organ indicates that the valvular lesion is of the more remote origin. When regurgitation is slight, the increase of power quickly acquired by the heart compensates completely for the detect, and no unfavourable symptoms are noticed until dilatution occurs, or

a new attack of endocarditis aggravates the original imperfection.

Usually, the earliest and by far the most commonly present symptom is heathlessness. It is noticed that when the child plays at any boisterous pame, he becomes very pale, and pants in an unusual manner. If very probe need, the symptom may be accompanied by some lividity of the lips, and pur about the chest. In advanced cases, where much dilatation has ensued, schopmen may be present, and is a symptom of great gravity; and somehave attacks of syncope are noticed. Palpitation is complained of in childand less commonly than in adult life; but if the patient be anamic, the best's action may be tumultuous on slight exertion. Amenia is a frepent consequence of the more aggravated forms of cardiac lesion plult, it is usually present if there be insufficiency of the acrtic valves; at even in this case it may not be noticeable as long as the child is kept met. A little girl lately under my care, with aortic and mitral regurgiat a slways had a good colour as long as she remained in the hospital; wite I the healthiness of her complexion was the subject of remark by who were acquainted with the serious losion under which she was hisuring.

Henorrhages sometimes occur. The nose may bleed repeatedly; and a fler children hemoptysis may be seen, especially if there be mittal press as well as regurgitation. A little girl, aged twelve years, with most obstructive and regurgitant disease and great hypertrophy of both windles, frequently expectorated blood. The symptom would be problemet with more frequently were it not for the children habit of swallong all sputa brought up from the lungs. Another common consequence of the pulmonary congestion induced by the valvular lesion and he resulting tendency to catarrh, is cough. This is usually short and hackage, but if loose, for the reason stated is rarely accompanied by expectoration. When dilutation of the heart occurs, ordema follows quickly, and the largest their presents the same distressing features which are so familiar

to every one in the case of the adult.

An occasional accident is embolism. This is sometimes the consequence of ulcerative endocarditis, disintegrating particles of an infective example of the circulation and deposited in various organs, where they produce the consequences known to follow the presence of such infarcts. This complication, which is accompanied by ich temperature and symptoms of blood contamination, has been already aftered to (see page 158). It appears, however, that an ulcerative process

is not necessary to the separation of portions of fibrinous matter from the valves. We occasionally meet with cases where a child, the subject of recognised heart lesion, but making no complaint and appearing to be little troubled by his infirmity, suddenly becomes paralysed on one side from obstruction of the middle cerebral artery. The symptoms which accompany the onset of the paralysis vary. The child may vomit repeatedly; or be seized by convulsions followed by unconsciousness; or pass into a state of delirium or even violent excitement. Sometimes the embolism takes place more quietly; and nothing is noticed until it is found that the child's face is drawn, and that one side of the body has lost its power.

A little girl, aged six years, had been subject for sixteen months to shortness of breath after any exertion, and at such times to blueness of the lips. She had never been known to have rheumatism; but, six months before her admission to the hospital, had had an attack of measles, which had been followed by whooping-cough. There was a suspicious history pointing to syphilis, and the child was being treated by one of my surgical

colleagues for keratitis. Her temperature was normal.

On May 10th, the patient was noticed to be dull and apparently sulky. She passed her urine and faces once involuntarily, which she had never done before; and her temperature on that evening was 99.6°. On the next morning the increury registered 99.4°, and the child's mouth was noticed to be drawn to the left side; she could not stand; her right arm was completely useless; and her right eye closed imperfectly. In addition, she was aphasic. Although drowsy, she could be easily roused, and she

took her food well, having no difficulty in swallowing.

On examination of the heart, a loud systolic murmur was heard all over the front of the chest, and also at the back; but it was louder on the left side, posteriorly, than on the right. In the left axillary region it was well heard, but became greatly diminished in intensity at the posterior axillary line. In front, the pitch of the murmur was highest at the base of the heart, and fell perceptibly towards the left nipple; but in intensity of sound there was little difference between the nipple and the upper part of the sternum. The point of maximum intensity appeared to be the pulmonary valves. The apex beat was in the fifth interspace in the nipple line, and the right border reached nearly a finger's breadth beyond the right margin of the sternum. There was no clubbing of the fingers nor any signs of evanosis, at least while the child was at rest. That evening (May 11th) the

temperature was 101.4°.

On May 12th (the second day of the paralysis), the temperature was 101.6° at 8 a.m., and rose in the evening to 103.8°. The incontinence of urine still continued, and the paralysis and aphasia remained the same. The child was perfectly conscious and intelligent, and tried in vain to speak. Her tongue, when protruded, deviated to the right side; the right arm and leg were perfectly flaccid, and their sensibility was diminished. The muscles responded well to the interrupted current. The temperature fell somewhat on the third day of the paralysis, but remained more elevated than natural, in the evening, for several weeks, with occasional rises. Thus, on one or two occasions it suddenly rose to 102°; and on one occasion to 104°, in the evening, and then quickly became normal. During the child's stay in the hospital there was no sign of embolism of other organs. Her right leg rapidly improved, and she regained the power of walking; but the arm continued powerless, and when discharged on August 14th, the patient was still unable to speak.

In this girl there was doubtless a congenital lesion of the heart, consist-

ing in part of narrowing of the pulmonary artery, and, as a consequence, the right side of the heart had become hypertrophied. It is probable, also, that there was insufficiency of the nitral valve, from endocarditis occurring after birth; and that it was from this source the embolus was derived, which had become arrested in the middle cerebral artery.

In another case, a boy, aged eleven years, who was suffering from stenoais and insufficiency of the mitral ornice, was taken suddenly with paralysis of the right side, combined with difficulty of speech, while recovering from

an attack of small-pox.

It is not always in the arteries of the brain that the embolus is arrested. The fragment may lodge in the kidney, producing albuminum; in the liver, causing enlargement and slight joundice; and in the spleen, leading to perceptible swelling of the organ. In the latter case, according to Dr. Gee, the infurction is peculiarly hable to be associated with fever of the heetic type, without the endocarditis to which it is owing being necessarily ulcerative.

There is one other result of embolism which may be noticed, although its consequences are not so immediately obvious. Aneurismal dilatations in the child are now known, from the researches of Dr. J. W. Ogle and others, to be due to this accident. Aneurisms scated on the small arteries of the brain, leading to fatal hemorrhage, sometimes occur in young subjects, and are doubtless to be attributed to plugging of the vessel by this means. The same condition is also occasionally seen in the larger arteries.

as the external diac.

Besides embolism, other occasional complications may be observed in cases of heart disease. On account of the rheumatic disposition of the majority of such patients, evidences of that constitutional state are often observable. Skin cruptions, especially eczema, orythema, and urticaria, are common; plearisy and pericarditis are not unfrequent lesions; and joint pains are often complained of. Another common complication is some form of pervous derangement. Chorea is liable to occur in the subjects of heart disease; and Dr. Sanson has remarked the occasional association of epilepsy with cardiac mischief. In some cases, impairment of nutrition is the only evidence of ill health. A little boy, aged seven years, was brought to the hospital with signs of mitral stenosis and insufficiency. Still, the boy had no cough, and did not appear to be breathless on exertion. For six months, however, he had been persistently wasting, although, with the exception of occasional abdominal pains, there was no evidence of digestive derangement, or other sufficient cause for the impaired state of his nutrition. In some cases the wasting is combined with anæmia, which may even reach an extreme degree.

The most common form of heart lesion met with in childhood is regurgitation through the mitral orifice. Next in order of frequency is regurgitant combined with constrictive disease. Then follow a combination of constrictive and regurgitant disease of the aortic orifice, and constrictive disease alone. Stenosis of the mitral orifice, unaccompanied by usufficiency of the valve, is not common in the child; and regurgitation through the aortic orifice is far meer than it becomes in after-life years. It will be unnecessary to describe the physical signs and special symptoms connected with these various lesions, since they do not, as a rule, present any peculiarities dependent upon the early age of the patient. With regard, however, to aortic regurgitant disease, it may be remarked that this form of heart lesion, as has been previously stated, is not always accompanied in the child by any striking pallor of the complexion; nor is it often indi-

cated by any marked alteration of the pulse. The pulse is regular weakened by raising the hand above the head; but the cloud hammer like beat of the artery is usually absent. Moreover, the pulse more superficial vessels, although visible if narrowly looks

seldom sufficiently marked to catch the eve unsought.

childhood, the fatal event is often brought about by some inthe complication. Children so afflicted are more weakened than is with a healthy subject, by casual derangements, and have less up which to bear up against a serious disease. When death is due to the heart lesion, it generally occurs in cases where the percent become firmly adherent to the substance of the heart, and has belt interference with the nutrition of the organ. The cavities become dilated, and the feeble walls are no longer equal to the discharge functions. Great congestion of the lungs follows, and there is stasis of blood in the systemic venous system, with its inevitable quences. In most cases of death from cardiac dropsy, the percent

found firmly adherent to the beart.

Sudden death is not very common from cardiac lesion in the chill it takes place it is probably the result of clotting of blood in the li sels of the heart. A little girl was under my care in the East Children's Hospital for chorea, which had followed closely up n of sub-acute rhoumatism. The child was low and depressed, and plexion was markedly anomic. The choreic movements were affecting the face, tongue, and eves, but were only moderate a When she took food into her mouth, the muscles of deglutition vulsively. On examination of the heart there was a loud bellows at the apex, conducted well into the axilla. This explently desome previous attack of rheumatism. During the girl's stay in pital, fibrous nodules were developed on the tip of each spinous p the vertebrie. The child was treated at first with chloral, afterwar quitine and iron. She took three ounces of port wine duit. the treatment, she wasted, and seemed to grow weaker. After a no improvement occurred, the patient was removed by her friends afterwards heard that she died quite suddenly on the following post-mortem examination was obtained.

Sometimes the clotting takes place more slowly. A little boy, from mitral regurgitant disease, with much dilated hypertrophy of ventricle, was noticed for two days to be uneasy and reviews, and duliness of manner. On the third day he was seized with dispose became gradually more severe. The child grew excessively result threw himself about in his bed. When I saw him (at 3 r. u) he will up in bed, supported by the nurse. His eyes were staring and ding, his face much congested, his lips and checks purple, his fablue. The breathing was laborious, and the nares acted. The bitton was excited and forcible, but the pulse at the wrist was extended. The boy was very restless, constantly changing his passible, and made no constantly changing his passible.

Six leeches were applied to the region of the heart. They be but the symptoms continued, the hydrity deepened, and the body few hours. No examination of the body was allowed; but ther little doubt that death was occasioned by ante-marken electing heart or large vessels near their origin.

Diagnosis. - The existence of a valvular lesion of the heart is as

most as readily in the young subject as it is in the adult. Even if a lid cry during the examination of his chest, the heart sounds can usually perceived during the short interval of inspiration. In most cases, however, if the patient be not frightened by abruptness of movement, and if he allowed to play with the stethoscope before the instrument is applied has chest, a young child will submit to the process of auscultation with-

at any complaint.

When a murmur is detected, we have to decide if it be of recent originarcent murmur is soft and of low pitch; but as time goes on it becomes after and its pitch rises. If the lesion affect the calibre of the ordice at the its generated, or interfere with the closure of the valves, it soon had to some enlargement of the heart and alteration in the position of the apex-beat. If, in a child who is suffering from acute or sub-acute hearstram, we detect a harsh, high-pitched, systolic murmur at the apex-beat and conclude that the cardiac lesion dates from a period considerably milener to the existing illness. In noting the position of the apex-beat, not its relation to the nipple, it is important to remember that in many challen the nipple lies at a lower level in the chest than is the case in the stat. Instead of the fourth rib, it is often placed on the upper border of the fifth. In such a subject the normal position of the apex-beat would be the lifth interspace just below the nipple and slightly to its inner side.

In every case of indisposition in the child, however apparently trifling it may seem, the heart should be carefully examined, for, as has been said, individual lesion may be present without giving rise to symptoms of discussion, and evidence of disease is sometimes found very unexpectedly. There are, however, certain combinations of symptoms which should at last exate suspicion. Attacks of palpitation in the child are less commonly than in the adult the consequence of functional derangement or hyperic disorder, and, if present in a marked degree, should suggest tables mischief. Frequent epistaxis in an anamic child is not uncombinate result of mitral disease; and if a child who is not anamic because breathless after exertion, especially if the shortness of breath is against the strongest against the str

The presence of a murmur at the apex is not in itself sufficient evidence of a serious lesson. Heart murmurs in children not uncommonly disappear. The statement is true not only of recent soft murmurs, such as are heard in cases of chores or acute rheumatism, but also of louder and harsher nurmurs which are known to be of longer duration. In all cases where a hash murmur is detected, signs of hypertrophy of the left ventricle should be surched for. If no chlargement be discovered, and the apex-beat romain its normal position, it is highly improbable that any serious valuate defect is present (see page 163). The apex-beat of the heart may, lowerer, be in an abnormal position without the alteration in site being the result of endocardial disease. The causes which lead to displacement of the present to clsewhere (see page 402).

Asin, a basic heart murmur may be produced by causes acting from thout. Pressure upon the large vessels by caseous bronchial glands an so narrow the channel as to give rise to a systolic murmur. In these laws to have continued as well be found, explanatory of the abnormal

Physomenon (see page 181).

The detection of a cardiac murmur will sometimes furnish an explanasom of symptoms which would be otherwise obscure. In all cases where employed occurs suddenly in a child, attention should be at once directed some local symptoms suggestive of the presence of an infarmay be found to be swollen; the liver may be enlarged, will diee; alluminuria may occur from embolism of a kidne may be noticed in the skin from obstruction to the circulate cutaneous capillaries. In all these cases the source of the subscovered on examination of the heart.

Prognosis.—As long as the cardiac lesion gives rise to no prognosis is very favourable. If a nutral nurmur, althoughty and high in pitch, be accompanied by no signs of hypileft ventricle, there is reason to hope that it may ultimately signs of enlargement of the heart are noticed, we cannot avaluate lesion will be recovered from; for a temporary dileft ventricle, such as is apt to occur in chlorotic girls. I decommon in the child; but as long as the health of the pauffer in no way from the disease, little apprehension of in need be entertained. Directly, however, any symptoms cating impairment of nutration or obstruction to the circulature for anxiety. Serious breathlessness, lividity on marked anaemia and perceptible loss of flesh, are all unpromi

The prognosis is more favourable in cases of mitral moof mitral stenesis. If the mitral disease has led to tricust speedy dilatation of the cavities of the heart may be antisigns of dropsy begin to be perceived, the danger is really judicious treatment and careful nursing the end may be

cannot in any case be far distant.

Attacks of rheumatism and chorea, being apt to aggravicesion, are greatly to be dreaded; and all forms of inflaffection, as they increase the work of the heart, are likely to consequences. Embolism is a very serious accident. I lodge in the middle cerebral artery and produce hemiplegition, although it may not destroy life, may lead to perman of movement of the limbs. In the second of my cases of cereferred to above—a boy eleven years old—the patient, two attack of paralysis, had very little use of the right arm, however, and had recovered the power of speech. If the affected, and the embolism occur in other areas, the

games. Measures should be taken to prevent fresh attacks of rheumatism, and the child should wear woollen underclothing all the year round.

Directly pulpitations, breathlessness after exertion, or animia, begin to be noticed, more active measures must be taken. Too energetic action of the heart must be quieted by digitalis. This valuable drug has always seemed to me to be well borne by young patients. The best form in which it can be given is the infusion, of which a child of ten years old will take, without any inconvenience, two drachms three times in the day. On account of the importance in these cases of keeping up a gentle action of the bowels, I usually combine the remedy with a mild aperient and a vegetable bitter. One druchm each of the infusions of digitalis, senna, and calumba, given three times a day before meals, is often followed by great benefit; or, if desired, the proportion of digitalis may be doubled. If the digestion is weak, a few drops of dilute nitric acid may be added to the draught. When any signs of anomia are present, iron should be given in addition. This medicine is best administered separately, and I prefer the exsecuted sulphate in these cases to all other forms of iron Four or five grains of the salt may be given in glycerine directly after each meal.

Great care is necessary in the matter of diet. The child is not to be overloaded with food because he is weakly and seems to be losing flesh, His meals should be small, that his stomach may not be oppressed; and the quantity allowed should be such as his digestion can bear and his tissues really assimilate. If the blood be overcharged with superabundant material which is useless for purposes of natrition, extra work is thrown upon the excretory organs, whose duty it is to eliminate it from the system. It is well to order four small meals in the day, of which one may consist of meat with vegetables, a second of a piece of fish or an egg, and the two others of milk and bread and butter. The quality of the food should be also attended to. All rheumatic subjects have a special tendency to flatulence and acidity; and this tendency is favoured by excess of starchy matters and sweets. It is often remarkable to note the immediate improvement which takes place in the condition of a child who has been pumpered and overfed "because he is delicate," when these simple rules are attended to.

When dilatation of the heart occurs, and leads to stasis of blood in the avstomic verus and general cedema, discretics are indicated. This condition must be treated in the child upon the same principles as are followed in the case of the adult. The kidneys must be stimulated to act by the acetates of potash and ammonia, spirits of nitrous other, juniper, fresh broom tops, squill and digitalis. One especially valuable diurctic in these cases is the tineture of cantharides. I have seen a formidable amount of dropsy clear away completely in a child of nine years old under the influence of ten drops of this remedy given three times a day, after other means had been used without making any impression upon the effusion. I have tried the resin of copaiba, but the drug has proved of little service in my hands. Drs. Leech and Brackenridge speak highly of the value of cafficin. The action of diurctics is greatly aided by dry-cupping the region of the kidneys, and afterwards applying a succession of hot linaced-meal poultices to the loins For aperients, I prefer the compound julap powder to elaterana, which has a very uncertain action on the child. Stimulants are of service, and unsweetened gin may be given in suitable doses as required. If it be necessary to puncture the legs, Dr. Southey's cannulso

should be employed; and Dr. Goodhart's suggestion that these instruments should be steeped in some boiling germicide before being used, in

one of distinct practical value.

When embolism occurs in a cerebral artery, producing hemiplegia, the bisulphite of soda may be given in doses of ten or fifteen grains thrustimes a day. This drug has a marked action in rapidly relieving the phlebitis which is so common in women lately delivered; but my expenence is too small to enable me to speak confidently of its value in the cases above referred to.

Dart 8.

DISEASES OF THE MOUTH AND THROAT.

CHAPTER I.

THE DERANGEMENTS OF TESTHING.

Tay period of active development of the milk teeth is always a time of trial for the young child. Many an infant seems healthy and sturdy up to this point; but when the time of teething arrives his nutrition falters and he begans to fail. On this account mothers, if they do not look upon the eruption of the teeth as a disease in itself, are at least in the habit of attributing every complaint which occurs during the first two years of life to the influence of this normal physiological process. In the medical profession the views held with regard to the influence exercised by teething upon the infant economy were at one time very similar. At the beginning of this century, dental development was looked upon as one of the chief causes of death in the infant. One author classes it amongst the fatal diseases of childhood. Others estimate the mortality from this cause at onetenth, one-sixth, one-third, and even one-half of the whole number of deaths under the age of two years. Even in the present day it is common to find dentition included in the etiology of almost every variety of nervous disorder occurring in the child.

The period of dentition coincides with that of the most active physical progress. Towards the end of the first year of life the follicular apparatus of the intestines is undergoing considerable development; the cerebrospired system is passing through a stage of rapid growth and high functional activity; and most organs and tissues of the body are in a state of active change. The evolution of the teeth is not, therefore, a solitary instance of developmental progress, but corresponds to a similar activity of growth in other parts. No doubt, a period, such as this, of quick transition is a period of exceptional susceptibility. Derangements of function are very liable to occur; but to attribute these exclusively to one of the many physiological processes of which the body is the seat, merely because this process is external and visible to the eye, while the others are internal and cannot be seen, is to generalize hastily, and from very insufficient

There is another reason why, at the time of teething, various forms of

illness are liable to arise. The stomatitis so commonly induced by the advance of a tooth in the gum, is a cause of pyreva. A feveral child a very susceptible to chills, and is liable to be disordered by the irritating influence of unsuitable food. In such a state, also, the digestive powerd the infant is weakened, so that the food on which he has been tarned may cease to agree. Derangements of the stomach and bowels, that zduced, if prolonged as they often are by improper treatment, cause sense interference with nutrition and not uncommonly bring the infant to the grave. To say, however, that in such a case the child dies from to the: is incorrect. He dies from mal-nutrition, brought on by persestate it forcing upon him food which is no food, because he cannot digest it. His diet, instead of supplying him with the nourishment he requires, femores, turns acid, and sets up catarrhal diarrhea; so that at last he sus un worn and exhausted by purging and starvation. The looseness of the howels, which is so apt to occur during the period of teething, carre be attributed with any justice directly to the process of dentition. The fever-ish child is attacked by intestinal catarrh, because his body for the time is more than usually susceptible to the influences which are capable of exciting that derangement; but teething is the cause, not of the purgue is \$\mathbb{E}\$ of the fever. So, also, in the case of pulmonary catarrh, which in some subjects is a common accompaniment of the eruption of each square tooth, it is to the pyrexia, and not to the accidental cause of the protathat the derangement is to be ascribed. In support of this view it may be remarked that diarrhea is a more common conplication of dentition dusing the warmer months, when the weather is liable to sudden and and pected changes, and the temperature varies rapidly while the drawed the child remains the same; and is less common during the winter, who never care is taken to guard the child's body from the cold. Again, the passenary accidents are more common in raw, damp weather, at the tuessus such disorders are especially ant to prevail.

On account of the early age of the infant, and for the reasons which have been given, the first dentition is more hable than the second to be a companied by serious disturbances; but even in cutting the second cut of teeth, digestive troubles are likely to occur, as will be afterwards de-

scrabed.

The first dentition begins under normal conditions in the middle of the first year, and ends toward the beginning of the third. The eruptor of the milk teeth may, however, be anticipated or delayed through in the peculiarity, or some abnormal constitutional state. Thus, case a percent occur in which the child is found to have a tooth when he is born. See teeth are usually sharp and book-shaped, and are often loose, consists merely of the crown of the tooth embedded in a fold of the guin. Heart has described another variety of congenital tooth, which is tirmly hie, 4 the socket. The tooth is destitute of enamel, and looks yellow, will a rough surface. Henoch attributes the cruption to a periosities of the veolar border, which pushes the rudimentary tooth outwards by such and exudation within the socket.

It is not uncommon for teeth to begin to be cut at the third or facts month; but in such cases the cruption of one or two teeth is usual to lowed by a pause, and the continuance of the process is deferred untuing usual age. In certain states of the constitution, dentition is early. The children with tubercular tendencies, or who suffer from a symmetric chexia, cut their teeth early, as a rule. In rickets, on the contract includion is always late, and in exceptional cases no tooth may appear untuits.

end of the second or beginning of the third year. Ordinary malnutrition, when the child has not become rickety, does not interfere with the evolution of the milk teeth. In chronic duarrhea, when the child is very weakly, and much wasted by constant purging, I have often noticed with surprise that the natural evolution of the teeth has been in no way retarded by the

distressing complaint.

In an ordinary case the milk teeth appear in the following order: — Lower central incisors, upper central incisors, upper lateral incisors, lower lateral meisors, first molars, cannes, back molars. Of these the first should appear between the seventh and ninth month. At twelve months old the infant should have cut eight teeth, and the four first molars should be in process of evolution. He should cut his eye-teeth (canines) between the sixteenth and twentieth month; and the whole number of the first crop (twenty) should have pierced the gum soon after the end of the second year. The teeth are usually cut in pairs; and after the completion of each group there is usually a pause before the evolution of the next group begins.

The order given above, although that which most commonly obtains, is yet often departed from in children whose health is perfectly good. Many babies cut their teeth "cross," as it is called. The lateral incisors sometimes appear before the central front teeth; the first molars may precede the lateral incisors; the last molars may precede the canines; and in a few instances I have seen a canine tooth cut before any of the first molars have appeared, but this last exception is a very rare one. Sometimes in rickety children, when dentition is greatly retarded, the first tooth to appear is one of the first molars. Thus, a rickety little boy under my care cut his first tooth—one of the first molars—at the age of two years. Another cut his earliest tooth—also a first molar—at lifteen months.

Although the full number of the milk teeth when dentition is completed is twenty, this number is not always reached. It may happen that certain teeth never appear at all. Thus, a little girl under my care, aged two years and nine months, was seen to have all the milk teeth except the two upper lateral incisors. On the left side there was a narrow space remaining between the left middle incisor and the capine; but in this space the gum was sharp, and there was no sign of a tooth. On the right side, the right central incisor and the adjoining canine were in contact. In the same way I have known the whole four cannes to be absent. In some cases the peculiarity is a hereditary one. In a case which came under my notice the left lower lateral incisor was wanting in a little girl of two years The same incompleteness of the milk teeth had occurred in the mother. This lady had three other children -all boys-whose early dentition had presented no deviation from the normal type. It is certainly currous that the irregularity which had occurred in the mother should have been reproduced in the only one of her children whose sex was the same as her own. It is important to be aware that incompleteness of the first crop of teeth does not necessarily imply that a similar irregularity will be met with in the second. Mr. Tomes, in his work on dental surgery, refers to the case of a little girl who cut none of her milk teeth, but in whom the permanent set appeared as usual. Sometimes, instead of too few, too many milk teeth are developed. A little girl between two and three years old lately came under my notice who had five perfect incisors in the lower jaw.

The process of dentition is much easier in some children than it is in others; but it is difficult to assign a reason for these differences. The fa-

cility with which the teeth appear seems to be dependent more upon individual peculiarity than upon actual bodily health. Teeth cut early are not always cut easily; and delayed dentition is not always, nor even usually, troublesome. A perfectly healthy child may cut his teeth with much suffering, although fully up to time; while a rickety child, although very late in teething, may suffer no inconvenience at all in the process.

Symptoms. - The symptoms which accompany the eruption of the milk teeth are very variable. Sometimes no signs at all are noticed, and nothing is known of the matter until accident discovers the presence of a tooth through the gum. Usually, however, the infant is restless and irritable, he flushes and is feverish. A copious secretion of saliva occurs, and the child "dribbles," the fluid flowing from his hips over his chin. At night he is disturbed in his sleep, and in the daytime may be noticed suddenly to give a little cry, or contract his features as if in pain. He also makes "munching" movements with his jaws, sucks his lips, and gives every indication of uneasiness in his gums. Most writers on this subject, following Hippocrates, describe a painful itching sensation of the gum, which is said to be present in these cases, and whether or not the sensation is correctly described as an itching, there is no doubt that it causes distress, and appears to be relieved by gentle frictions with the finger or any other smooth object. On examining the month, the gum is found to be swollen and cushiony, and sometimes, shortly before the tooth appears, is very tense and hot. At this time, friction, which before was pleasant, becomes very painful. The gum is evidently tender, and the child may be sometimes seen to hold his month half open, as if he feared to close his jawa. All the symptoms subside when the tooth merces the gum.

The pyrexia of teething is very irregular. It is often higher in the morning than at night, and is liable to rapid variations. Thus, a little boy, aged fifteen months, had eight teeth, and was cutting his left lower molar. At 6 a.m. his temperature (in the rectum) was 99. At 10 and it had risen to 103.8°; and at 10 a.m. was 102.2. It gradually fell during the night (being taken every four hours), and at 10 a.m. on the following morning was 100°. It then rose again to 102° at 6 p.m.; fell to 98° at 3 a.m. (third day), and at 10 a.m. stood once more at 103.8°. A good dose of caster oil was then given, and the temperature at once became normal.

In a teething infant the mercury often registers 101 at 8 or 9 a.m.; indeed, in a young patient such an amount of fever in the morning is alone a circumstance of great suspicion, and should at once lead us to examine the state of the gums. Few diseases, at this early age, cause so much pyrexis at this period of the day.

The symptoms which have been enumerated do not necessarily herald the immediate appearance of the tooth, but will be often found to come and go—waxing and waning in severity, and sometimes subsiding altogether, so that the infant passes through alternate periods of suffering and ease for some days, or even weeks, before the tooth comes through the gum. Usually, more distress is experienced during the eruption of the cannue teeth than at any other period of dentition.

Complications.—The symptoms just described may be looked upon as natural to the process of teething. In many cases, other symptoms are noticed, expressive of derangements which do not follow naturally from the evolution of the teeth. They arise as accidental troubles, and must be attributed to the ordinary causes of ill health acting upon a body in a state of irritation and fever, and therefore pecuharly susceptible to their unfluences. These are stomatitis and aphtha; repeated vointing or distributes.

more or less prolonged, from catarrh of the stomach or bowels; cough true pulmonary catarrh; citits; various forms of skin disease, and cortan troubles of the pervous system, such as squinting, convulsions, etc.

The stomatics is of the simple form, as a rule, and consists of an erythematous redness of the mucous membrane of the gums over a considerable rea. The affected gums are somewhat swollen, and are not and tender to the touch. If the tenderness is great, the child may refuse to suck the bottle or its mother's breast. High fever always accompanies this complicates. The ulcerative form of stomatitis is also sometimes present, and

has the characters described in the following chapter.

Attacks of complany and durrhora, from acute gastric and intestinal calarrh, are common in teething children. For the reasons which have best stated, infants, whether teething or not, are at all times liable to ready Lambance of indigestion; indeed, at this age, digestive troubles form a large proportion of their ailments. Therefore, vomiting is especially apt to cour when the stomach is irritable and weak from pyrexia, unless the dads diet be promptly modified to suit the altered state of his digestive egas. In the same way, whether from the irritation of undigested food, or the sensitiveness of the heated body to even trilling variations of the esternal temperature, purging of a mild character is a very common sympba. If the teeth are cut in rapid succession, a looseness of the bowels my prevail to a greater or less degree during the whole period of denti-Len If this looseness remains confined within moderate bounds, it may less apparent harm to the patient; but it should not on that account be well to continue, for at any time a severe attack of inflammatory diarmay supervene, with not improbably fatal consequences. This serious wo but is especially liable to occur in hand-fed babies, who, while they are suffering from intestinal irritation, are naturally more than commonly sensitive to the disturbing influence of undigested food. The ordinary durings of teetling consists of green or yellow matter, with small lumps of oad. It is often passed with straining, and its passage is preceded by string pains.

heases of chronic diarrhosa, the influence of teething is often distinctly produced. The irritation of the gum set up by the advancing tooth solds to maintain an irritable state of the bowels, so that, although the actual purging may be readily kept under control, an intolerance of milk and the termentable articles of food continues to prevail, and is very difficult to become. Often in such cases, in spite of the most careful dicting, attacks of looseness are frequent; the child remains weak and low, and seems to make no progress towards recovery. When, however, the tooth appears, in pruse occurs in the process of dentition, immediate improvement is about it the motions become healthy, and flesh and strength begin to re-

HELL

Pulmmary catarrh, with a hard cough, is a common complication of feeting; and the high fever by which these attacks are accompanied may cate great anxiety, as it gives a false appearance of gravity to what is really a truling miment. The child coughs a more or less hard cough, which may even have a "croupy" sound; his nares dilate in inspiration, and the breathing is hurried. His mouth is hot and dry, and dribbling, if it had been previously noticed, ceases when the fever begins. The child is very irritable and restless; his tongue is furred, and his bowels are confined. The catarrh is usually relieved by appropriate remedies; but if care he not taken, and the child be exposed to cold or draught, a really severe bronchitis or broncho-pneumonia may be induced.

Otilis is a not uncommon accident at this period. Dr Wosker has a plained the mechanism by which inflammation of the middle car is produced. Irritation is conveyed from the inflamed gum to the ote gar, and is then deflected to the vessel supplying the tympanic membrane to a consequence, this membrane becomes acutely congested, giving me to severe pain; and if the irritation persist, it may lead to inflammation as suppuration within the tympanic cavity. The membrane soon became perforated, and a purulent discharge issues from the external and in meature (see otitis).

The forms of skin disease which are liable to arise in teething may are the crythematous rashes and eczematous cruptions. The forms of usually transient, and readily subside; but the latter may spread over a greater part of the body, putting the child to the greatest distress for

constant itching, and obstinately resisting treatment.

Of the nervous disorders which are apt to occur at this period it is an difficult to say how far they are due to the actual process of teethar a sw what degree the rapid development of the cerebro-spinal system is answer able for these accidents. In some impressionable infants a very tesswollen gum may. I believe, like any other variety of irritation in an put of the body, be sufficient to induce an eclamptic attack. In many cases the convulsion is probably to be ascribed to otitis, set up by the state I the Trousseau has suggested that a high degree of fever may by h. 3 self a sufficient cause for the nervous trouble; but I have never met well a case of convulsions in the child which I could attribute to this cause alice for the initial convulsion, which is so common at the beginning of was acute diseases in early life, is probably owing to other causes than the elevation of temperature. It is easy to understand that an excitable after whose whole nervous system is in a state of disquiet from pain, distances: aleep, and continued deutal irritation, may have convulsions induced to very slight additional stimulus. In such a child a lump of miles a food, or a sevbalous nodule in the bowels, may increase the irritation 6 as irresistible degree, and it is probable that some such secondary cause the has a share in the production of the eclamptic seizure.

In the second dentition, the order in which the teeth appear is a regular than in the case of the first. The eruption of the permanent test begins between the ages of five and a half and seven years with the pearance of a permanent molar behind the last of the temporary test Next come the central incisors about the eighth year; the lateral is an at about the muth; the first and second bicuspids in the place of temporary molars at the tenth and eleventh; the cannot between twelfth and thirteenth, and the second molars at about the tradition to the above sequence that I have noticed is that in rare construction of the central incisors precedes the appearance of the cartain and

In certain exceptional cases the milk teeth have been known to be tained into adult life. Some years ago Mr. Napier showed at a metal of the Royal Medical and Chirurgical Society the cast of the month of a polar lady of twenty-five in whom the milk teeth were still retained, with the completion of the upper central incisors. The same abnormality had securing the case of the lady's sister, and it had been also noticed in one of the mother's relatives.

The beginning of the second dentition in delicate children is descompanied by signs of gastric or intestinal irritation. The child were sensitive to changes of temperature, and is subject to attacks of the

ness of the bowels. He is often irritable and restless; looks pale, with dark circles round his eyea, and alceps badly at night. His stools often contain mucus in large quantities. Such children are very liable to the so-called "night terrors," which in all cases, so far as my experience has extended, are merely attacks of nightmare, the consequence of indigestion and acidity, and can be at once arrested by diet and suitable treatment. If, however, care be not taken to modify the child's diet to suit the degree of digestive weakness, the derangement continues and the patient begins to lose flesh; indeed, in some cases a great degree of emaciation is reached.

Draggosis.—The clinical importance of the first dentition consists in the frequency with which the process is found to complicate all the various derangements and diseases to which infancy is liable. The pyrexia induced by teething often infuses an element of obscurity into a case which would otherwise present little difficulty. In infants we must be always prepared for this source of confusion, and should never forget to ascertain

the state of the gums before bringing our examination to a close.

In the case of pulmonary cutarrh attacking a teething child, the combination of fever with cough, rapid breathing and active nares, suggests the presence of pneumonia. It will, however, be noticed that the child does not look ill; his cough is looser and less hacking than the cough of pneumonia; his pulse-respiration ratio is not perverted, and the history is not that of inflammation of the lung. In searching further for a cause for the pyrexia, the gums will be noticed to be tense and swollen, and the source of the fever is immediately explained. We must not, however, in all cases where the gums are hot and uneasy, at once conclude that they are the sole cause of the symptoms noticed. It sometimes happens that serious cerebral disease occurs in a teething child; and if, mistaking their nature, we attribute the nervous symptoms to dental irritation, we make a mustake which the friends of the patient are not likely readily to forget. Therefore, nervous symptoms occurring in the course of teething must in overy case receive careful attention. Hendache, mild delirium, vertigo, startings, twitches, and convulsive attacks are so commonly the consequence of general nervous disturbance from any cause, that they have lost all claim to be considered special manifestations of cerebral disesse. If, however, the bowels become obstinately confined, the pulse slow and irregular, the breathing unequal and sighing; and if, in addition to these suspicious symptoms, we notice that the child frequently frowns and avoids the light; that he is sullen and drowsy, lies with his eyes half closed, and screams out suddenly as if in pain, we have every reason to fear the occurrence of tubercular meningitis. In all doubtful cases the effect of a mild aperient should be tried. Castor oil brings rapid relief in most of the disturbances of a teething child. Therefore, if the nervous symptoms disappear after the operation of this simple remedy, their purely functional origin is at once apparent.

In the case of diarrhosa from intestinal catarrh occurring in a tecthing child, there is not the same source of fallacy as in the other complications, for in ordinary cases looseness of the bowels at once causes pyrexia to

subside.

Irratment.—The derangements which occur during dentition must be treated upon ordinary principles, and the reader is referred to the various chapters devoted to these derangements for information upon this subject. It may, however, be remarked that it is especially important in a teething child to keep the belly warm, and to avoid all sources of chill. Also, that

it is essential, in all cases where signs of gastric or intestinal disturbant are noticed, to reduce at once the quantity of fermentable food ware > being taken, as fermentation and acidity are the earliest consequenced the catarrhal derangement. In cases of diarrhos there should be no testation about arresting the looseness as quickly as possible. A doccastor oil should be given; and if the purging do not cease after the atm of the aperient, it will yield readily to bismuth (gr. v.-x.) with around chalk powder (gr. v.), or to one-grain doses of oxide of zinc. If few i high, or the gum seems to be especially painful, great relief will follow aperient dose of castor oil. This at once reduces the pyrexia and cannot tension and uneasiness of the gum. The irritation of the swoller and > flamed gum may be reduced almost immediately by rubbing the affirm part with the finger, moistened with fresh lemon-juice Some smartness at first excited by the application, and the child's waitings are mercan but after a few minutes the smarting subsides, and with it disappears to of the discomfort previously experienced. This practice is commonly am told, amongst the native nurses in the Cape Colony.

The practice of lancing the gum, which at one time was looked upon a sovereign remedy for all the disorders incident to the period of teether, has now but few supporters. The only condition for which I should inclined to have recourse to it is that in which convulsive attacks over a child whose gums are very tense, swollen, and temler. In such a where it is our object to remove all sources of irritation, the gums and temler by hastening the evolution of the tooth below, is, of course, putting the state of the convergence of the course, putting the state of the convergence of t

to very unnecessary pain.

If, during the second dentition, signs of digestive disturbance are noted and the child looks pale and begins to waste, and especially if the yapper called "night terrors" are noticed, the bowels should be acted upon by mild aperient every three or four days; the diet should be regulated a stricting the quantity of farmaceous food and sweets (especially fort, timpotatoes, puddings, cakes, and fruit), and the child may take an arrest grains of bicarbonate of soda two hours after each meal. I have never a case of "night terrors" which has resisted this treatment.

CHAPTER II.

STOMATITIS.

INFANTS and young children are very liable to derangement of the mucous membrane hinng the interior of the mouth. Partly on account of the irritation of the gums resulting from dentition, partly on account of the ready sympathy which exists between the membrane lining the buccal cavity and that of the digestive apparatus with which it is continuous, an inflammatory condition of the mouth is a common disorder. In a healthy child the lesion produces little more than passing discomfort, and readily subsides. In a cachectic or weakly subject the derangement may be more serious, and in some cases the inflammation passes into severe ulceration or even gauginers.

The simple form of stomatitis, which is often a complication of teething, has already been described. In the present chapter two other varieties of disease resulting from inflammation of the mucous membrane will be considered, viz., aphthous or followlar stomatius, and ulcerative stomatius. The following chapter will be devoted to a serious and often futal

discuse -gangrene of the mouth, or cancrum oris.

APHTHOUS STOMATITIS.

The derangement called aphthous stomatitis (follicular stomatitis or aphtha) is a common source of inconvenience to young children. It is induced almost invariably by derangement of the stomach, and is often seen during the progress of the first dentition -a time at which so many forms of gastric and intestinal disorder are apit to arise. Actual irritation of the mucous membrane of the mouth may also give rise to aphtha; for children who are over indulged with sweets often suffer from this com-

plaint, even if the digestion is unimpaired.

Symptoms.—Aphthic consists of a vesicular cruption of the mucous membrane of the mouth. Pearly gray or yellowish vesicles appear, varying in size from a pin's head to a millet-seed. They are circular or oval in shape, and their base is surrounded by a red areola. After two or three days the vesicle ruptures and a round ulcer remains. The base of the ulcer is grayish in colour, from the presence of a schaceous secretion; the edges are thickened, and there is reduess of the mucous membrane surrounding the sore. Under appropriate treatment the ulcer soon heals, and the complaint is at an end. The number of the aphthic varies from two or three to fifteen or twenty, or even more. They may occupy any part of the mucous membrane, but usually appear first on the inner side of the lower hp and guins; afterwards on the tip and edges of the tongue, the cheeks, and on the palate.

Aphtha are sometimes accompanied by a considerable rise of the temperature, and the thermometer may mark 103' or 104'; but fever is not

an invariable rule. The tongue is very sore, and the child, if an infant, sucks with great difficulty, or may even altogether refuse the bottle or the breast. He is previal and thirsty; often vomits; has a sour small from the breath, and shows all the signs of disordered stomach. Often the bowels are relaxed.

If the sores are so numerous as to be almost confluent, the child's condition may cause some anxiety. He refuses all nourishment on account of the smarting excited by the movements of the tongue in the act of smallowing. His breath is offensive; salivation is profuse; the fontanelle becomes deeply depressed, and the sub-maxillary glands are sometimes enlarged. This severe form is seldom seen except in weakly babies, and may come on at the end of an attack of diarrhea. In these cases the unfavourable termination of the illness may be hastened by the impediment thus created to the taking of nourishment. In weakly or cachectic children the complaint is sometimes obstinate; for although the course of each individual ulcer may not be unusually prolonged, fresh vesicles continually appear as long as the digestive derangement to which they owe their origin remains unrelieved. Again, in rare cases, the ulcers are slow to heal, and may give some trouble before they are cured.

Daynosts.—Aphthæ are not difficult to recognise. In the vesicular stage the nature of the decangement can scarcely be mistaken; and when the ulcers have formed, their circular shape, uniform size, and the limitation of the inflammation to the immediate neighbourhood of the sore, will prevent the disorder being mistaken for the more scrious lesion—ulcem-

tive stomatitis.

Prognosis. The derangement is of little consequence, as a rule. Even in the each ctic child, in whom the distribution of the sores is more extended, and their course more obstinate, than in the healthy subject, any darger which may be present is due more to the accompanying general condition than to the local complaint. In a healthy subject, the derangement, under

judicious trentment, will readily subside.

Treatment.—In ordinary cases of aphths all that is required is a dese of thubarb and soda, with a grain of gray powder to clear away unhealthy secretion from the bowels, and attention to the cleanliness of the mouth. After each meal the mouth should be washed out with a piece of linearing, or a large soft brush, soaked in topid water. Afterwards, giverine and borax (half a drachm to the ounce) may be applied with a soft came is hair pencil. If an ulcer is slow to heal, it may be touched gently with a solution of nitrate of silver (ten grains to the ounce of water).

In the more obstinate cases, attention must be paul to the general condition of the patient, and any chronic derangement of the alimentary canal must be remedied. In a cacheetic child, the use of an alcoholic stimulant in sufficient doses will often cause a speedy improvement in the state of

the mouth.

ULCERATIVE STOMATITIS.

While follicular stomatitis is more common during the first eighteen months or two years of life, the ulcerative form of stomatitis is most frequently seen after the age of two years, when the first dentition has been completed. The disease is a common one in hospital out-patient rooms and appears to be predisposed to by insanitary surroundings, a poor distary, a weakly constitution, or a cachectic state. On this account it may be seen in children who are overfed during convalescence from an acute ill ness, and is an occasional consequence of a gastro-intestinal disorder. It

said, also, sometimes to be epidemic. Its immediate cause is often unleadness of the mouth, allowing of the accumulation of tartar on the such, and sometimes it is set up by the irritation of a decayed tooth. In fici-ty children, and those whose teeth decay rapidly and whose general paintion is unsatisfactory, alceration of the gums is not an uncommon succe of discomfort. The influence of feebleness of health, and an inafficient distancy, in producing the derangement, is so marked as to som to justify Dr. Cheadle's suggestion that many cases of alcerative to matter occurring in ill-nourished children may be due to undeveloped

L addition to the causes which have been mentioned, ulcerative stomatives may be one of the consequences of a special constitutional disease. Thus, it is sometimes present in cases of lymphadenoma, being then due to the development of the lymphoid growth in the sub-nucous tissue.

Symptoms.—The ulceration begins in the gums, and is often confined to The guins at the affected part become red, swollen, and spongy-bing, either generally or in patches. Their edges, especially where they as up between the teeth, are soft, red, and unusually prominent, and they belvery easily. The colour then grows deeper and more purple, and often at the borders of the gum the tooth is of a greenish-yellow colour. here is some prin in mastication; salivation is copious, and an offensive of ur is noticed from the mouth. Soon a soft, pultaceous, gravish-yellow a ster forms upon the inflamed mucous membrane. This appears to arise imm gangrenous softening of its most superficial layer, and adheres very waly to the tissue beneath it. If detached, an ulcerated surface is disamost irregular in shape, grayish in colour, and bounded by a well-defined logit red line. If treatment is not promptly resorted to, the disease usuby spreads from the gums to the tongue, the cheeks, and the lips. On the longue the lesson is usually limited to the part of the organ in contact with th affected gum; and, indeed, in the majority of cases, the ulceration is cantred to one as le of the mouth, and both cheeks are rarely affected at be same time. The shape of the ulcerated surface varies according to its est. On the lips it is more or less circular; on the gums it is clongated, and on the interior of the cheek, from conjunction of several neighbouring thera it is irregular or sinuous.

As a consequence of the ulceration of the gums, the corresponding teeth often become loose, and sometimes fall out. Chewing is very painful, and the child is unwilling, by movement of his jaws, to increase his discomfort. It is the motions necessary for swallowing the copious saliva seem to be purful, for a young child allows it to flow away from his half-open mouth, like the breath, the salivary secretion is horribly offensive, and is often straked or more or less discoloured with blood. If there is disorder of the stomach, the effort of retching may cause a more copious hemorrhage from the inflamed and alcerated surfaces; and the blood, mixing with the wanted matters during their passage through the mouth, may appear to

been with them from the stomach.

When the cheek becomes affected there is some swelling, but this is molerate, and no induration can be detected. The sub-maxillary glands are swellen and sometimes painful. The general health of the child suffers much less than might be expected. During the first few days the temperature may rise to 102°, or even higher; but the pyrexia quickly missles, and the nutrition of the patient appears to undergo little change that the particular of the complaint is very variable. If proper measures are taken, the ulceration is soon at an end; but if left

untreated, the lesion may persist for months, and is said sometimes to puss into emerum oris,

Programs.—The general redness of the mucous membrane; the pultaceous matter adherent to its surface; the peculiar factor of the breath these symptoms, together with the large size, the irregular shape, and the want of uniformity of the ulcers, will serve to distinguish this complaint from the preceding. From cancrum oris it is distinguished by its slower course, its want of induration, and the absence of black slough. The exudation cannot be confounded with the leathery, false membrane peculiar to the diphtheritic inflammation, moreover, the latter disease is not usually accompanied by ulceration of the mucous membrane.

Proguests.—Ulcerative stomatitis is rather inconvenient than dangerous. However severe the affection may appear when first seen, it is tractable enough when judicious measures are adopted; and the worst results that can follow are loss of teeth, with perhaps a superficial necrosis of an alterdar process.

Treatment.—In every case of ulcerative stomatitis our first care should be to rectify any deficiencies in the sanitary surroundings of the patient, or to remove him at once to a more healthy locality. Fresh air should be especially insisted upon, and the child should pass a large part of his time out of doors. His thet should be rearranged, giving meat, eggs, and milk in suitable quantities, especially avoiding sweets and an undesirable excess of farmaceous fook. Alcohol is of great value. The child may take port wine, diluted with an equal quantity of water, with his dinner, or two or three teaspoonfuls of the brandy-and-egg mixture several times in the day.

In addition to the above measures, no time should be lost in prescribing chlorate of potash. This remedy has an almost specific action upon this form of ulceration. The solution, however, must not be too weak. Three grains, dissolved in a teaspoonful of water, may be given every four hours to a child of two years old. For an older child, the dose may be increase i to five or six grains. In some cases, larger quantities are found to be necessary, and may be given to quite young children without apprehension. A case which has resisted the remedy when given in five-grain doses, may vield to it promptly when the dose is raised to fifteen. Of local applications, the best is tepid water. Cleanliness is of great importance, and after each meal the child, if old enough, should be directed to wash his mouth with warm water, so as to prevent food from collecting about the inflamed surface. In the case of younger children, the mouth should be swabbed out with a piece of soft linen rag dipped in warm water, as directed for aphthe. Other applications which may be used are powdered alum, or a powder of chloride of lime. These should be applied dry to the ulcerated surface with the finger, and are especially useful when the ulcars are indolent and slow to heal. Underwood speaks highly of the decoction of cinchons, made sharp with dilute sulphuric seid, as an application to the sores. Local treatment, however, with the exception of careful cleansing of the mouth, is seldom required. Few cases will be found to resist the chlorate of potash treatment, especially if this be combined with plenty of fresh air, and the employment of an invigorating diet with a sufficient quantity of alcoholic stimulant. No local treatment can be expected to succeed if these measures are neglected.

CHAPTER III.

GANGRENOUS STOMATITIS.

GANGRENOUS stomatitis (canerum oris, or noma) is fortunately much less common than the other inflammatory affections of the mouth and cheeks. The disease is a very serious one, and in the large majority of cases proves fatal to the child. Even when recovery happily occurs, the destruction of tissue, if at all extensive, leads to very unsightly contraction of the side of the face.

Consulion.—Cancrum oris is seldom seen, except in hospital practice, or amongst the poor. It appears to be one of the consequences of a weakly habit of body, and is most probably predisposed to by insanitary conditions and insufficient food. The cases which have come under my notice have been in children at the East end of London, hving in miserable, squalid dwellings, and very poorly clothed and fed. Sometimes the gangarene arises as a sequel of a specific fever or serious inflammatory disease. Thus, it has been known to follow measles, typhoid fever, scarlating, and small-pox. It may appear in scrofulous and tubercular subjects, or in children who have been exhausted by a prolonged attack of bronchopneumonia, or entarrhal derangement of the bowels. It is doubtful whether the injudicious and prolonged use of mercury can set up the disease. That it can do so, although stated positively, has been denied with much reason. In any case, it is important not to mistake the early symptoms of the disease for those of mercurial poisoning.

Ulcerative stomatitis is said, in rare cases, to end in cancrum oris. The two diseases appear to be induced by very similar conditions. A little girl, aged five years, died in the East London Children's Hospital from extensive gangrene of the right side of the face. A few days afterward, her brother, aged seven years, was admitted with severe ulcerative stomatitis, inside the left check. The parents of these children were very poor, and the patients themselves had been half-starved and very insufficiently clad. Neither had lately suffered from any acute disease. Cancrum oris is rarely seen after the sixth year, and girls are said to be more subject to it than

boys.

Morlad Anatomy.—On post-mortem examination of cases of gangrenous stomatitis, the affected part of the check or lip is found to be swollen, tense, and hard to the touch. It presents, at its most prominent part, a dry, black, well-defined slough. This varies in size and shape, according to the extent to which the mortification of the tissues has spread. It may dip more or less deeply into the substance of the check, and always involves both surfaces. The tissues in the neighbourhood of the slough are thickened, infiltrated, and hardened. Often the dry, black eschar occupies the surface of the check; beneath it, the tissues are swollen and indurated,

in the interior of the mouth, at the affected part, the mucous memis seen to be occupied by a greyish ulcerated surface, or a moist,

loose slough, which can be readily scraped away with the handle of the

scalpel.

The gums at the seat of disease are often sloughy and soft; the teeth

are loosened, and the alveelar processes blackened and necrosed. Some-times the lymphatic glands in the neighbourhood are enlarged.

According to Rilliet and Barthez, the smaller blood-vessels of the diseased cheek are obliterated by coagulæ where they pass through the murtified tissues. In parts merely infiltrated and swellen they are still permeable, although their walls are thickened. Batta Segale states that he has discovered micrococci and bacilli in the detritus obtained from the gangronous lesson, but it is not clear that the nome was dependent upon the presence of these organisms.

Other organs may be the seat of disease. Broncho-pneumonia is very common, and pyremic abscesses have been found in the lungs. Sometimes gangrene of other parts has been seen, especially of the lungs and the

vulva or scrotum.

Symptoms.—In some cases pain in one side of the face is the first symptom complained of. The child looks pale and ill; the face begins to swell, and at the same time, or soon after, examination of the cheek detects a firm spot, around which the tissues are soft and cedematous. At this stage, inspection of the interior of the mouth will discover a small greyish ulcer of the mucous membrane, corresponding to the hardened spot felt in the substance of the cheek. The breath has a gangrenous odour, and a dark bloody saliva escapes from the mouth. There is little or no fever; the pulse is small and frequent, and the child is unwilling to take solid food, probably from the pain excited by mastication. Soon the affected cheek becomes tense and shining, the swelling increases, and a small red spot forms on the surface. At the same time a brown slough

developes on the mucous membrane.

The ulcer is not always seated on the cheek. It may occupy the gum. or be placed at the junction of the gum with the cheek. Wherever it first appears, it soon spreads, and may involve the gum, the check, the lip, and perhaps the whole side of the mouth. When the internal slough separates, which it may do on the third or fourth day, it leaves a ragged older At the same time, in severe cases, the red spot noted on the outer surface of the cheek becomes deeper in colour, and rapidly changes into a dry, black slough. Sometimes the internal and external sloughs are separated by infiltrated and a dematous tissue; but often the two sloughs come into centact, so as to involve the whole depth of the cheek. In this case, when the slough separates, a ragged opening is left, of variable size. In the interior of the mouth the guins are more or less extensively destroyed; the corresponding teeth get loose, and often fall out, and the maxillary bone may become necrosed. The separation of the slough is often unattended by hæmorrhage, but sometimes copious bleeding takes place. The five, on the affected side, where it has not been invaded by the gangrenous process, is swollen and cedematous, and the infiltrated eyelids can no longer be onened.

At this stage the general condition of the child varies. If he have not been exhausted by previous acute illness, although weak, he is not prostrated, and may be able to sit up in bed without assistance. In most cases, however, he is excessively feeble and helpless; there may be great drowsiness; the pulse is scarcely perceptible; diarrhea may come on, and general ordema may occur. Sometimes the appetite persists, and the claid takes liquid food with avidity; but, usually, towards the end he refuses food, and even drink. If broncho-pneumonia supervene, as often happens, the temperature, which had been normal, or even below the natural level,

rises, and the respiration becomes hurried and laborious

In fatal cases the duration of the illness varies according to the rapidity with which the gangrenous process spreads, and to the condition of the child at the time when the disease begins. In very rapid cases the child may die in five or six days. Usually, death takes place between the tenth and fourteenth day. If the child be in an enfeebled or cachectic state at the time when the first symptoms are noticed, the gangrene usually spreads rapidly, and the end may be reached before the slough has had time to separate. If broncho-pneumonia arise, or a profuse diarrhea be set up, or septicamia be induced, or gangrene appear in another part of the body, the illness may end in death rather abruptly.

If recovery take place, it is usually in cases where the gangrene rapidly limits itself, and does not spread through the entire substance of the check. The slough is then thrown off, and a reparative process is set up, which ends in more or less puckering of the affected side of the face. The fall of the slough is, however, not always followed by repair. In some cases the gangrene continues at the borders of the wound, and the morbid process

goes on unchecked.

Diagnosis.—Cancrum oris in its mildest form is distinguished from a bad case of olcerative stomatitis by its rapid progress, the induration of the cheek at the base of the olcer, and the infiltration of the tissues around. Magnant pustule presents symptoms somewhat similar to those of cancrum oris, but differs from it by always beginning on the external surface and extending inwards to the mucous membrane. In gangrenous stomatitis, the inucous membrane is the first part to be affected.

Promoss. -The disease is fatal in the large majority of cases. If it lead to perforation of the cheek, especially if the gangrene be widely spread, death is almost certain. I have known one case recover after perforation of the cheek; but in this instance, the gangrenous process, although it penetrated deeply into the cheek, had no great lateral extension. When recovery took place, a deep puckered cicatrix was left in the cheek at the site

of the discuse.

If a complication arise, such as broncho-pneumonia or diarrhea, the child's small chance of recovery is still further reduced. As long as he continues to take nourishment well, and to digest it, we may retain some hope of recovery. If he begin to refuse his food, or even to receive it with in-

difference, the sign is a bad one.

Treatment — As in all diseases which result from debility and malnutrition, measures should be at once adopted to improve the general health, and provide the child with suitable nourishment according to his age and digestive capabilities. Pounded meat, strong beef-tea, eggs, and milk, should be given in small quantities at frequent intervals, taking care that the stomach is not overloaded, and that the powers of digestion are not overtaxed. Stimulants are of great value. Port wine, or the brandy-and-egg mixture, should be given several times a day with food. In this disease, a child bears stimulants well. Half an ounce of port wine, or two terspoonfuls of the egg flip, can be given every two, three, or four hours, to a child of five or six years of age. The bowels must be attended to, and if much milk is being taken, a terspoonful of compound liquorice powder should be administered every other night. Fresh air is also of great importance, and the window of the room should be kept open night and day. On account of the factor of the breath, which causes a most offensive odour in the neighbourhood

of the patient, the room must be frequently sprayed with a solution of ar-

bolic seid (one part in thirty of water).

For local treatment, our first care should be to destroy the diseased surface in the interior of the mouth with a powerful caustic. Strong action acid is usually employed for this purpose. The acid should be applied one and effectually. The operation must be performed with care, so as as a touch the teeth, or any part which is not the actual seat of disease, at immediately after the application the mouth should be well syrand on a solution of carbonate of sods or chloride of lime. Besides name sot strong hydrochloric acid, the acid nitrate of mercury, intrate of siver al the strong solution of perchloride of iron have been used, and all he their advocates. Dr. J. Lewis Smith speaks highly of a combination of stphate of copper (2 ii.) with puly cinchone (2 ss.), in four curies of size. This application, which was originally recommended by Maunsell and Frason, is milder than the others; but applied carefully twice in the day to said to have remarkable efficacy. If a stronger caustic is employed a seoud application should not be made within twenty-four hours of the tot indeed, the operation should only be repeated if the further spread of to gangrene is unmistakable. The fector of the breath must be corrected frequent syringing with a disinfecting agent. A solution of chi mate soda (liq. soda chlorinata 3 j., aque 3 j.) is perhaps the most use one part of carbolic acid to ten parts of water, as recommended by Law raque, may be employed for the same purpose

The internal administration of quinine and iron seems to be let do in these cases, given in full doses. A child of three or four years of take well two grains of quinine and twenty drops of perchibinde of the with glycerine and water, every six hours. After separation of the should any sign of repair should be encouraged by stimulating applicators. I weak solution of sulphate of zine (gr. iij. to the oz.), or any ordinary loss.

for granulating wounds, may be used for this purpose.

CRAPTER IV.

THRUSH.

Transa is a parasitic disorder, and is due to a fungus which attaches its if to the mucous membrane of the mouth and gullet. The complaint is of importance, not so much in itself, for when it appears in a healthy child the vegetation is readily dispersed, as on account of the debility and serious intestinal and other derangements by which it is often accompanied. Strictly speaking, thrush is a symptom rather than a disease, and often indicates a condition of the system which should give ruse to most serious

approbension.

Crosston. - Thrush is a cryptogamic growth which finds its nidus in aftered secretion from the mucous membrane. It is most common in infants during the first few weeks or months of life, and any derangement which involves the mucous lining of the mouth may fend to its production. In such subjects, the vegetation is the expression of a local state, and this local state may itself be the consequence of a cachectic condition or constitutional disease. The development of the fungus is favoured by heat of weather, want of cleanliness, and indigestible food. It is consequently very common during the summer months amongst hand-fed infants, especially amongst those who are supplied with a highly fermentable diet, and are allowed to suck their food from dirty bottles. In such cases, the passage through the mouth of sour fluid, and the derangement of the stomach which results from fermentation and acility, maintain a state of constant oral catarrh which forms a congenial medium for the development of the parasite. In a severe form the complaint is never seen except in imperfectly nourished infants, whose food is ill-selected, and whose general management leaves much to be desired. Imperfect ventilation, and general insuntary surroun lings, are no doubt agencies which further the invasion of the fungus and assist its growth. New-born infants crowded together in Foundling Hospitals often suffer greatly from such influences, and in these institutions thrush is a common and much-dreaded visitor. Even after the first infancy, the later stage of many acute and chronic forms of disease is hable to be complicated by the presence of the parasite, for in the young child a catarrhal condition of the alimentary mucous membrane often forms a necessary part of such illnesses.

In children suckled at the breast, the parasite is rarely seen; and if, on account of some temporary derangement, it succeeds in establishing itself upon the mucous membrane, it is readily dislo leged by suitable treatment, and quickly made to disappear. Thrush does not seem to be contagious in the ordinary sense of the term. No doubt, if the mycelium be purposely brought into contact with the mucous membrane of a child who is in a favourable condition for its reception, the plant may flourish in its new situation; but in a child whose mucous membrane is in a healthy state, the

experiment will be tried in vain.

Markid Anatomy. - The parasitic growth which constitutes timely and sists of the mycelium and spores of a cryptogramic vegetation while we first described by Robin under the name of oidium albicaus. The furns has now been identified by Haller as identical with the citium lacts was results from the acid fermentation of milk. The mucous numbrane dismouth is first seen to be red, and its secretion has a distinctly seel retion. Then, in the course of a few hours, little white points appear that the reddened surface, especially on the cheeks and the inner surface of lips. These increase in number and in size, and by the second are a seen to have united into patches which cover a considerable extent of we face. Even before the appearance of the white points, a gentle semple; the mucous membrane reveals to the microscope many spores of the 🗠 gus. These are elongated cells-egg-shaped bodies - which are often tached to one another by their ends, so as to form groups of two three, four. The white points are found, on examination, to consist of there are nected spores, combined with scaly epithelium from the mucous mentors

detached spores and molecular deposit.

The white, newly-formed membrane coats the interior of the mouth ad gullet; but is usually confined to parts covered with scaly epithehum. " it avoids the masal passages, and soldom penetrates into the largar. Perot, however, states that he has seen evidence of its presence on the male cords. The advance of the membrane down the alimentary and was 's a long time supposed to be arrested at the cardiac and of the stummer by Pairot asserts that the fungus is occasionally to be discovered in the storach and bowels. In these situations it presents a peculiar appearant In the stomach it is seen as small granules, separate or grouped and acing in size from a millet-seed to a particle invisible to the naked eye. It smaller are pointed; the larger are slightly depressed in the middle b colour, they differ little from the mucous membrane on which they oplaced, but some have a faint yellow tint. They adhere firmly to the face, and cannot be scraped off or washed away. The thrush granules of the principally the posterior surface, especially the neighbourhood of the principally the posterior surface, especially the neighbourhood of the principally the posterior surface, especially the neighbourhood of the principally the posterior surface, especially the neighbourhood of the principal p terior curvature, and lie nearer to the cardia than to the pylorus. So rounding them, the mucous membrane retains its colour, or is of a reser violet tint. Parrot examined sections of the gastric mucous mentions. and found the more superficial portions of the glands to be destricted the parasitic vegetation, which had penetrated into their interior, and last also advanced, although to a less extent, into the intervening tissue to cording to Wagner, the spores and filaments can be sometimes detected within the blood-vessels of the part.

In the intestines, Parrot states that he has succeeded in discovered befungus only in rare cases. In each instance its seat was the court. Whether the growth has the power of attaching itself to the anuse of clear, for an examination of the whitish pultaceous matter some times of the orifice of the rectum, revealed merely pavement epithelian, is stated layers, with some doubtful cells which presented a certain analogy of the filaments of thrush. On the inucous membrane of the mouth the thrush membrane is at first white, and firmly adherent. After a few to its colour becomes browner, and its connection with the nucous are less intimate, so that it can be readily upped away with a brush or pass of

wet rag.

In all cases of death from the serious intestinal derangement of the stitutional cachexia of which thrush is a chief local expression, extract atrophy of the tissues is a striking phenomenon. The infants are pro-

in a state of profound malnutrition, and present, according to Parrot, fatty degeneration of the kidneys, the lungs, and the brain, sometimes ulceration of the stomach, and, not unfrequently, his morrhages within the

cranual cavity.

Symptoms.—In cases where the parasitic growth attaches itself to the muccus membrane of a sturdy infant, the appearance of the white points is preceded by reduces and soreness of the mouth, and a rise of temperature. The child is noticed to suck with difficulty, and, if hand-fed, may refuse the bottle. He seldom, however, declines the breast for this reason. Often he makes movements with his lips, cries if a finger is introduced into his mouth, and is evidently uneasy. His temperature often rises at night to 103 or 104. At the same time there may be a little looseness of the bowels, preceded by colicky pains. The motions are shinly or green, but not very offensive. Often they are acrid, and cause some reduces and excoriation of the nates. This is looked upon by nurses as a satisfactory symptom, being considered to indicate that the thrush "has gone through" the child. In many cases there is derangement of the stomach, and vointing.

The above constitutes the whole of the symptoms. Although the temperature is raised, the stools have an innocent appearance, and the face expresses no distress. In the mouth, the thrush is limited to a few white patches, looking like particles of curd adhering to the mucous membrane. They are seen on the inner side of the cheeks and lips, on the tongue, sometimes on the hard palate, but seldom, in these cases, at the back of the threat. They may be removed with a little trouble, and leave the mucous surface on which they had been seated raw-looking and bright red. When thus removed, similar little patches quickly appear in their place, but after

a few days the surface cleans, and the child is well.

This simple variety is the shape the complaint assumes in ordinary cases, and practitioners whose experience is collected entirely from families in easy circumstances may have observed it in no other form. In hospitals and no lums where infants are admitted it is seen as a much more serious complaint. In babies who have been neglected or fed injudiciously, and confined to dirty, ill-ventilated, foul-smelling rooms-poor, miserable little objects, who have sunk from these causes and the consequent bowel deringement into a state of extreme atrophy and weakness, the whole of the interior of the mouth and fauces is often completely limed by the white thrush membrane. The layer adheres closely to the mucous membrane, and can only be detached with great difficulty. If this be done, the mucous surface beneath is seen to be raw, and sometimes ulcerated. According to Valleix, shallow ulvers on the hard palate may precede the appearance of the parasittle vegetation. An infant so affected cannot suck, and, indeed, often can hardly awallow. His month is dry; his lipitare red and dry-looking, and at the surfaces where they come into contact, white scattered particles of thrush can be perceived, even when the hps are almost closed. The child's eyes and cheeks are sunken; his face is pale and haggard, and marked with a well-defined nasal line which becomes a deep furrow on any movement of The buttocks and genitals are often covered with an ervthematous or eczematous redness, and ulcerations may be noticed on the internal malleoli, and sometimes also on other bony projections. His skin is loose and is excessively inelastic, often lying in lax folds upon the belly. The child whimpers feebly, but never cries. His mouth has a sour, or even a cadaverous smell. The motions, more or less profuse, are equally offensive. He gets weaker and weaker, and gradually sinks out of life. Sometimes the condition known as "spurious hydrocephalus" is noticed before death. The

temperature varies. Sometimes, on the first appearance of the parset, the internal temperature is found to be 101, or higher, although the extensive field cold; but after a time the temperature falls below the level dealth, and may be only 96° or 97 in the rectum. In many of these area the secretion of urine is duminished. According to Parrot, it often entire albumen; and this pathologist is disposed to attribute the cerebral amount a which are apt to occur in these cases to toxic causes, from returns in the blood of urinary elements.

In these severe cases the general symptoms depend upon the integral catarrh, or other primary lesion, whatever it may be, which has reduced to infant's strength, and prepared the way for the invasion of the parameters the illness ends in a profuse distribute, but the bowels are not invasion relaxed. In some cases, an attack of catarrhal pneumonia, or pulmary catarrh, with collapse of the lung, may bring the life of the miant pre-

maturely to a close.

Dragness.—Thrush is not difficult to detect. We have marely to commine the mouth of the infant, and observe the white adherent pages aprinkled over the surface of the mucous membrane. If a parties of these patches be detached and placed under the microscope, the characteristics.

teristic spores and filaments will at once be noticed.

It is possible that, in the rare cases where diphtheratic false manbear is seen on the interior of the lips and mouth, it may be mistaken for databut diphtheritic membrane is thicker, tougher, and more leathery is suffered, less white in colour, and under the increacepe shows no spins. Moreover, the superficial corvical glands are enlarged and tender is therm. In cases of thrush they are not affected.

Particles of curd chaging to the gums and checks of a child who has just taken his bottle have exactly the appearance of disseminated pursof thrush; but they can be readily wised off with a small brush of federand on their disappearance leave no reduces of the muccus membrase.

Programs.—In cases of thrush, the probabilities of the child's recent depend partly upon his general condition, partly upon the extent of a covered by the vegetation. If thrush appear in the mouth of a substitute symptom is one of little consequence of some temporary deray the symptom is one of little consequence, and the parasite can be read dispersed. In a child, enfeebled and wasted by chrome the state of three rangement, or the vectim of inherited syphilis, the appearance of three the mouth is a symptom of the utmost gravity. In such a case, the only chance of recovery depends upon the rapid introduction of notice ment into his system, but a deranged condition of the mucuus management into his system, but a deranged condition of the mucuus management in the rapidity with which the fungus is seen to grad over the surface, may be taken as a measure of the severity of the chrost derangement. If it rapidly cover the whole intentor of the mentic throat, the child's chances of recovery in his weakly state are small to see

Treatment.—In mild cases of thrush, our first care should be to receive the temporary gastric derangement which has allowed the parameter to effect a lodgment on the mucous membrane. The diet must be parameter as recommended in the chapter on infantile atrophy; and if the large are relaxed, the looseness must be arrested by suitable treatment page 626). If not relaxed, they should be acted on by a dose of the with a grain of gray powder. Afterwards, a draught containing a large grains of carbonate of sods, with an aromatic, should be given they four times a day. If there is nausea, the stomach should be cleared——

pemetic of sulphate of copper (half a grain in a teaspoonful of water), or teaspoonful of specacuanha winc, given every ten minutes until voniting

Fresh air is of extreme importance. If the weather is suitable, the fild should pass much of the day out of doors; and especial care should taken that his sleeping-chamber is sufficiently ventilated, and that deal lines is not allowed to remain in the room to vitiate the air.

With regard to local treatment:—Perfect cleanliness is indispensable, breetly the infant has taken the bottle, his mouth should be swabbed out tak a piece of soft linen rag, or a large camel's hair brush, moistened with an water. Afterwards, the whole of the interior of the mouth should be brushed over with a solution of borax (half a drachm to the ounce) in the sweetened with glycorine. If this treatment be repeated after each real, it will not be long before all signs of the fungus lave disappeared.

In the more severe examples of the complaint the same local treatment most be employed. If the fungus be suspected to have passed into the ralist the chall may be forced to swallow a few drops of the wash diluted ma water. If superficial ulceration are seen, ten grains of sulphate of are may be added to each omice of the wash, for use as an application to the morous membrane. The chief difficulty in these cases is to improve the shild's nutrition and increase his strength. If the parents are in a posting to supply a wet nurse, this method of feeding should be adopted t wea. If the child is forced to trust to the bottle, ass' milk or the milk of the goat is preferable to that of the cow. Eather should be given parrentised according to the method recommended elsewhere (820 page White wine whey is a valuable resource in these cases, and if the blut be much reduced in flesh and strength, with small digestive power, be may subsist upon it entirely for the first few days. A dessert-spoonful I firsh cream shaken up with each bottleful of the whey makes it more istations, and is a very digestible addition to the meal. In all cases, the becal treatment will depend upon the accompanying conditions, and esperuly upon the nature of the illness in the course of which the local complant has appeared. Often the child is the subject of a chronic intestinal This must be treated as directed absendere (see page 640). If be parging is moderate, and there is no reason to suspect the presence of Seration of the bowels, much benefit may be often derived from a powder Dataning one grain of rhubarb, with one grain of powdered bark, and are grains of aromatic chalk, given two or three times in the day.

Fresh air, with warmth to the belly, and the most perfect cleanliness, by only of the child's body and linen, but also of all spoons, cups, feeding-

lottles, etc., used in his nursery, are essential to his recovery.

CHAPTER V.

PHARYNGITIS.

Physicistry, or sore throat, is common at all ages, and is a frequent resplant in early life. The disorder may be met with as a simple cutart to mucous membrane; as an inflammation affecting especially the track follicles; as an eruption of herpes in the pharynx, or as part of a ser constitutional disease. Four varieties will then be considered, vir. and cutarrhal pharyngitis; follicular pharyngitis; herpetic pharyngitis, as to be real archaryngitis.

SIMPLE CATARRHAL PHARYNGITIS.

Consation.—Catarrh of the pharynx, like catarrh attacking other part of the body, is usually the consequence of a chill. Any cause with clines the body to be affected by changes of temperature will help to use the disorder. It is, therefore, common in scrofulous subjects, in chiral enfected by confinement to heated, ill-ventilated rooms, and in the confinement in houses where the air is containnated by an imperfect system dramage. Direct irritants to the throat will also set up pharyng the also at once passes beyond the limits of an ordinary pharyngual catarrh. Per children of the poor are often brought to the hospital with seven seek the throat from attempting to drink boiling water out of the spoot of kettle. In the above cases the disorder is a primary lesion. It may ever, occur secondarily to some general disease. Thus, catarrh of the pharynx is an invariable consequence of meastes and scarlatina. It is a common in typhoid fever, in rheumatism, and in ervarp has. In all case the derangement is an acute provess, although, if frequently repealed a tends to set up a relaxed and congested state of mucous mumbrane.

Symptoms.—In mild cases, the first symptom is usually a sore feelin. It the throat, which is increased by swallowing. On examination of the throat the back of the fauces, the soft palate, and the tonsils are intered be red, and the latter may be slightly swellen. The tongue is furned the child is thirsty. In scrofulous subjects the temperature almost disciply rises, and there is a certain amount of pallor and languor in the slighter forms little more is to be discovered. After a day or two the begins to snuffle, and the throat affection disappears as a usual extent comes established.

In the severe variety the earlier symptoms are more pronounced. To child feels ill and looks tired. His face is pale, his eyelids are distactionally complains of weariness and aching in the limbs, and asks to go to be. Often he sits over the fire and says he is cold. In a few hours senter the throat begins. The fauces are found to be red and the totals to slightly swollen. Whitish pultaceous matter may be seen at the species of the crypts of the tonsils, and sometimes at the back of the pharma.

scrofulous subjects the temperature generally rises to 104° or 105°, and in such children the glands of the neck, although little cularged, are tender when the neck is pressed. The tongue is thickly furred, and in most cases the nasal passages and the gastric mucous membrane are also the seat of catarrh. Moreover, the eyes look red and watery, and the child avoids the light. In a day or two the catarrh often spreads to the Eustachian tubes, so that there is some deafness. The voice is usual, and swallowing causes great pain, so that the child refuses all solid food. The bowels are usually confined; but if there is any intestinal catarrh, the disorder may be accompanied by purging.

After twenty-four, or, at the latest, forty-eight hours, the fever considerably duminishes, but the temperature may remain at 100 or 101' for a day or two longer. Usually, after the third or fourth day the symptoms begin to subside, and by the end of the week the child is convalescent. If the patient has suffered many times previously, the deafness may not subside

with the other symptoms, but may persist for a week or so longer.

A scald in the throat is accompanied by great nervous prostration. There is severe pain in swallowing, and consequently an almost entire inability to take foot. The mucous membrane of the mouth, palate, and pharynx, looks whitish; raw patches are seen, from which the nucous membrane has been removed, and there is much swelling. Often the larynx is also injured, so that scute laryngitis is set up, and cedema of the glottis may be induced.

Dispussive. An ordinary pharyngitis can usually be readily recognised. The chief difficulty is to exclude diseases of which pharyngitis is a promi-

ment symptom, especially scarlatina and measles.

In scarlatine, the pharyny usually presents a peculiar appearance. The redness is of a very bright colour, and is diffused over the whole of the fances. Often it is punctiform on the soft palate, or, even if the redness here is uniform, the punctate appearance can be detected at the edges of the redness. Moreover, in scarlatina, the feeling of soreness begins quite subdenly, as a rule, and the attack is accompanied by vointing and a very rapid pulse. In twenty-four hours the characteristic eruption is to be discovered.

If the signs of catarrh are general, and the sore throat is accompanied by slight ophthalmia and running from the nose, measles may be suspected. Indeed, the invasion of the eruptive fever is accompanied by symptoms which cannot be distinguished from those of an ordinary catarrh. If, on the third day, the fever is as high, or higher, than on the first, the continuance of the pyrexia tells in favour of the exanthem; but no positive opinion should be hazarded until after the fourth day, when, if the case be one

of mensies, the characteristic rash may be expected to appear.

Treatment.—It is not often that medical advice is sought in a case of ordinary entarth, the derangement being one which is considered especially suitable for domestic medication. If, however, the fever is high, the medical practitioner may be called in. A feverish child should be confined to his bed. He should take a grain of calomel, followed by a saline aperient, and his diet should consist of milk, broth, and dry toast. A cold compress, or a layer of cotton wool, may be applied to the throat. If the case be seen early, it is useful to prescribe the hypophosphite of lime, which has a really remarkable influence in cutting short an ordinary catarrh. For a child five years of age, three grains of the salt may be given with five frops of spirits of chloroform and ten of tincture of cardamoms, in two teaspoonfuls of water, three times a day. A mild catarrh is often arrested at

37

once by this means, and even in severe cases the course of the derange is sensibly shortened by the remedy. The pyrexia usually subsides and all the pyrexia us after the action of the aperient. If it persist, a drop or two of tractured acomte may be given in a teaspoonful of water every two or three hour

If the throat remain relaxed after the subsidence of the pyrovia, a two. astringent gargle, if the child can use it, or a rhatany or tauma have sucked two or three times a day, will produce a bracing effect. In case where there remains a great sensitiveness to chills, the susceptibility are be considerably diminished by the daily use of a cold douche, minimustre.

in the manner elsewhere recommended (see page 17).

Severe scaleds of the throat usually occur in the younger children if the pain he severe, it may be allayed to some extent by suching are by administering, occasionally, a teaspoonful of crushed recon which a attempts that here is sprinkled. Small doses of opium are often necessarian and this remedy applied locally, as by spraying the throat with givener and water, made anodyne with a few drops of laudanum, is were beneful If the child cannot swallow, be may be fed through a stomach-tube prothrough the nose, as directed in a previous chapter (see page 15). Rou alimentation is very unsatisfactory in young subjects.

If laryngitis occur, it must be treated as described elsewhere -

page 410 j.

FOLLICULAR PHARYNGITIS.

Chronic inflammation of the follicles of the pharynx is an electrate ver plaint which is often seen in children. The disorder is an important or as it may induce deafness, and frequently gives rise to a persistent coul

which is a cause of much anxiety to the patient's relatives.

Causation.—Follicular pharyngitis is especially likely to attack strams subjects, and those who belong to families in which there is a course rheumatic tendency. The disorder is not often seen in very your dren, although Dr. Morell Mackenzie has met with it as early as the table year. It is most commonly found in children of eleven or tweire warage and upwards. It sometimes appears to follow certain special tools such as measles, scarlatina, and small-pox. In other cases it is equivalent excited by exposure to cold acting upon a weakly frame. This said seek the disorder are often ill-nourshed and feeble-looking, and the ist coupled with the cough which is so common a consequence of the may give rise to fears of consumption.

Morbal Anatomy. The follicles are enlarged and their walls the less. They are filled with a cheesy secretion consisting of degenerated questions cells, molecules, and oil-globules; and sometimes contain concrete 22

carbonate of lime.

Symptomic. - The case is seldom seen until the derangement is a loss to It is then, usually, as has been said, the cough which excites the same the parents. The cough is frequent and hard, and the child often his voice, and when questioned complains that he has a "trainer in le throat. The symptoms vary in severity from time to tune. When the case is severe, the cough is accompanied by pain shooting up and head or ears. It often comes on in paroxysms, and these are apt to act the night. There is also an uneasy sensation in swallowing, and to a may complain that "coughing makes his throat sore." In missing a so the disease extends to the larynx, producing hourseness, and into us be tachian tubes, causing dulness of hearing. If the posterior mares are # tacked, the sense of small may be impaired; if the soft palate, the ase

of taste may be affected. Loss of these senses is not common in the child, or is difficult to ascertain; but a certain impairment of hearing is frequently complained of. Indeed, I am informed by Mr. Reeves that of the children who are brought on account of deafness to the Ear Department of the London Hospital, a full third owe their infirmity to this affection of the throat. In such cases, a peculiar flattening of the nostrils is often produced, owing to the swelling of the posterior nares. The appearance is similar to that which has been so often remarked upon as resulting from a chrome enlargement of the tonsils, and is indeed produced, like it, by the disuse of the nasal passages in respiration. Disease of the middle car, with discharge from the meatus, may be also a consequence of the pharyngeal affection. A catarrh is very apt to spread along the Eustachian tube into the tympanum; and the secretion being unable to escape through the occluded tubes, accumulates, and leads to ulceration of the tympanic membrane, and otorrhea.

In mild cases of follicular pharyngitis there is little interference with deglution; but when the disease is more pronounced, swallowing may be difficult as well as painful, and the attempt to swallow is said sometimes

to give rise to spasm of the pharynx.

On inspection of the fauces, we find small eminences scattered over the mucous membrane at the back of the pharynx. These are rounded or clongated in shape, and may be so numerous as to present a granular appearance. Their colour, and that of the whole mucous membrane, is deeper than natural, and enlarged superficial veins may be seen running in the depressions between the prominent follicles. If the disease is extensive, similar granules are found on the pillars of the fauces and on the tonsils. Sometimes mucus, more or less stringy and turbid, may be seen chaging to the tonsils, or hanging down from behind the soft palate, and this may be mixed up with yellow-looking exudation from the diseased follicles.

In scrofulous children, ulceration is very apt to occur. The ulcers are sented in the follicles. If isolated, they are small and circular, but when placed closely together, they are larger and irregular from junction of the borders of neighbouring sores. The uvula is clongated, and its surface is

dotted over with enlarged glands.

Diagnosis.—The diagnosis of follicular pharyngitis presents no difficulty. If the patient is brought on account of cough, examination of the chest usually reveals no sign of disease, while inspection of the throat discovers the characteristic granular appearance of the pharynx.

Prognosis.— In children, the discuss can usually be arrested by suitable treatment, but it may tend to recur afterwards from slight exposure. Follienlar pharyngitis may be associated with phthisis, and, according to

Dr. Hornee Green, is sometimes a cause of it.

Treatment —As children suffering from this complaint are usually weakly and under-nourished, the general health must be first attended to, and the child will often be greatly benefited by cod-liver oil and tonics, such as iron and quinne. A little sound claret diluted with water may be given him with his dinner. In fact, the constitutional treatment recommended in cases of strongly marked strumous diathesis is often required.

For a cure of the local disorder, local treatment is essential. In mild cases, a more healthy action of the pharyngeal mucous membrane may be induced by astringent applications, especially by brushing the throat two or three times duly with the glycerine of tannin, or with equal parts of strong perchloride of iron and glycerine. Dr. J. Sawyer speaks highly of the local application of borax. A saturated solution should be sprayed into

the throat for several minutes, three or four times in the day, at an interval after food. The extract of encalyptus, in the form of a lozenge, is also

serviceable when secretion is copious.

In more severe cases, it may be necessary to destroy each follicle separately by a caustic or the galvanic cautery. The latter, which can be put cold into the throat and rapidly heated in situ, is no doubt the most convenient. Moreover, its action being instantaneous, the application is less painful than that of the more slowly-acting eacharotic. If a caustic be used, nitrate of silver, properly employed, is one of the most successful. The throat must be first cleansed with a brush soaked in warm water then with a piece of lunar caustic, sharpened to a fine point, each enlarged follicle or ulcer must be touched separately. The number of follicles to be destroyed at one visit must vary according to the sensitiveness of the child, and the distress produced by the application. On the first occasion, only one or two may be destroyed as a trul test.

Instead of the lunar caustic, other caustics, such as Dr. Morell Macken-

zie's "London paste," may be employed.

HERPES OF THE PHARYNX.

Herpes on the skin is a common cruption in the child. Sometimes the

rash appears on the pharvnx, and produces great discomfort.

Causation.—The causes of herpes are doubtful. The complaint is said to be excited by exposure to cold, but a constitutional tendency appears to be necessary to its development. There is no doubt that, as Trousseau first pointed out, pharyngeal herpes is especially common during outbreaks of diphtheria, and that in such cases the zymotic disease may become en-

grafted upon the herpetic eruption.

Symptoms - The complaint begins with febrile symptoms, followed after a few hours by soreness of the throat. The child complains of a painful feeling in deglutition, which is usually distinctly confined to one apot. On examination, a few whitish vesicles are seen clustered together on the soft palate, on one of the pillars of the fauces, or on one of the tonsils. Around them, the mucous membrane is redder than natural, and swollen. Sometimes the vesicles are more numerous, and more generally distributed. The vesicles last from twenty-four to forty-eight hours, and may then disappear without rupture, or burst, leaving little white spots from macerated epithelium, or circular ulcers which soon heal. Sometimes, instead of healing rapidly, the ulcers become covered with pultaceous exudation, and, if the sores are numerous, the exudation may form a continuous layer. More usually, however, the patches are small and isolated. Their scat is generally the soft palate, or one tonal; seldom the back of the pharynx. After three or four days the exudation becomes detached and disappears. Sometimes more than one crop of vesicles is noticed. Often, herpes of the pharynx is associated with the same condition of the lip; and the resicles are said sometimes to invade the larynx and the openings of the Eustachian tubes, so as to affect the respiration and the sense of hearing.

Inagnosis. When the disease is seen in the vesicular stage it is readily recognised. If, however, inspection is delayed until the patches of exudation have formed, the case may be mistaken for one of diphtheria; more especially, as this form of the complaint is often associated with outbreaks of that disease. If, however, herpea of the lip is present, and especially if small circular ulcers can be seen mixed up with the small patches of exu-

dation, we may suspect pharyngeal herpes. Still, it is often impossible to

distinguish the case from a mild attack of dipletheria.

Treatment.—The complaint requires little treatment. Attention must be paid to the bowels. If the tongue is furred, it is well to administer a mercural purge, such as a grain of calomel with two or three grams of While the pyrexia lasts, the child should be kept in bed and put upon slops-indeed, the pain induced by deglutition will prevent his wishing to swallow solid food. If the fever is high, timeture of aconite may be given in doses of one or two drops, every hour, or two hours. If the discomfort in the throat is great, it may be relieved by inhalations of steam, medicated with compound tineture of benzoin (51 to the pint). If in the stage of exudation there is any factor of the breath, inhalations or sprays containing creasote or carbolic acid (ii) xx. of each to the pint) may be made use of. As an internal remedy for children, Dr. Morell Mackenzie speaks highly of arsenie. Three or four drops of Fowler's solution may be given three times a day, directly after food, to a child five years of age. If there is any doubt as to the nature of the complaint, and diphtheria be epidemic in the neighbourhood, the treatment for that disease should be at once adopted.

TUBERCULAR PHARYNGITIS.

In children, the subjects of tuberculosis, the pharynx, like any other part of the body, may become affected as a consequence of the diathetic state. The pharyngeal complaint is only a part of the general disease; but it may occur in children in whom no pulmonary symptoms are present, and in subjects who have not previously suffered from delicacy of the throat.

Morbal Anatomy.—The mucous membrane is the seat of ulceration, which is limited at first to one side of the fauces. The ulcers are due to the execution and breaking down of gray granulations themselves, and not to the development of these granules around a sore formed by the disintegration of ordinary cheesy matter, such as may result from proliferation of the cellular contents of a glandular follicle. Frankel states that in a previously sound portion of the velum palati he has been able to follow the whole process with the eye. Thus the gray nodules have aprung up, have become caseous and disintegrated, and have been replaced by ulcers under his own immediate observation. On microscopic examination, the base of the ulcer is seen to be intiltrated with round cells, which permeate the sub-independent tissue, and even reach to the muscles. The same cells also infiltrate the cellular tissue of the glandulæ. The special gland cells are often in a state of fatty degeneration, and tend to become cheesy.

The other organs of the body are also the seat of the gray granulation.

Symptoms.—The first symptom pointing to the throat is soreness, and this seems to be exceptionally severe, for the child makes it the subject of continual complaint. In deglitition the pain often shoots up to the ears, and usually becomes so great on taking solids that no persussions can induce the child to swallow anything but liquid food. In addition to pain, there is sometimes difficulty in deglitition, and liquids may return through

the mouth and nose.

On examination of the throat, the mucous membrane is seen to be ulcerated. The ulcers generally begin on one ade—on the tonsil or one of the pillars of the fauces, and spread slowly to the soft and hard palate and the back of the pharyns. According to Frankel, they begin as gray isolated or confluent nodules, which afterwards undergo caseous degeneration and alteration. They tend to spread transversely rather than in a vertical di-

rection, and seldom penetrate deeply into the tissues. The floor of the ulcer is irregular and cheesy; the borders are congested and undermoded. In the neighbourhood of the sores, gray miliary nodules can be districtly seen dotting the mucous membrane. If the uvula is not invaded by the destructive process, it often becomes atrophied. In the opposite case, a swells to a considerable thickness, and may be dotted over with hard and

ules. Eventually it may be eaten away.

The ulceration may spread extensively. In a case reported by Dr file—a child six years old—the whole of the pharvny down to its maps with gullet was covered with yellow purulent matter. The innecessary brane was extensively destroyed, so as to lay bare the pharvng all music. The soft palate, back and front, was in the same condition. The nyules destroyed, as well as the mucous membrane of the tongue, half way to a foramen execum. The right tonsil was gone, and the any pignificant folds were ulcerated superficially. The true vocal cords and the my below them were unaffected.

As a consequence of the ulceration, the voice acquires a nasal quilt as it does in most cases of pharyngata. The glands of the took book enlarged along the borders of the sterno-mastoid muscles, and at the new

of the jaw.

When the case is first seen, the general nutrition of the chall is not necessarily unsatisfactory. The degree to which it is impaired dejected a great measure upon the period at which the pharyngeal affection and in the general disease. If it occur early, the child, although that > 1 emaciated. His thinness is no doubt chiefly due to the influence of the cachexia upon nutrition, but is probably also in part the consequence of ficulty and pain in swallowing, which is a bar to the taking of softwent for The general symptoms are those of tuberculosis. There is fever but a dom a very high temperature, the evening rise not often passing level 102' or 103'. There is usually cough, and an examination of the may detect signs of consolidation; but in some cases no exidence of talcle can be discovered at first in either the chest or the abdomen. As h disease advances, however, argus of mischief become manifest in other per of the body. Spots of dulness may be discovered at the aprece of lungs; a secondary catarrial pneumonta becomes developed; and tubercular peritonitis are to be discerned, or symptoms of tubercular ingitis occur; and sometimes a persistent purging is set up, with all signs of tubercular ulceration of the intestines.

pharynx lies in separating it from syphilitic ulceration of the same post. The distinction is, however, easier in the child than it is in the ability in young subjects the latter disease is almost invariably a caugement of in young subjects the latter disease is almost invariably a caugement of invariably a caugement of the parents, we can find no residual. If, then, by careful questioning of the parents, we can find no residual patient himself shortly after birth; if the child bear about him necessary patient himself shortly after birth; if the child bear about him necessary and linear cicatrices about the angles of the mouth, prominence of the family of patient incisors have appeared and show no sign of malformation—in solution as case we may exclude syphilis with tolerable certainty. If, on the other hand, a hereditary tendency to phthisis can be discovered, or if other hand, a hereditary tendency to phthisis can be discovered, or if other hand, a hereditary tendency to phthisis can be discovered, or if other hand, a favour of tubercle. Still, a history of syphilis, although paring strongly to this cause for the ulceration, does not make it terms.

the pharyngeal disease is a result of the venereal taint, for a syphilitic child my fall a victim to tuberculosis. Nor, again, if signs of tubercle are to be beovered in other organs, can we, from this circumstance alone, positively relade a syphilitic origin of the throat lesion, unless we are supported in this judgment by the family and personal history of the child. Fortunately, bacrer, careful observations of the fauces itself furnishes sufficient evibase. In syphilis, the ulcers have sharper edges, penetrate more deeply, kal to pro luce contractile scars, and have no gray nodules in their neighburhood. Tuberculous ulcers, as has been already remarked, are supertrad as a rule, with irregular nodular, croded, and undermined edges, and a cheesy floor. In their neighbourhood, gray miliary nodules are seen underneath the epithelium. Moreover, in tuberculosis, the ulceration speeds very slowly, and the cervical glands are invariably enlarged. In sophiles, the extension is more rapid, and the glands of the neck are rarely indurated and swollen. Again, syphilitic ulceration is not accompanied by fewr while in tubercular pharyngitis the temperature is always elevated. The hypnosis will therefore rest upon the complete absence of all syphilitic besory, either family or personal; the appearance of the sores themselves, wate the gray unliary nodules in their neighbourhood; the enlargement of the superficial glands, and the presence of fever.

Progress.—The disease is always fatal; and, indeed, the pharyngeal been tends to hasten the end by the rapid exhaustion it induces through the difficulty of supplying a sufficient quantity of nourishment. Death

usually occurs in from two to six months.

Instruent. - Little can be done in the way of treatment in retarding the downward course of the illness. Nutritious food in small bulk, such as meet essence, pounded meat made liquid with gravy, yolks of egg, milk, ste, should be given; and the strength of the patient may be also supported by doses of the brandy-and-egg mixture or port wine. If the child be sawilling or unable to swallow, nourishment must be administered by the stemach-tube passed through the nose.

We must endeavour to relieve the distress of the child by soothing applications. Brushing the affected part with glycerole of morphia is recommended by Isambert. For a child of seven or eight years old, the strength of the application may be one grain in three drackins. Inhalations of

mean also appear to relieve.

CHAPTER VI.

QUINBY.

Accrz inflammation of the tonsils, or quinsy, is a frequent complaint of later childhood, but is comparatively rarely met with during the first few years of life. One of the peculiarities of the affection is its disposition to recur. A first attack leaves behind it a tendency to a second, and the same subject will be found to suffer from the disease again and again under the influence of apparently trivial causes. A common consequence of these repeated attacks is a hypertrophied condition of the tonsils. This may be a source of great inconvenience, and may even have a serious ef-

feet upon the health and general development of the child.

The tonsils are often found to share in a general inflammation affecting the mucous membrane of the mouth and fauces, and in scarlatina and diphtheria they are almost invariably inflamed and swollen. The name "quinsy" is, however, applied to a special primary affection which appears to be something more than a mere local complaint. Acute tonsillitis has, indeed, been compared to croupous pneumonia—another disease which is no longer regarded as a purely local inflammation. In each of these forms of illness, we find general symptoms severe out of all proportion to the local lesion; a rapid rise of temperature which often precedes the more special symptoms, and a critical fall on the fifth or sixth day. In each dis-

ease, too, the attack appears to be due to very similar causes.

Causation.—Although occasionally met with in young children, quinsy cannot be said to be common until about the eighth or ninth years. In all cases there is probably a special individual susceptibility rendering the patient more liable to be affected by cold and damp, which appear to be the ordinary causes of catarrh. Any influence which exercises a depressing effect upon the system will no doubt assist the action of these causes, and some observers are disposed to believe that in unfavourable subjects such depressing influences alone are capable of exciting the attack. There appears to be a distinct connection between tonsillitis and acute rheumatism. Quinsy is common in rheumatic subjects, and attacks of rheumatism are often preceded by acute inflammation of the tonsils. Indeed, so frequently is this the case that quinsy has been looked upon as an early manifestation of the rheumatic tendency.

The inhalation of sewer gas is another common cause of tonsillitia. Immates of houses where the waste-water pipes run directly into the soil-pipe, or where the main soil-pipe is defective and loaks under the basement floor, are often subject to repeated attacks of quiusy, and also to a slower inflammation of the tonsils, which resists all treatment as long as the pa-

tient remains in the vitiated atmosphere.

Chronic hypertrophy of the tonsils is not always the consequence of the acute form of the disease. In scrofulous children, enlargement of these glands may arise from a process of slow inflammation. The same thing is be discovered, and in families where the other members are strong and britisy. In these cases it will be generally found that the patient, if he has not suffered from repeated attacks of the acute form of the disease, has been long exposed to insanitary or other depressing influences by which his development and general nutrition have sustained distinct injury. The child may have lived in a vitiated atmosphere, been overworked at achief, or here subjected to other sources of depression which have reduced his strength and diminished his vital powers.

The chronic inflammation of the tonsils, which is the consequence of a higher tendency, is seldom seen before the fifth or sixth year. When the hyerrophy occurs in children of healthier constitution, it often begins easer, being found in infants under twelve or eighteen months old. It has been suggested by Robert, that in such young subjects the enlargement may be a consequence of teething, and it is possible that the change in the hands may have some connection with the general glandular activity which

is known to prevail at this period of life.

Metad .inatomy.—In acute tonsilhtis, the inflamed tonsil becomes swollen with inflammatory exudation. An increased production of epithelial cells takes place in the recesses of the gland. The crypts are distended with them, and the cells appear as creamy-looking masses at the orifices. Almost at the same time the lymphatic follicles swell and soften, and form also sees which run together so as to give rise to a considerable collection of pas. This is eventually expelled by one or more openings. The inflammation then subsides, and the swelling more or less completely disappears. It selion happens that both tonsils are attacked at exactly the same time. Usually, the inflammation begins first on one side, and partly runs its course before the tonsil on the other side begins to suffer. There is also more or less inflammation of the soft pulate and pillars of the fauces, and the salivary glands may participate in the inflammation and get hard and swellen.

In tonsils permanently enlarged from chronic inflammation, the increase in are is due to an inflammatory hypertrophy of the sob-mucous connective tessue. The glands are enlarged and hard, and their surface is often

DETEL

Symptoms.—The inflammation begins with a chill, or even a distinct new, and the child complains of a feeling of dryness and aching in the regon of the fauces. His temperature rises to between 102' and 103', and he looks and feels ill. Often there is general aching and soreness of the body, such as is experienced at the beginning of attacks of severe estarth; the pulse is rapid and full, and the tongue is thickly-coated with fur. On inspection of the throat, the tonsils are seen to be swollen and rividly red, and there is also redness of the soft palate, uvula, and pillars of the fauces. The uvula is not, however, swollen at the first, although

hter it is apt to become ædematous.

As the inflammatory process increases, the pain and aching at the back of the throat grow more distressing, and the discomfort is increased by a section of thick mucus from the inflamed mucous membrane. Deglution is accompanied by a sharp pain, which often shoots up into the ears and side of the head, and all movement of the jaws is painful. The child after I or unable to avallow, and often an attempt to do so produces a change sensetion, and a return of the fluid through the nose. Singing in the errs and deafness are often present, and the voice of the sufferer has a recular nasal quality which is very characteristic. At the height of the disease, the temperature is often as high as 104°; the skin is moist and

clammy; the pulse is rapid and compressible; there is a feeling of great

prostration, and the face is pale, haggard, and distressed.

If one tonsil only be affected, at the end of five or six days a yellowish spot can be detected on the reddened and glossy surface of the gland. In a few hours, or on the following day, the abscess bursts at this point, and this harges a large quantity of thick pus, to the great and almost immediate relief of the patient. Often, however, at this time, or shortly before, the opposite tonsil begins to swell, and the discomfort, if it had partially abuted, returns.

The swellen gland may reach a large size. It can be felt externally behind the angle of the jaw, and often seems to block up the whole passage of the throat. When the inflammation runs its course on both sides at the same time, there may be difficulty of breathing, and the face assumes an agoinzed expression of distress. Fortunately, any but a favourable termination to the complaint is excessively rare; and the child's friends may be comforted by the assurance that the severity of the symptoms is out of all proportion to the actual danger of the illness, and that recovery may be expected with confidence. When the abscess bursts, its purulent contents are almost invariably availlowed by the child; but the cessation of much of his distress, the relief shown in his face, the rapid fall of temperature, and the improvement in his general symptoms, allow us to infer, even without examination of the throat, that evacuation of the matter has occurred.

After discharge of its contents the gland begins to diminish in size; deglutition, although still painful, is accomplished with greater case; the languard expression of the face disappears, and the desire for food begins to return. Often, at this time, a discharge of blood takes place from the abscess. The appearance of blood from the mouth may be a cause of great alarm to the child's relatives, and it is well to warn them of the possibility

of its occurrence.

The duration of the disease is from one to two weeks, according to whether both tonsils or only one becomes inflamed. Convalescence is short, and after the cessation of the attack, the child quickly recovers his attenuath

In a considerable proportion of cases, especially if judicious treatment is early adopted, the inflammatory process stops short of suppuration. The redness then begins to diminish, and the swelling to subside, at the end of forty-eight hours, or in the course of the fourth day. In many of these instances, the red and swellen tousils are speckled over with gray patches from the secretion at the months of the follicles, and sometimes shallow ulcers are seen on the inside of the cheeks and lips, or on the tongue, but rarely on the tonsils themselves. In this form of the disease, the febrile action is less high than in the suppurative variety, but the depression and feeling of illness are fully as severe. When occurring in this form, tonsillitis is probably always a consequence of insanitary conditions. The cases are often met with in groups, several innates of the same house or row of houses being attacked almost at the same time. Although included under the name of quinsy, the disease is probably distinct in its nature from the suppurative variety, and, if suitable treatment be adopted early, it can be rendily arrested.

In chronic hypertrophy of the tonsils, the glands are enlarged and hard. They can be felt externally behind the angle of the jaw, and, on inspection of the throat, are seen as two globular bodies projecting towards one another, so as almost to touch in the middle of the throat. The anterior surface is smooth and shining, but the internal face is irregular from the open-

of the glandular recesses. Their colour is usually of a pale brick red, of when at all congested, as they are apt to be on the occurrence of the ictiesty-hill, they become of a deeper tint, and yellow curry masses appear the oritices of the crypts. At these times, they often meet in the middle on, and the friction of the two bodies against one another may, as Dr. V Poore has pointed out, be a cause of superficial ulceration. One of the results of this chronic enlargement of the glands is the frequent recurrence of attacks of inflammation, which, although amounting to no more than superficial pharyngitis, are yet a source of great discomfort. Usually, a brast once in the twelve months, the inflammatory process is more severe,

althe patient passes through a regular attack of quinsy.

A child who suffers from this chronic enlargement of the tonsils, presents way very characteristic symptoms. He has often an unhealthy appearance, being undersized, pale, and thin. The imperfect state of nutrition in such pulsats is well seen in cases where one member of a family is alone afletel. The frail appearance of the child then contrasts strikingly with the robust and healthy look of his more fortunate brothers and sisters. It has been supposed that this imperfect performance of the nutritive prosixes is due to the impediment to respiration set up by the swollen bodies, med the consequent insufficient combustion of waste products in the body. Leanet, however, think this a satisfactory explanation of the phenomenon. I appears to me to be rather the result of the striking susceptibility to this almost invariably manifested by these patients. Their gastric mucon membrane is therefore kept in a state of almost continual enturn. As sousequence, digestion is laboured and imperfect, and the nutritive needs of the system are unsufficiently supplied. Such children are often excee-Their complexion is sallow, with a dark dis-tionation under the eyes. They sleep badly at night, dreaming and talkby motherently. Their bowels are often confined, and their stools lightof up al and offensive. Sometimes the face turns suddenly white, and the could complains of flatulent pains and of distention of the belly.

In all cases where the enlargement of the glands is at all considerable, the nuccus membrane in the neighbourhood of the tonsils is habitually categorish and relaxed. The child snores in his sleep; speaks with a thick has been of voice, and may be dull of hearing from the turgid state of as Eastachan tubes. Slight hemorrhages often occur at night from the unface of the glands, and blood-stained saliva may flow from the child's open mouth on to the pillow. Sometimes the posterior nares are almost completely closed to the passage of air. The nostrils then become fattened so as to narrow the usual apertures. In such children, the palate is often high and arched; the upper jaw is small; the teeth are crowded and overlap, and the front of the jaw is curiously rounded at the lips.

In extreme cases, the entrance of air through the larynx is impeded; often sufficiently so to induce a state of permanent collapse at the bases of the large. The lower end of the sternum, with the cartilages connected with it withen forced backwards so as to present a cup-shaped depression at that punt. The upper portion of the sternum is made prominent, and one form of pigeon-breast is produced. This variety of the pigeon-breast may be readily distinguished from a somewhat similar condition in the rickety that. In the latter, the whole sternum protrudes, from softening of the him. In the former, the upper part of the breast-bone is prominent, and the depression at the lower part is the result of yielding, not in the ribs, but in the cartilages.

Figure of the breath is a common consequence of enlarged tonsils, for

the glandular recesses become filled with a cheesy, decomposing secretion. Cough is also a frequent symptom. It is often distressing and paroxysmal, and when combined with the pallid, weakly appearance above referred to may give rise to fears of consumption. Such apprehensions are sometimes rather confirmed than allayed by the results of a physical examination of the chest. In many such cases, a peculiar hollow quality of breath-sound, probably conducted from the pharynx, is heard with the stethoscope at each supra-spinous fossa. To an inexperienced observer, this sign may suggest consolidation of the lungs. There is, however, no dulness on percussion, and the abnormal quality of breath-sound is heard principally in expiration, and is greatly diminished, or even completely suppressed, when the child opens his mouth widely.

Diagnosis.—Primary inflammation of the tonsils can only be mistaken for the secondary inflammation which occurs in scarlatina and diphtheria. In the first case, the absence of the characteristic cruption at the end of twenty-four hours is quite sufficient to exclude the infectious fever. But, besides the rash, the appearance of the inflamed mucous membrane is very different in the two discases. In scarlatina, it is more widely diffused, and of a more brilliant red, than at the beginning of quinsy; and on the soft palate the redness is usually punctiform, which is not the case in tonsillitis.

In diphtheria, the nah-coloured leathery appearance of the false membrane is different from the curdy patches of quinsy; and in the former disease there is early swelling of the cervical glands. In inflammation of the tonsils these glands are not usually affected.

Prognosis.—In quinsy, the prognosis is rarely otherwise than favourable. Cases are said occasionally to have happened in which suffocation has resulted from the inflammation. Rilliet and Barthez have referred to such a case, in which a little girl, aged thirteen, died of suffocation on the second day; but it is very doubtful if this was an uncomplicated case of quinsy, and the accident is one not greatly to be dreaded.

In cases of chronic enlargement of the tonsils, the glands, if left alone, usually become smaller after puberty. But while they remain swollen they give rise to so much inconvenience as well as induce so much interference with the nutritive processes, that measures should be always adopted for their early reduction or removal.

Treatment.-In every case of quinsy it is advisable, as an important preliminary to further treatment, to clear out the bowels with a good mercurial purge, followed by a saline draught. Lauseed-meal poultices, or a cold water compress, must be kept applied to the throat, and if old enough to gargle, the child may use a weak solution of chlorate of potash sweetened with glycerine. If the case is seen early, aconite given frequently, in very small doses, is found in many cases to have a distinctly beneficial effect. It reduces the temperature, promotes the action of the skin, and often quickly brings the inflammation to a close. The tincture should be used in doses of one drop in a tenspoonful of water every hour. Guaincum is greatly praised by some authors. It can be given in doses of three or four grains in a teaspoonful of glycerine several times in the day; or the child may suck a guaiacum lozenge every three or four hours. The saherlate of soda is another remedy which has been lately held up as a specific in certain cases of quinsy. This drug, like the preceding, is aspecially adapted for cases which arise under the influence of cold and damp, and may therefore be supposed to be allied in their nature to rheumatism. To a child of ten years old it may be given in doses of ten or fifteen grama every four hours; or half that quantity every two hours. If the salt be

repended in mucilage flavoured with tincture of orange peel, and sweetlied with spirits of chloroform, the resulting mixture is not unpleasant to
tchild. If given sufficiently early, it is often found to shorten, in a rerelation manner, the course of the inflammation, and prevent suppuration.
The old-fashioned treatment by salines, with moderate doses of antimonial
ties, following the indispensable purge, finds favour with many practitionir, and is no doubt often very successful. Attention to the bowels, inthed, must never be neglected. A good dose of calomel, or gray powder,
with colorynth or jalapine, renders the after-course of the disease much less
largeing, and, if all irritation of the throat is avoided, greatly helps the

abent along in his path to recovery.

Astrongent gargles can only be allowed in the early stage of the disease. A solution of alum (twenty grains to the ounce) may be used in this way, but is only admissible if the febrile action is mild, and if the cose is seen which the first twenty-four bours. At a later period, ordinary astringent by a strongent do much more harm than gook. There is, however, an acceptant to this rule, for brushing the surface of the inflamed tonsils with the pure solution of the subaccetate of lead is often attended with surposing relief to the discomfort. This application may be used once in the lay shatever be the period of the illness. Another application which is often of service is the bi-carbonate of so la, applied in the powder. An ormany throat brush, well charged with the powder, may be used to convey be latter to the tonsil.

Directly signs of suppuration are noticed, the child should be made to inblothe steam of hot water, and hot poultices should be sedulously applied
to the threat. If old enough, the child should be directed to gargle fremently with warm water, to which, if there be any fector, a little ('ondy's
lud has been added. If necessary, the matter when it forms can be let
but by a touch of the lancet, but in most cases it will be safe to allow it to
init its own way to the surface. Still, if signs of dyspines are noticed,
the swelling is very large, operative interference is advisable. After the

places has been evacuated, quinme should be given in full doses.

The diet must consist at first of milk and broth. When the difficulty of wallowing becomes great, strong meat essence should be given, and the tength may be supported, if the child appear very weak, by the brandy-ai-zg mixture, or port wine. In cases of the non-suppurative form of the disease, where, although the depression is great, februle action is modified and the inflammation is accompanied by shallow ulcers on the tongue at cheeks, chlorate of potash is very useful, and may be given in doses of the ten grains every three or four hours. These cases also are greatly emitted by purgation, and Epsom salts with quinine form a good combination. A child of twelve years of age will take well two grains of quinine, with half a drachm of sulphate of magnesia, and five drops of dilute sulphores all the symptoms with remarkable quickness. In young children, a glass of port wine, given quite at the beginning of the attack, seems that

In the chronic form of tonsillar enlargement, it is of extreme importance improve the general nutrition of the child. It will be usually found on the provest the suffers from repeated attacks of gastric derangement. Our care must be to improve the condition of the digestive organs by the cass recommended elsewhere (see (iastric Catarrh). A broad flannel bandar, to protect the stomach from chills, is here of extreme importance.

Usually, when the gastric mucous membrane has been restored to a healthy state, the general condition of the child improves, although the size of the tonsils has undergone no diminution. Cod-liver oil and iron wine, or quinine and tonics generally, may be given to hasten the return of flesh and strength. A little alcohol, in the form of light claret, is very useful in these cases. As special internal treatment of the swollen tonsils, Mr. Lennor Browne speaks highly of the influence of a combination of sulphide of calcium and iodoform (half a grain of each), given three times a day, in reducing

cing the size of the glands,

Of local measures, no doubt the best and most effective proceeding is excision. The tonsils having been removed, the tendency to catarrh in a great measure subsides; the digestion improves; the child begins to regain flesh and colour, and the congested state of the mucous membrane, which had been the source of so much discomfort and inconvenience, is at once relieved. The operation is a by no means painful one, and as followed by such immediate improvement that it should be recommended in every case. Often, however, the suggestion is not approved of by the parents, and other means of reducing the size of the glands will have to be resorted to. The tonsils may be painted twice a day with a mixture of equal parts of tinct, iodi and liq. potassie; or once a day with the pure tinct, iodi. Powdered alum may be applied according to Quinart's method, rubbing it into the gland vigorously with the finger; or the throat may be brushed twice a day with glycerine of tannin. These applications are, however, of doubtful efficacy. I have used them myself, and seen them employed by others, but even if the size of the glands is reduced for a time by such means, the improvement is seldom a permanent one. Dr. Morell Mackenzie speaks highly of a paste composed of equal parts of caustic lime and soda with spirit. This is to be applied to different parts of the swollen surface once or twice a week. Other caustics, such as nitrate of silver, Vienna paste, and chloride of zinc (in the stick) have been used, and the galvano-cautery has also been employed. By the use of these agents, small portions of the enlarged and toughened glands are destroyed on each application; but the size of the tonsels is but slowly reduced by this means -indeed, the patience of the child's relatives is usually exhausted before any definite results have been obtained. A more rapid method is that recommended by Dr. Gordon Holmes. A thin stick of nitrate of silver is pressed into the tonsillar crypts, and worked round for a few seconds. Small sloughs are thus formed, which are soon discharged. The process can be repeated every other day, and by this means, with little suffering to the child, for the operation is followed by but little external soreness of the throat, the size of the glands may be quickly and materially reduced. Another plan is to inject a solution of ergotin (; j.-jss. to ; j.) with the hypodermic syringe into the enlarged tonsal. Three to five drops may be slowly introduced into the gland once or twice a week. The operation seems to cause some pain, and is so greatly dreaded by the child that it is difficult to persevere with it for long together. I have never seen a case where the glauds have been appreciably diminished by this means.

French authors recommend sulphurous baths as efficacious in reducing the size of the glands, but I cannot speak from my own experience of

the value of this method of treatment.

CHAPTER VII.

RETRO-PHARYNGEAL ABSCESS.

Commons of matter occasionally form in the loose cellular tissue at the back of the pharynx. The disease is of importance, as the abscess, by its situation, interferes seriously with the functions of respiration and deglatera, and gives use to symptoms which, unless referred to their true once, may be a source of considerable perplexity.

the atter.—Retro-pharyngeal abscess is more common in childhood that in after years, and during the first twelve months than at a later pened of life. In eighty-nine cases collected by Gautier, nearly one-third

of the patients were infants under a year old.

Scrofulous tendences appear to have a powerful influence in favouring the courrence of the disease. In the subjects of this distinction, the abscess isometimes found to occur as a sequel of one of the acute specific diseases—of scarlatina, measles, diphtheria, or crysipelas. Caries of the cervical vertebre, to which such children are prone, may induce it; and it may face tousilhtis, ulcerations about the mouth, or eczema of the scalp or back of the neck. In many cases, however, the cause of the malady is obscure. It has been attributed to exposure to cold, to the action of irritaria such us too hot liquids, and to injury from fish-bones, pins, and is too bot liquids, and to injury from fish-bones, pins, and is too bot liquids. Indeed, such substances

have been occasionally discovered in the contents of the abscess.

Morbol Anatomy. The collections of matter situated behind the postener wall of the pharynx vary considerably in size. Sometimes they are as large as a hen's egg, and may even extend for a considerable distance upwards and downwards. They are not always scated in the middle line; tales, more commonly, perhaps, they are placed at an appreciable distance to me side. They are almost invariably single, and their contents consist of jurient and cheesy matter. Sometimes the abscess may open spontaxonsly. In other cases it may set up ulceration in a large vessel, such as the carotid, and give rise to fatal harmorrhage. Occasionally it has been known to force its way along the cellular tissue of the neck, and open into the mediantimum or the pleural cavity. In a case which was under the care of my colleague, Mr. Parker, in the East London Children's Hospia little boy fifteen months old—the abscess formed a fluctuating swellug, the size of a hen's egg, below and behind the angle of the lower jaw in the right side. There was also a soft, cushiony tumour at the back of be pharvax. After the abscess had been opened externally, pressure on the pharyngeal swelling caused pus to well up through the wound.

In young infants, the primary sent of the suppuration appears to be the barphatic glands which he along the posterior wall of the pharynx. Kormann states that with his finger he has been able to detect enlargement of these glands in certain cases of thrush, ulcerative stomatitis, ozena, etc., but that only in one instance has he known the indammation to pro-

cative of caries of the vertebra of the neck. These sync

described elsewhere (see page 178).

Pain or difficulty in swallowing, is perhips the first sy. The presence of the pharyugeal swelling so interferes will food that the patient may have the greatest difficulty in ment. Liquids can often be swallowed, but solid matter great effort, or not at all. Sometimes the obstacle appear in these cases, the child, if an infant, sucks eagerly for a then suddenly throwing back his head, discharges the atthrough the mouth and nose. As a consequence of the uninterference with nutrition invariably follows, and the child idly. It must be said, however, that cases are sometimes in no difficulty of deglutition is present, and nutrition appearanced by the presence of the abscess.

Dyspnæa is another symptom which is usually to be a occurs at the same time with the preceding. There applied interference with the entrance of air into the lungs, for all the child makes a curious grating or whisting sound, a time the soft parts of the chest sink in, and the epigastri. The dyspnæa varies in degree. It is subject to paroxysal but in the intervals the respiration is far from tranquil, lies down, the breathing is always especially difficult, and therefore particularly noticeable at night. In severe castobliged to raise himself in bed in order to breathe with ease, and may often be found sitting up in his cot with beneath his body. He cries fretfully if disturbed, or invite food or drink, and will not willingly make any attempt of dyspnæa is always increased when pressure is made extilaryex.

Cough is usually present, generally dry and hard, but oxysmal like the cough of pertusais. The voice has a nascially if the swelling is high up in the pharynx. It is seld

case be uncomplicated.

Stiffness of the neck is a characteristic symptom, for head upon the shoulders is always painful. Consequently the head in a curiously rigid way, sometimes inclined to

filled with fluel, but may feel firm like a solid growth. The finger should be passed round the horders of the prominence so as to define its limits. The swelling does not always come into view when the mouth is opened; for not only is it often obscured by more or less frothy mucus, but its situation may be such that it is not readily discovered. If, then, we suspect its existence, the finger should be rapidly passed upwards to the back of the nose, and downwards behind the glottis. By this means the position of the abscess can usually be ascertained.

The above symptoms are to be discovered in most cases of the disease; but the course and form of the illness vary greatly according to whether

the suppuration is an acute or chronic lesson.

In an acute suppuration behind the pharynx the symptoms are very much more pressing and severe than in the more chrome form of retropinryngeal abscess. The disease generally begins with high fever, severe headache, and vonuting. After a few days, stiffness of the muscles of the neck is noticed, with a peculiar fixed position of the head, and there may be swelling of the neck and great tenderness. In some cases, the stiffness extends to the muscles of the jaw, so that the mouth can be opened only imperfectly. At the same time, or soon afterwards, there is difficulty in swallowing, and the breathing is laboured and stertorous. If the child is had down these symptoms are increased, and often the recumbent position induces a state of somnolence approaching to stupor. If the symptoms are not relieved, the condition of the child becomes more and more distressed, His face is swollen and lived, and the jugular veins are prominent. He lingers for a few days in this state, and then dies, exhausted from manition, or sufficiented in a paroxysm of dyspinos. Death is often preceded by a series of convulsive attacks.

In the more chronic cases, there is little or no fever, and the symptoms generally are much less argent. There is, however, usually a noticeable

interference with nutrition, and the loss of flesh is considerable.

The duration of the disease varies greatly. In some cases it runs a very acute course, and ends fatally in a fortught or three weeks. This form is most common when the suppuration occurs as a sequel of fever. In other cases, the dysphaga and dysphagas continue for months before

their true significance is realised.

A little girl, aged three years, was brought to me at the hospital for difficulty of breathing. The mother stated that two years previously, while teething, the child had suffered from an eruption on the head. This had been quickly followed by a swelling at the right side of the neck, which, after growing larger for two months, had burst. Very shortly afterwards the breathing had been noticed to be oppressed, and the respiration had begun to be accompanied by a peculiar whistling or rattling noise. This symptom had continued ever since, and was always worse at night. The child was said to sleep very heavily, with her eyes only partially closed. Sometimes she had seemed to have a difficulty in swallowing.

When first seen, the child was lying asleep, resting on the right side of her chest. She was sweating profusely about the head and neck. Her face was flushed, and the eyes were only partially closed. The mouth was open, and the narcs were notionless in respiration. At each breath the intercostal spaces sank in deeply, and the epigastrium was depressed. With each inspiration a peculiar grating noise was heard, which seemed to proceed from the throat. The expirations were less noisy, but still abnormal. The glands along the edge of the sterno-mastoid, and those below the jaw.

were enlarged and painless, and the larynx and traches seemed pushed out of the middle line to the left.

On inspecting the fauces, a swelling about the size of a plover's egg could be seen at the back of the pharynx. On pressing this with the finger, it felt firm like a solid tumour.

The swelling was punctured with a large trocar and canula, and half an ounce of thick pus was evacuated. After the operation the breathing became quieter, and swallowing was effected without difficulty. The absences continued to discharge for some days and then healed. When the child left the hospital she seemed well in health, but some thickening remained at the back of the pharynx.

In this case, the disease had lasted for two years, and was apparently the consequence of slow softening of a cheesy gland at the back of the pharynx. The cervical glands were also enlarged and caseous; and from one of these, scated behind the angle of the jaw, a quantity of cheesy matter was scooped out by my colleague. Mr. Reeves.

Whatever be the length of its course, a retro-pharyngeal abscess, if unrecognised, generally terminates in death. As has been before remarked, the child usually dies suffocated in a paroxysm of dysphora, or gradually wastes away from starvation and exhaustion. Even spontaneous bursting of the abscess appears to be attended with great danger, and cases are reported in which suffocation has been the consequence of the passage of the purulent matter into the traches.

Durquosis. — Amongst the various causes of dyspaces in the child, it must not be forgotten that retro pharyngeal abscess is one; and in every case where the breathing is difficult and stertorous, the pharynx should be examined as a matter of routine. If this be done, the diserse is not likely to be overlooked, for a finger passed to the back of the pharynx at once detects the presence of the abscess. Moreover, information may be sometimes gained from mere inspection of the neck. Any unusual prominence of the traches, or displacement of that tube to the right or left of the maidle line, suggests an extra-laryngeal cause for the dysparea. So, also, if we find the child sitting up in bed and refusing to lie down; or if laid down, starting up again in an access of suffocation, we should suspect external pressure upon the larynx. The more characteristic symptoms are : Stiffness and swelling of the neck, and difficulty of swallowing, combined with orthopnos and studulous breathing. The most characteristic sign is a swelling at the back of the pharynx, which is not, indeed, always to be seen, but can invariably be felt by digital exploration.

The disease is more likely to be misapprehended in the acute than in the chronic form; for the violence of the symptoms, the lividity of the face, the urgency of the dyspinea, and the stertorous character of the breathing, suggest the presence of membranous croup. But in that disease, stertor is present from the beginning; the dyspinear is not increased by pressure made upon the trachea, and is relieved when the head is low; the voice rapidly becomes hourse and then whispering; and unless the pharynx be the seat of false membrane, there is no difficulty in swallowing.

Edema of the glottis also presents many points of similarity with abscess of the pharynx; but in the former case the strider is only marked in inspiration, the expiration being noiseless; and when the finger is passed into the threat it detects no tumour, but can feel the thickened epiglottis and the swellen ary-epiglottidean folds. Still, the two deceases may be present together; but if a tumour can be felt at the back of the pharynx on digital examination, the nature of the disease cannot be doubtful.

Prognosis.—If the abscess is detected in time, the prognosis is favourable. When death occurs in this disease, it is usually in cases where the case of the symptoms has been overlooked, and no attempt has been made to relieve the child by the only means which are likely to prove effectual. The worst cases are those in which the abscess is the consequence of curous disease of bone; but even these may end in recovery if the

matter be evacuated before the child has become exhausted.

Treatment.—In the treatment of retro-pharyngeal abscess, no time should be list. Directly the tumour is recognised, it should be opened, whether furtation be present or not. In order to avoid any risk of penetration of the pass into the larynx, it is perhaps safer to use a large trocar and canula but the abscess may be opened with a knife without danger if care be taken to bend the child's head promptly forwards when the incision worde. The bistoury should be guarded to within half an inch of its pent by winding adhesive plaster round the blade. The opening must be made as near the middle line as possible; and the instrument may be pushed boldly forwards, for the pus often lies at some distance from the surface. If a trocar be used, the abscess sometimes refills, and may require a second puncture after a few days.

The general health of the child must be attended to. Good diet and a certain quantity of stimulant should be allowed; and he may take quinine and old liver oil. When convalescent, the patient will be benefited by a

wat to the seamde.

Part 9.

DISEASES OF THE DIGESTIVE ORGANS.

CHAPTER I.

INFANTILE ATROPHY.

INFANTILE atrophy, or the slow wasting which is a familiar symptom a hand-fed babies, is one of the commonest causes of death in early miner. The child ceases to digest his food—possibly he has never begun to desegradually dwindles away, and after a longer or shorter period, desegradually dwindles away, and after a longer or shorter period, desegrad half the symptoms of starvation. This condition, which, under the name of marasinus, finds a large place in the mortality returns of all countries is a perfectly curable complaint, and may be arrested at almost any star by the exercise of judgment and care in the feeding and general many-ment of the infant.

Causation.—Infantile atrophy is the consequence of insufficient near-timent. The child wastes because he is starved. But it is not to actualize the child wastes because he is starved. But it is not to actualize the feeding that the starvation is usually to be ascribed. A table food from a breast which secretes milk poor in quality and insufficient to the child's support, will, of course, grow slowly thinner, but an infantise piled largely with farinaceous compounds from which his feetile days. It organs fail to derive even a minimum of nourishment, will waste with parting rapidity. Starvation is then a relative term. The tissues may be starved, although the stomach is regularly filled. In every case, the partition of the infant is dependent upon his power of extracting a sufficient of nourishment from his so-called "food." It may seem uninconstant insist upon so self-evident a matter; but in practice it is common to have about the child to understand that feeding and nourishing are not quite the same thing.

For efficient nourishment, four classes of substance are indispensively, albuminates, hydro-carbonates, fats, and salts. It is further necessare that these should be presented to the child in such a form that they can be digested with case. The most perfect food for infants, the order fact, which can be relied upon in itself to furnish all these requirements and malk. Milk contains nitrogenous matter in the curd, fat in the cream of

sides sugar and the salts which are essential to perfect nutrition. In the milk of the mother or of a good nurse the new-born infant finds these elements combined in exactly the proportions best adapted to supply all the wants of his system. In the milk of animals, the proportions deviate more or less widely from the human standard. Cow's milk, especially, contains a larger proportion of card and cream than is found in human milk, but less augar; and although to an exceptionally sturdy infant this difference may be immaterial, for a child of ordinary powers it will be necessary, by suitable preparation, to bring the milk into closer resemblance with the

natural diet of which he has been deprived.

The chief obstacle to the digestion of cow's milk by young babies is not, however, the mere difference in the proportion of the several constituents. Were this so, dilution with water and the addition of sugar of milk would be sufficient to perfect the resemblance between the two fluids. A more important difference is the denseness of the clot formed by the curd of now smilk. Ample dilution with water does not affect this property. Under the action of the gastric jurce, the particles of casein still run together nato's solid, compact lump. This is not the case with milk from the breast. Human milk forms a light, loose flocculent clot, which is readily disintegratal and digested in the stomach. The difficulty which even the strongest children find in digesting cow's milk, is shown by the masses of hard and which a child fed exclusively upon this diet passes daily from the bowels. This difference between the two milks is answerable for much of the tomble and disappointment experienced in bringing up infants by hand. But it is not merely new-born infants for whom a diet of cow's milk is inappronate. Gastrie and intestinal disorders often date from the time of rewing; and this is partly the consequence of an abrupt change from human to cow's milk in cases where little or no care is taken to make the het a digestable one. The heavy curd of cow's milk is often difficult of hastion, even by children of ten or twelve months old, if they have been accustomed only to the breast; and unless measures are adopted to hinder the arm clotting of the casein, serious dangers may arise.

The difference in the constitution of the milk of the woman, the cow, the ass, and the goat, are seen in the following table prepared by MM. Ver-

Buts and Becquerel :-

	Sp. Gr.	Water.	Solida	Sugar.	Casein an I Ex- tractives	Butter,	Salts.
Coman.	1032.67	889.08	110.92	43,64	39.24	26.66	1.38
Com.	1033.38	864-06	135 94	38,03	55.15	36.14	6.64
Ariss.	1034.57	890.12	107.88	50,46	35.65	18.53	5.24
Gentat	1033.53	844.90	153.10	36,91	55.14	56.87	6.18

The milk of the ass approximates most nearly in composition to that of the human breast, and is much more digestible than the milk of the cow. The goat yields a milk which chemically resembles very closely that the cow, but in practice it is found to be far more digestible by the child. This is no doubt due to the looser clot formed in the stomach by coagulated curd.

As cow's milk diluted with water is considerably less digestible than the

milk of the human breast, it is not surprising that a weakly child should fail to derive sufficient nourishment from such a diet. If he be fed web large quantities of farinaceous food, his difficulties are still further in creased. The new-born infant has only a feeble capacity for digestra: starch. His salivary secretion is excessively scanty, and his paneros or scarcely be said to furnish any secretion at all. According to the capen ments of Korowin, of St. Petersburg, it is not until the end of the thank month after birth that the pancreatic fluid is found to have any appreciable action upon starch. The two secretions upon which the digestion of start chiefly depends are therefore almost completely absent in early infancy by it is to a being quite unprepared by unture for this diet that farmaceous substances under the misleading name of "Infants' Foods" are so more sally given. Many babies are fed with them exclusively from their tarts. others take them in large quantities as an addition to the breast-ank. In either case, the meal is in great part undigested, and gives rise to much that lence and pain in its passage along the alimentary canal. It must be better in mind that the effect of an indigestible diet is not merely the within it. ing of nourishment. To the weakness of starvation or semi-starvaten must be joined the additional weakness induced by catarrh of much membrane from the constant passage along the bowel of undigested and fermenting food. The irritation thus set up gives rise to repeated attack of rounting and diarrhosa; and even between the attacks, although the irritation is for the time less severe, the child is restless and unconfict able, crying and whining, and unable to sleep from the colicky prize it be belly. Unfortunately for the infant, this consequence of his mountain diet is often mistaken by ignorant or too anxious attendants for same of hunger; and while the poor sufferer is still labouring to dispose of his as meal, another supply of food, which his craving forces him eagerly to said low, increases his difficulty and discomfort. It is not, then, surprise that the infant, extracting no nourishment from his frequent meals, growed the thinner and more feeble, and sinks at last, worn out by purgang, pain and want of sleep.

The symptoms of indigestion which always precede the more prenounced signs of infantile atrophy, sometimes come on quite suddenly well unexpectedly in an infant who has been fed with judgment, and has a first appeared to thrive. The falling off is due, in the majority of cases to some casual derangement of the stomach and bowels which in luces as acid change in his food. The child consequently ceases to be acid to be gest his milk. The fluid undergoes fermentation in his stomach, and exerates an acid which irritates the delicate unicous membrane and incress the disturbance of the digestive organs. Severe symptoms are often up consequence of this indigestion, so that, unless timely measures are tails to avert the danger, the child's life may be sacrificed. An attack of second tric catarrh, induced by a slight chill, is the commonest cause of the as den indigestion; but sometimes the derangement is the result of our feeding, the child's meals being too large or too frequently repeated. again, the feeding apparatus may have been neglected, so that mill pot into a durty, sour bottle, has begun to ferment before the child available! In warm weather, milk soon becomes sour, even in clean vessels, miled. if some time have clapsed since the milk was drawn from the uddet if may be delivered at the house in a slightly send state, although appearant to be perfectly fresh to the eye, the smell, and even to the taste.

There is one other cause of infantile indigestion and bowel complete which should be mentioned, as the fault is a common one. In boundary

there it is the custom to prepare for the infant in the morning the whole ay's supply of food, an acid change in the mixture almost invariably takes bace, so that in the afternoon or evening the food is no longer it for the half's consumption. The change may occur without necessarily producing any alteration appreciable by the senses. Test paper will, however, it wacidity, and the microscope will probably reveal bacteria in active tection.

A derangement of the stomach and bowels, occurring suddenly from the first three causes, not only interferes with the infant's nutrition for the time but often produces much more serious consequences. It may set up a border in the digestive system which is never afterwards recovered from and start a process of gradual wasting which ends only with the death of the child. It is, indeed, in incidents of this kind that the chief danger of artificial feeding consists; for a diet arranged originally with the and judgment ceases to be appropriate in these altered conditions. As immediate change, is imporative if the derangement is to be remedied; and for some time afterwards a careful watch must be kept over the in-

fut subgestion, lest the disorder return.

Infantile atrophy is seldom seen to any serious extent in infants at the bread, but sometimes a certain degree of malnutrition is observable in bukes who take no other food. This may result from different causes. As agant may be consigned to a wet-nurse whose own child is much older thin her adopted suckling. It is well-known that, as time passes, human salk becomes proportionately richer in curd and cream. An infant, newborn and with naturally feeble digestive power, put to the breast at a late perod of lactation, may consequently fail to thrive; or may even suffer indigestion and bowel complaint through the richness of the milk. Ague, in some women, the milk, although abundant, is of poor quality, and had ient for the support of a strong baby, so that the child soon shows *As of deficient nutrition. Human milk is also affected by dietetic and customal causes, and the secretion is apt to be influenced by the general state of health. There are many reasons, therefore, why a child, even while at the breast, should be subject to casual derangements. Still, these are assally trifling, and seldom produce any serious effect upon his nutrition.

It sometimes happens that a mother's milk is not well suited for the normalment of her offspring, even in cases where the secretion is copious, the child a sturdy boy, and the health of the mother in every way satisfacfor Some years ago I was asked by a gentleman to go and see his child a hitle boy of seven months of age. I found that the child had been sufficing for some weeks from severe abdominal pains. He was excessiveby perush and fretful, and at night would wake up with a scream, and twist about his body under the influence of severe griping pain. His bowels were very confined, and the motions consisted almost entirely of curd. He was taking nothing but the breast. Aperients had been found to relieve the cald for a time, but the symptoms always returned when the effect of the purgative had passed away. Whenever the breast was stopped for a lew lays, he immediately improved, but relapsed as soon as suckling was resumed. The child had lost flesh, and was evidently suffering from his inability to digest the curd of his mother's milk. It was therefore a matter of great importance to enable him to do so; otherwise he would have to be remail, and fed in a different way. The mother had herself, by taking salines and other medicines, and by making many modifications in her diet under pedical advice, endeavoured to alter the quality of her milk, but without MICCOSUL

Several methods of remedying the evil were tried. The intervals between the times of suckling were increased, so as to give a longer period for digestion; but this change had no effect whatever. Alternate meals of barley-water were then given from a feeding-bottle. By this means, the quantity of milk taken by the child in the course of the day was diminished, and the interval between the times of suckling was still further increased. No improvement, however, followed the alteration. The griping pains still continued, and the constant fretfulness of the child was most distressing to the mother. The plan was at last adopted of giving the child barley-water from a bottle immediately before he took the breast, in the hope that by this means the milk might be diluted directly it reached the stormen. This method succeeded perfectly, and the child had no further unpleasant symptoms.

In this instance, the infant's stomach was in a perfectly healthy state. The fault lay in the mother's milk, which was too heavy for the child's powers of digestion. In the large majority of cases of indigestion in infants reared at the breast, the fault is in the digestive organs of the child, an attack of gastric catarrh having rendered him for the time incapable of digesting his mother's milk. In these cases, the indigestion is a temporary failing, and is easily remedied by suitable treatment. Without judicious management, the derangement may be prolonged indefinitely; and it not unfrequently happens that the mother is directed to wear her baby under the mistaken

notion that her milk is untit for its support.

Morbid Anatomy.—In cases of death from infantile atrophy, the tissues are found excessively wasted, and there is complete absence of adipose tissue from the body. The general pathological appearances are such as have been already described as common to cases of thrush (see page 572).

Symptoms.—When a child at the breast depends for his support upon a scanty supply of poor milk, he suffers no pain, but wastes persistently. The infant is peevish from hunger, and at times cries violently. For the same reason he sleeps little, and at night is very troublesome. In the day-time he often lies quietly sucking his tingers until they are raw. His fontanelle is level or depressed; his skin is moist; his bowels are confined; the motions scanty and often almost solul. He soon becomes pale and flabby, and does not grow. If the milk, although poor and watery, is abundant, the child frequently requires the breast. He sleeps much, and often is found asleep with the nipple still in his mouth. This, indeed, is a common sign of watery milk. If noticed in a child who is not thriving, but in whom no positive derangement can be discovered, measures should at once be taken to change the nurse, or supplement the breast-milk by a suitable dist.

In hand-fed babies, infantile atrophy is often seen in its most extreme degree. A child fed with unsuitable food is not only starved, but is kept in a state of continual distress; so that we find persistent wasting combined with symptoms more or less striking of gastric and intestinal dis-

turbance.

The loss of flesh is noticed from the very beginning. Its rapidity depends partly upon the kind of food chosen; partly upon the natural strength of the child, and his capacity for extracting nourishment from his unwholesome diet. A puny infant, fed with large quantities of arrow-root, or other equally inappropriate food, wastes very rapidly, and at the end of two or three months, if he lives so long, may actually appear to have made no advance in size or in strength since his birth. Such an infant is pale and miserably thin, his skin is dry, and has a faint yellow that; his eyes are hollow; his cheek-bones project; his lips are livid, and their

alightest movement shows a deep furrow encircling the corners of the mouth; his expression is uneasy and languid; his feet and hands are habitually cold, and he whines and cries fretfully for hours together. These children often have a ravenous appetite for food, and will swallow greedily whatever is offered to them. The meal, however, produces merely a temporary relief, and as soon as the griping pains to which it gives rise make themselves fell, the child's wailings are renewed. The abdominal pains excited by the indigestible nature of his food are often very severe. The infant may become quite stiff and rigid from his suffering, and scream with white, drawn face and staring eyes until exhausted. Sometimes the griping gives rise to a convulsive fit, although this is rare, but the irritation of the bowels, and acidity, not unfrequently excite signs of nervous irritation; we notice sudden starts and twitches, a slight squart, a peculiar rotation of the eyeball upwards, and contractions of the tingers and toes.

Eruptions on the skin, such as strophulus and urticaria, are common; and in the later stage of the illness, aphtha or thrush may appear in the

mouth. The state of the bowels varies. It is probably dependent upon the degree to which the mucous membrane is irritated by the child's unsuitable diet. If this irritation be only moderate, the bowels are usually confined. The infant is restless, and may be noticed to be feverish at night. His tongue is coated with a thick white fur. He is evidently in a state of great discomfort, for his temper is pecvish and fretful, his movements are uneasy and jerking, and he occasionally breaks out into piercing cries, drawing up his knees and twisting about his body under the influence of abdominal pain. At night the griping is especially violent; the child scarcely sleeps at all, or if he be quiet for a moment in uneasy sleep, he soon starts up again, screaming with a fresh attack of pain. The motions are scanty and rare. The bowels sometimes remain confined for twentyfour hours or longer, and when they are at last relieved, hard, clay-coloure I balls, tinged with green mucus, are expelled with great effort and straining. These balls consist of hard curd and farinaceous matter. A full dose of castor oil, which clears away the curd, allays the symptoms for a time; but usually, if the same diet be persisted in without any change, they return in a day or two, and the child is in the same distress

In almost all cases of infantile atrophy, the ordinary uniform course of the derangement is interrupted by intercurrent attacks of vomiting and diarrhoes. These attacks not only greatly increase the impidity of the wasting, but, if of great severity, may bring the illness abruptly to an end.

Troublesome vomiting in a young baby, the consequence of gastrac catarrh, is a very serious ailment. All food swallowed is instantly returned, and clear fluid, like water, or bile-stained micus, is occasionally ejected. The vomited matters, and even the breath of the child, have an offensive, sour smell. The belly is swollen and often seems tender; the hands and feet are very difficult to keep warm; the eyes grow quickly hollow; the hids close imperfectly; the complexion is sallow or half jaundiced, and the fontanello is deeply depressed. At first the tongue is thickly furred, later it is not to have a red, glazed appearance. The child is very fretful. He soon becomes too weak to cry loudly, but whimpers feebly to hunself in a pitiful way, and scarcely seems to sleep at all. If no diarrhear complicate the ailment, the bowels are confined, and the patient often seems to be disturbed by flatulence, for he draws up his legs uneasily

with a troubled grimace. If treatment do not succeed in checking the disorder, the vomiting continues, and is excited by the least movement The complexion becomes earthy, the hands and feet grow purple, and the temperature in the rectum may fall as low as 96 or 97. At this period, thrush usually appears in the mouth, and death may be preceded by

symptoms of spurious hydrocephalus.

Steady, persistent vomiting such as has been described, is less common. than are shorter attacks of sickness accompanied by diarrhoa. These are apt to occur in children at an early period of the atrophy, and must be looked upon as an effort of nature to relieve the alimentary canal of its unwholesome burden. It is only at a later period of the illness that ther are ant to become obstinate, and when thus confirmed, the ailment is very difficult to overcome. A chronic diarrhosa, such as is elsewhere described (see page 633), often arises in the course of infantile atrophy, and, if not treated judiciously, determines a fatal issue to the illness. In most cases indeed, death is the consequence of a persistent looseness of the bowels which nothing will arrest. But, in an infant reduced to a weakly state by a long course of improper food, any acute ailment, however apparently trifling it may be, will often prove fatal. A new symptom occurring at a late period of atrophy is therefore to be regarded with very serious ap-

Diagnosis.—A state of extreme emaciation may be present in the infant as a result of other causes than injudicious management and unwholesome feeding Infants, the subjects of inherited syphilis, are often excessively puny and feeble, and acute tuberculosis may attack a child of a few months old and gravely impair the nutrition of the patient.

In the first case, the symptoms induced by the syphilitic poison are sufficiently distinct. The child snuffles and cries hoursely. His skin is dry, wrinkled, and of the colour of old parchment. It is sprinkled over with the characteristic coppery or rust-coloured spots, and the buttocks and perimeum, often, also, the genitals and upper parts of the thighs, are the colour of the lean of ham. Mucous tubercles are probably to be discovered at the margin of the anus and the lips. The corners of the mouth are fissured, and the nostrils red-looking and excorated. The bridge of the nose is flattened, and an examination of the belly will probably detect enlargement of the spleen. None of these symptoms are to be found in simple infantile atrophy. The earthy tint of the face and body sometimes resulting from chronic digestive trouble is very different from the purchment-like hue of the inherited disease; strophulus, arising from the same cause, can hardly be mistaken for the coppery spots of syphilis; and hourseness, snuffling, and the other symptoms which have been enumerated, are never the consequence of weakness and wasting, however profound.

In acute tuberculosis, the temperature is elevated, and a thermometer in the rectum will be found to mark 100° or 101° in the evening. In infantile atrophy, there is no pyrexia; on the contrary, the bodily heat is usually lower than in health. Moreover, in the former disease, the child coughs, and even if the lungs are not the seat of pneumonia, a cheking rhonchus will be discovered here and there about the chest. In tuberculosis, too, a slight amount of cedema of the legs is almost invariably

present in the infant.

Syphilis and tuberculosis having been excluded, the diagnosis is easy. The wasting must be due to chronic digestive derangement, or to unsuitable food, or to both of these causes combined. In the case of either chronic vomiting or chronic diarrhuea, the characteristic symptom of these

be using as extreme, there is no irritability of stomach, and the bowels to be builtually confined. In these cases the child is previal and fretful. In these cases the child is previal and fretful. In belly is distended, and his skin dry and dull-looking. The most line merching the corners of his mouth is well-defined. His feet are often sold, and the bodily temperature in the rectum is sub-normal (97°-97.5°). His stools consist of hard light-coloured balls, or of unformed putty-like matter. The child is subject to attacks of abdominal pain, and is very

now and troublesome at night.

Progress. Unless the infant be reduced to a state of extreme weakass and depression, the prognosis is not unfavourable. It is often surprising to mark the immediate improvement which takes place when the child
is just to the breast, or is supplied with a food he is capable of digesting.
It sens of spurrous hydrocephalus have been noticed, if the mouth be the
cat-of thrush, or if a chronic diarrhox have been established, the prognoas is more serious, and, indeed, these cases often end unfavourably.
Chome vomiting, however, can usually be arrested by judicious treatment,
if the infant retain sufficient strength to respond to the restorative measare adouted.

Treatment.—In endeavouring to improve the nutrition of a child who a suffering from infantile atrophy, we have to take into account the degree of reakness of the infant, and the more or less disordered state of his digestre organs. If a wet nurse can be procured, a return to the breast, if the dad can be persuaded to take it, usually arrests at once all unfavourable supptoms; especially, if the alteration in the mode of feeding be aided by a sprient dose of castor oil, followed by an antacid and stomachic mixture. In many cases, however, this method of treatment is not within our each and we have to trust to a judicious revision of the child's dietary

and general management.

The successful rearing of an infant by artificial means is not a difficult matter. It requires intelligence and tact; but, above all, it requires watch-blaces. If we are vigilant to detect the first signs of discomfort and acidity and at once modify the diet accordingly, we may be sure of preserving a healthy tone in the stomach, and warding off all the accidents to

which a child less carefully nurtured might possibly succumb.

buring the first month after birth, the infant usually is able to obtain the malk from its mother's breast. This, however, may have to be supparented by other food, and sometimes the babe is forced to depend entirely upon artificial feeding from the beginning. For the first six weeks he may be fed with condensed milk diluted with water, or thin barely-vater, in the proportion of one teaspoonful of the milk to the half bother Preserved milk at this time almost invariably agrees well. Care must, bowever, be taken to use only milk from a tin which has been newly-opened; for when exposed to the nir, the milk, although still apparently lash, rapidly breeds bacteria, and becomes unfit for the child's consumption. In hot weather, too, the barley-water should be freshly made twice in the day. Like the condensed milk, it must be kept in a refrigerator or other cool place, and should never be heated to the boiling point after it has once been made, as to do so excites rapid fermentation.

After six weeks, or, at the most, two months, have elapsed from birth, the thill should be put upon cow's milk. It is important, especially in warm sewher, that this should be perfectly fresh. If slightly acid from keep-me, and often is when delivered at the house, the acidity should be neutral-

by the addition of a little carbonate of soda.

To make this milk an efficient substitute for human breast-milk, it will not be sufficient to sweeten it with sugar and ddute it with water. It is necessary, in addition, to prevent the firm clotting of its curd under the action of the gastric juice. This may be done by using lime-water to delute the milk, adding it in sufficient quantity to partially neutralise the gastric secretion, and thus in a great measure prevent coagulation in the stomach. To do this effectually, at least a third-part of the mixture should consist of lime-water. To two tablespoonfuls of fresh milk, add an equal quantity of hot filtered water, and alkalmise by two tablespoonfuls of hime-water. The infant should suck this food from a feeding-bottle. Its temperature when taken should be 95°. If too cool after being prepared, the feeding-bottle should be allowed to stand for a few minutes in a little basinful of hot water.

Another plan by which the casein of cow's milk may be made digestible, consists in mechanically separating the particles of curd by the addition of some thickening substance, such as gelatine or barley-water. This method of preparing the milk is to be preferred to the previous one, as it leaves the gastric juice unaltered, and does nothing to impair the child's digestive power. It merely forces the curd to form a multitude of small clots, instead of running together into one large, dense lump. For a chili of two months of age, the milk should be diluted with an equal quantity of burley-water, and be sweetened with a small tenspoonful of sugar of milk.

The proportion of milk taken by the infant for each meal should be gradually increased as he grows older. From a half, the quantity may rise by degrees to two-thirds, and then to three-fourths, and a larger quantity of milk-sugar may also be added.

Barley-water rarely disagrees even with the youngest infants, although in them the capacity for digesting starch is very feeble, as has been already explained. If preferred, however, instead of barley-water, the milk may be diluted with plain water, and the thickening material be supplied by a teaspoonful of isingless or gelatine. Mellin's food, too, may be used from the first, and is almost always well digested.

Farinaceous matters, unless guarded by malt, as in Mellin's food, should

not be given to a child younger than six months.

The milk prepared in one of the ways described must be given in suitable quantities and at regular intervals. Six or eight tablespoonfuls will be enough to make a meal for an infant of four or five weeks old. The child should take his food half reclining, as when in his mother's arms, and the bottle must be removed directly its contents are exhausted. After taking his food, the child should sleep for two hours. Any sign of fretfulness or discomfort at this age must be taken to imply indigestion and flatulence. If this be the case, a tenspoonful of some aromatic water, such as cinnamon or dill, may be added to the next bottle of food. The feeding apparatus must be kept perfectly clean. It is well to wash out the bottle directly after it has been used, with sods and water, and then to let it stand in cold water until again required. It is desirable to have two bottles and to use them alternately.

When the child is six months of age he may begin to take farinaceous food. A teaspoonful of Chapman's entire wheaten flour, baked in an oven, can be given once or twice a day, rubbed up, not boiled, with milk. If there is constipation, a similar quantity of fine oatmeal may be used instead of the flour. When the farinaceous food is first begun, a teaspoonful of the flour rubbed up with milk can be added to the meal of milk thick-

and with Mellin's food. Later, the flour can be given with milk as a sep-

No beef-tea or broth should be allowed until the baby is at least ten touths of age. At that time he may begin to take weak beef, real, or atten broth, and may also have the yolk of an egg lightly boiled, or saten up with milk in the bottle. The child may take light pudding at age of twelve months, but no meat for several months longer.

All changes made in the diet from the earliest period to the latest bould be made cautiously, and their effect carefully observed. If the scal appear to excite indigestion and flatulence, the new food must be twen on the next occasion in smaller quantity, or we may wait for a week

before giving it a second time.

Scrupulous cleanliness, and the purest air attainable, are of great importance. The child should be washed over the whole body twice a day—were with soup. He should wear a flaunel binder round the helly. No lope or soiled huen should be allowed to remain in the nursery, and the radow of the room should be kept open as much as is practicable. The fafant should be taken out of doors for several hours in the day; and while they care is taken to guard his sensitive body against sudden changes of temperature, he must not be covered up by too-heavy clothes, and shut off from every breath of air for fear of his catching cold. A child ought to lie tool at hight, and the furniture of his cot, although sufficiently thick to aske necessary warmth, should not be cumbersome so as to be a burden.

The above directions, strictly carried out, will be found to succeed in most cases where the child's digestive organs have not been irritated and reasonable means. Often, however, the infant only comes under observation after attempts—more or less injudicious—have been made to mar him, and advice is sought because the measures adopted have been hard to be unsuccessful. Exceptional cases are also sometimes met with, were the infant from the first is unable to digest cow's milk. However arefully the food may be prepared, each meal either excites vomiting, or produces great accility and flatulence, and the general nutrition of the child

me mes gradually impaired.

In every case of milk indigestion, we should inquire carefully as to the

stowed upon cleanliness in the feeding apparatus.

The inshility to digest cow's milk may be a natural peculiarity of the that or a merely temporary incapacity arising from a disordered state of the ingestive organs. In the first case, if a wet-nurse cannot be procured, or is objected to, we may give the milk of the goat or ass. Either of these Is really well digested by children who find cow's milk too heavy. The wilting of a third or fourth part of barley-water still further increases the distibility of the meal, and Mellin's food may be dissolved in the mixture with advantage. Both these milks should be boiled before being used. has milk sometimes has laxative properties which boiling will remove. Be the same means the strong flavour of goat's milk may be diminished, although this is often not objected to by the infant. An aromatic, such as sample of tenspoonfuls of cinnamon water, added to the milk, seems often to supply a stimulus to digestion; and I have known infants who were invariably troubled with flatulence and discomfort after a meal of plann my milk and barley-water, digest perfectly the same mixture when thus constraint. If test paper show slight acutity of the milk, a purch of biansuate of soils should be always added to the bottle.

Condensed milk is often recommended in these cases, and is usually

well digested, but the nourishment it supplies is very insufficient for a growing baby. The child may get fat, but is usually lethargic and dult A)though big, he is not strong; and unless the milk be largely supplemented by Mellin's food, the infant will probably drift into rickets before he is seven or eight months old. The same may be said of the other foods containing preserved milk, as Nextle's and Octth's Swiss milk food. They are often more easily digested than undiluted cow's milk, but after the first few months should not be rehed upon to supply the whole nourishment of the baby. In all cases it is advisable to revert to fresh cow's milk as soon as this can be done with safety. There is another reason why an infant should not be allowed to derive his whole nourishment from timed and preserved foods. It is now a recognised fact that hand-fed babes are hable to a form of scurvy, and if the child be entirely deprived of fresh milk and other anti-scorbutic foods, this consequence of injudicious

feeding is very likely to be brought about (see page 253).

It is in cases where ordinary cow's milk is digested with difficulty that Dr. Robert's plun of pancreatising the milk is so valuable. Pancreatised milk is prepared in the following way: To a pint of new cow's milk is added half a pint of boiling water, two teaspoonfuls of Benger's pancreatic solution, and twenty grains of bicarbonate of soda dissolved in a bule water. The whole is stirred up in a jug, which is afterwards covered, and then placed in a warm situation under a "cosey." At the end of an hour, the contents of the jug are emptied into a sauce-pan, and the mixture is builed for two minutes to stop further action of the pancreatine upon the milk. The food is then ready for use. It may be sweetened to the child's taste with sugar of milk. In milk so prepared, the casein is peptonised by the action of the pancreatine, and the main difficulty in the digestion of the milk is removed. This method is, in my opinion, far preferable to that suggested by Prof. Frankland. In the latter method (artificial human mill), the cow's milk is diluted with a third part of whey, and no doubt by this means the normal proportion of casein in woman's milk may be exactly imitated; but the process does nothing to render the stiff curd more digestible, and the firm clotting of the case in is just the difficulty which it is so essential to overcome.

A temporary incapacity for digesting milk on account of gastric derangement, is a common phenomenon in the young child, and, indeed, is the most frequent cause of failure in hand-feeding. If a change be rot made in a diet which evidently disagrees, it is not long before a catarrie of the gastric mucous membrane becomes established. This derungament, when once confirmed, is not always easy to control, and, if very stringent measures are not promptly taken, may lead to the death of the child. A mild form of gastrie disturbance sufficient to prevent the digestion of nulk, is not unfrequently met with, even in children at the breast It is indicated by a sour smell from the mouth, a slight sallow tinge of the skin, and by the vomiting of each meal directly after it has been swallowed. Sometimes the bowels are relaxed, from participation of the intestinal mucous membrane in the derangement. A condition such as this may exist almost from birth. It is a common accident in hand fed babies and if neglected, leads, as has been said, to serious and perhaps fatal consequences.

In children at the breast, the derangement is usually quickly remedied by the administration two or three times a day of a few grains of bicarbonate of soda, and half a drop of the tineture of nux vomica, in a tenspoonful of some aromatic water. In infants artificially fed, the disorder is not so easily cured, and a complete change in the dict will be required. The purceatised malk is very useful in these cases, and in conjunction with the hadine mixture just referred to, will often quickly restore the digestive extans to a healthy condition. If this do not succeed, it will be necessary as stop all malk-food for a day or two. The youngest infants bear a temperary deprivation of milk exceedingly well; and when, as in the derangement spoken of, the symptoms are the direct consequence of fermentation and healthy, a withdrawal of the fermentable material is followed by implication of the symptoms. Even in the most obstinate and protracted cases of gastric derangement in young babies, the withholding of malk-food, combined with proper measures to support the strength and maintain the heat of the body, will be generally successful in restoring the infant to health. The same treatment is of equal service in cases of severe

acute gastric catarrh in hand-fed babies.

Some time ago I was asked to see an infant two months old, whom I cound suffering from acute gastric catarrh, and in a state of great exhaustion. Size had been brought up by hand, and was being fed upon milk and barby-water in equal proportions. This she vomited as soon as it had been wallowed, bringing it up curdled and intensely acid. There was a sour smell from the breath, and although the disease had only lasted a few lave, the eyes were hollow, the face looked pinched, the fontanelle was deeply depressed, and she lay motionless on the nurse's lap with her eyes half closed. Her hands and feet were cold to the touch and looked purple. Firs day or two her bowels had been much relaxed. She was taking small does of lead and opium to check the diarrhoa, but each dose was returned are st unmediately. The child was ordered to be kept warm and perfectly Let. A week mustard poultice was applied for an hour to the epigastrium. Is milk was stopped, and the child was fed with weak yeal broth and thin busy-water mixed together in equal proportions, and given cold at interas seemed desirable. As a result of this treatment, the vomiting stopped stonee, and the child when seen three days afterwards was found to be maily improved. The breath had lost its sour smell, the face was no leger pinched, the eyes were not hollow, the fontanelle was not depressed, when asleep the child closed her eyelids. The motions were still the watery, although the number was natural. The medicine and diet was continued for a few days longer, and the child was soon well.

The most important part of the treatment in this case was the substitution of real broth for milk. Directly the supply of fermentable matter was supply fermentation ceased, and was no longer formed, and the digestive that returned to a healthy condition. Here the derangement was acute. In the following case the complaint was chronic, the inability to digest

cox's milk having extended over a lengthened period.

A little park ten months of age, very thin and weakly-looking, had been would at the age of eight months. Since that time she had been unable to direct milk, vomiting it at once whenever it was given to her. For hearly two munths, therefore, she had been fed on two dessert-spoonfula of firmacoous food made with water into a thick cream, and given every two hours with a spoon. She refused to take it from a bottle. Twice a lay the food was made with beef-tea instead of with water. After a meal for dald often vomited, but when this happened she was immediately fed with. The result of such a diet was to be expected. The child, although the maths old, could not sit up. She was becoming rapidly thinner. She shelt very little, crying and whining the greater part of the night. She was

said to show no signs of abdominal pain, but the bowels acted three times a day, and the motions were relaxed and horribly offensive. The feet were

almost always cold.

Such a case, which is far from being an uncommon one, is readily treated, however severe may be the vomiting, by restricting the diet to equal parts of weak veal broth and thin barley-water, given cold in small quantities at a time; by warmth to the belly and extremities; by perfect quiet, and by suitable remedies. The best sedative is liq. arsenically—half a drop for the dose—given with a few grains of bicarbonate of soda in some arounsite water. It may be sweetened with spirits of chloroform. After a few days of such treatment, the power of digesting milk usually returns. But at first it should be given sparingly, either pancrentised, or freely diluted with barley-water, and only once or twice in the day. If the imbility to digest milk continue, the case must be treated as described under the head of Chrome Drurhoz (see page 640).

It may be necessary to begin the treatment by a dose of castor-oil, or rhubarb and soda, to clear away undigested food from the bowels. If the child is very weak, white wine whey is very useful. This may be sucked from a feeding-bottle, or given with a syringe-feeder, and the infant, if feeble, may take it in large quantities. Alternate meals of this whey, and of weak veal broth diluted with an equal proportion of thin barley-water, forms a very suitable diet for such cases. Mellin's food, dissolved in thin barley-water, or plain whey and barley-water, is also very useful; and a dessert-spoonful of fresh cream, shaken up with a teacupful of plain or

white wine whey, is a very valuable resource in obstinate cases.

For the treatment of constipation, cohe, looseness of the bowels, thrush, and the other accidents attendant upon improper feeding and general mismanagement, the reader is referred to the chapters treating of these special subjects. In conclusion, it may again be remarked that success in the artificial feeding of infants depends, in the first place, upon the selection of a suitable diet; and in the second, upon extreme watchfulness to detect the earliest signs of indigestion and acidity, and to make the necessary changes in the food which have been indicated above. Action must be prompt, for delay is often fatal. A food must be changed directly it ceases to agree, and any symptom of indigestion must be met at once with a suitable remedy. A derangement which in the beginning might have been arrested without difficulty soon assumes serious proportions, and if allowed to continue, will quickly bring a weakly infant to the grave.

To make white wine whey: - Put a breakfasteupful of new milk in a saucepan on the fire. When it comes to the bod, add a wine-classful of sound sherry. Then bod again for one minute and strain off the curd. Sweeten with white sugar,

CHAPTER H.

CASTRIC CATARRIL.

Charge of the stomach in early life is a derangement of common occurrence. It is met with in two forms—a febrile and a non-febrile variety. A first attack renders the gustric mucous membrane more susceptible than before, and predisposes to a second: on this account, the disorder is frequently found to recur repeatedly in the same subject, and serious interference with the child's nutrition may be the consequence. Catarrh of the stomach, unnecompanied by fever, is perhaps the commonest derangement to which children are exposed. It is a perpetual danger to hand-fed baires, and forms, indeed, the chief obstacle to the successful rearing of infants. The disorder as met with in early infancy has been already described (see Infantile Atrophy). The present chapter treats only of catarrh as it affects older children, after the period of infancy has passed by.

Constion.—In childhood, the mucous membrane is especially liable to be affected by chills, but the "cold" does not always show itself in the form of sore-throat or cough. A gastric or intestinal disorder is a familiar consequence of exposure to changes of temperature, and to this cause most cases of the derangement can be attributed. A child who has suffered from many such attacks, often acquires an extraordinary susceptibility to afternations of temperature, and the most trilling chill will be sufficient to induce a return of his complaint. In such children, the mere going out with cold feet into raw, damp air, is a common cause of a fresh attack. Insufficient clothing is sometimes the sole cause of the derangement. Children whose parents have a foolish objection to flamel, often suffer greatly from continued catarrhs. I have known cases where complete loss of appetite and persistent wasting resulted from this deficiency, and ceased at once when proper measures were taken to protect the child's body from the cold.

Certain constitutional states predispose the child to be readily affected by chils. In rickets, a susceptibility to catarrh is a marked feature of the disease. Pulmonary and gastric catarrhs are of constant occurrence in such subjects, and if the disease be present in a severe form, may lead to a rapidly fatal usue. Scrofulous children, again, are very prone to suffer from catarrhal disorders, and gastric derangement in them is very common from the cause. There is one peculiarity of gastric entarrh, as it occurs in serofulous subjects, which is of importance. It is that the complaint is almost invariably accompanied with fever. In such children, the recurring attacks of pyrexia, lasting from a few days to a week, which are often complained of, are cases of the febrile variety of acute gastric catarrh.

During the second dentition, the trifling februle disturbance which is excited by the passage of the tooth through the gum, may render the child recommon authors and attacks of gastric catarrh at this time are recommon.

Besides exposure to cold, irritation of the mucous membrane by unsuitable food may be a source of catairh. In infants, as has been already described, this is the cause to which the derangement can be most commonly attributed. In older children, also, gastric catarrh may be produced by similar means, and may be set up by excess of rich sauces, fruit, or sweets. As in the case of a chill, the susceptibility to suffer from these causes may be increased by temporary or constitutional states. During the evolution of a tooth, food which would be readily digested at another time. is often found to dusagree.

Morbid Anatomy.—A mucous membrane, the seat of catarrh, is injected in spots, and a layer of tough mucus covers its surface. In the stemach the mucous surface is often found softened, but this condition, which, under the name of gelatinous softening, or gastro-malacia, was at one time regarded as a pathological feature of great importance, and the cause of the symptoms which had been observed during life, is now admitted to be a mere post-mortem change which has no practical significance. The gastric membrane is thickened, and exhibits patches of redness. The stomach often contains much mucus, and not unfrequently fermenting food.

Symptoms.-Attacks of gastric catarrh may or may not be accompanied by elevation of temperature. The severe acute attack, with high fever, is the less common, and is limited, or nearly so, to the subjects of strums. The subscute, non-februle gastric derangement is much more often met with. It is milder in character and more quickly subsides; indeed, from the slightness of the symptoms by which it is accompanied, the attack may pass almost unnoticed, or be spoken of as "liver" or "biliousness,"

In the acute februle form, the child feels chilly, or even shivers, and then becomes very feverish, the temperature rising, perhaps, in the evening of the first day or two, to 104°. The patient con-plans of no pain, but is languid and irritable. He has a sallow complexion, and looks dark under the eyes, but his general expression is placid, and unless the child is tired by exercise, there is none of the punched, hargard aspect which is so common in cases of really serious illness. The appetite is lost, and there is some thirst. The tongue is usually furred on the dorsum, but may be clean and red at the tip and edges. Voniting is not common, but may occur, although it is rarely distressing. If the catarrh affect the intestual inucous membrane as well as that of the stomach, there is some durrhosa; otherwise the bowels are confined. Purging, if present, may be accompanied by some pain in the belly, but this, as a rule is insignificant. At night the child is often restless, and is disturbed by dreams from which be may wake in great terror. During the day, if the catarrh is severe, he is generally drowsy, and sits or lies about without wishing to join in the sports of his companions. While the attack lasts, nutrition is in abeyance, and the flesh and strength manifestly suffer. After a week or ten days, the pyrexia, which had been gradually subsiding, disappears; the appetite and spirits return, and the patient is convalescent.

Often the gastric catarrh is accompanied by symptoms pointing to a similar condition of other tracts of nucous membrane. The child may suffer slightly from catarrh of the nose; the throat may be a little sore; the eyes may be weak and distressed by a strong light, or there may be slight cough. Even if the fever is high, delirium is not common, but there is occasionally some frontal headache. If the catarrh pass along the duodenum

to the common bile duet, a mild jaundice is noticed.

In many cases, an attack such as the above passes off, and the child does not suffer again from a similar illness. Often, however, the catarrh, instead of occurring in one solitary instance, returns repeatedly at short intervals. Cases of recurring gastric catarrh of greater or less severity are far from uncommon; and these attacks, if the intervals between them are short, may exercise a very injurious influence upon the health and general development of the patient. Children, the subjects of such entarrhs, become pale and thin, for their nutrition is being constantly interrupted. By its influence upon appetite and digestion, the catarch checks for a time the introduction of nourishment into the system, and nutrition is hardly restored on the cessation of the attack when a return of the derangement suspends it again as before. In this way the child may become an almost constant sufferer from disordered stomach, and his continued ill health and persistent wasting excite the gravest apprehensions amongst his relatives. Such cases are often supposed to be cases of consumption; and, indeed, if there be any unherited chest weakness, long-continued interference with nutrition, such as is produced by a frequent recurrence of these attacks, may go far to encourage the tendency to phthisis.

In the non-februle variety, the symptoms are much less striking, for, pyresin being absent, the spirits are less depressed and the patient utters no complaint. Most children suffer at times from what is called "biliousness." For two or three days together they lose their appetite, more and lie about, have a dull, pasty or sallow complexion, and look dark under the eyes. At night they sleep budly, and they are restless and irritable in the day. These symptoms are produced by a temporary catarrh of the stomach which interferes for the time with the digestion of food, but passing off, leaves no ill consequences behind. When, however, the attacks are frequent, digestion is weak, even in the intervals of comparative health, and nutrition becomes seriously impaired. Such children complain often of flatulent pains in the sides, and may be subject to attacks of syncope from pressure upwards of the distended stomach against the heart. Their bowels are usually costive. The appetite varies greatly. Sometimes it is excessively keen; at others it is poor and capricious. In many cases, indeed, the child seems to have no appetite at all, and the greatest difficulty is experienced in making him swallow his food.

These symptoms may be greatly aggravated by an unsuitable dietary. If a cluld who suffers from the condition described be supplied with an excess of fermentable food, such as potatoes, puddings, jams, and sweet cakes, he is kept in a state of chronic acid dyspepsia which is a source of constant discomfort to himself and anxiety to his friends. The whole system being full of acid generated by fermenting food, the child is wayward and cross to temper, and excessively fidgety and restless. His speech is often hesiting, and he may statumer in his talk. His muscles are irritable and twitch easily, so that he winks his eyes and distorts in nervous fashion the corners of his mouth. The so-called nervous habits of children often owe

their origin to this derangement.

Sickness is not a common symptom in these cases, for gastric catarrh is by no means always accompanied by irritability of stomach. Sometimes, however, the child at rare intervals brings up a large quantity of sour-smelling fluid and mucus. Frontal headache, more or less severe, is rarely about, and oftentimes the pain is distressing. The wearing periodical headaches of children are not uncommonly owing to this cause. The urine is noticed from time to time to be thick with lithates; and, in rare cases, quantities of fine uric acid sand are passed, precipitated by the free acid with which the urine is charged.

In some cases a curious condition of the tongue is noticed. On the

dorsum are seen rounded or oval patches, which appear to consist in a removal of the epithelial covering. The surface of the patches is distinctly depressed, and the colour is that of the dorsum generally. The edges are circumscribed and irregular. The number of these patches is usually three or four. They may be seated on the dorsum or on the edges of the tongue. At times, small rounded ulcers (aphthæ) and red elevated papillæ are seen at the tip of the tongue in addition to the depressed patches on the dorsum

If aphthe are not present, there is no pain or soreness.

Symptoms such as the above show a high degree of digestive derangement, aggravated by an unsuitable dietary, and are almost invariably the consequence of repeated attacks of catarrh of the stomach. Under such circumstances, nutrition is interfered with, the child wastes perceptibly, and the apprehensions of the parents are carried to a high degree. When, on the other hand, the indisposition is only occasional, and the symptoms are not severe, little attention is excited. The child is supposed to be a bilious subject, and unless the attacks become so frequent as to cause an evident diminution in bulk, or some new symptom is noticed which excites the

alarm of the friends, medical advice is considered unnecessary.

In cases where, owing to the mildness or infrequency of the attacks of gastric derangement, general nutrition has not suffered, the occurrence of fainting fits may induce the parents to apply for medical assistance. Attacks of syncope, more or less complete, are not uncommon in these cases. Naturally enough, they give rise to great anxiety, especially if conjoined with palpitations and flatulent pains about the chest. They are then considered to be symptomatic of heart disease. Thus, a little girl, aged eleven years and a half," fainted for the first time six years ago. She has since fainted on five different occasions. At these times she has always been noticed to be dull and languad, with a poor appetite, but otherwise has seemed to be well. Is subject to sharp pains in the left hypochondrium, under the influence of which her face will become ghastly white. She aleeps badly, talking and moaning, and often hes awake at night. Has never suffered from worms; howels are confined. Has sometimes a sallow complexion." This young lady, who was a well-grown, well-nourished garl, with perfectly sound organs, soon lost all her symptoms under suitable treatment.

In some cases, the non-febrile form of the complaint is accompanied by more serious symptoms. There may be severe pain in the epigastrum violent headache, and distressing retching and vomiting, first of food and afterwards of bilious or watery fluid. Such attacks are usually soon over They are commonly produced by the introduction of some irritant into the stomach, and cease soon after the complete ejection of the offending matters from the body. For some days afterwards the child is languid, his digestion weak, and vomiting is easily excited.

In children of eight or nine years of age or upwards, the dyspepsia induced by repeated attacks of gustric catarrh may give rise to more or less severe pain after food, a tendency to vomit, pyrosis, and other symptoms such as accompany the derangement in the adult. These symptoms are seldom met with except in children who are habitually over-fed, or are indulged with rich sauces and highly-spiced and stimulating food. They

usually quickly subside under a change of diet.

Diagnosis.—The febrile form of acute gastric catarrh often presents some difficulty in the diagnosis, for the symptoms are frequently indefinite, and the case may be mistaken for one of far more serious disease. Such cases have been confounded with cases of acute tuberculosis, and they often

present a strong likeness to the mild form of enteric fever. The principal points upon which the diagnosis is founded will be best illustrated by the narration of the following case seen in consultation with Dr. G piher.

A little girl, aged seven years, of a strumous disposition, had been delicate and subject to occasional failure of appetite for some months. For about a week she had been feverish, the buddy temperature rising sometimes as high as 104 Fahr. Her appetite had been completely lost, but she had not suffered from sickness. The bowels, at first sluggish, had been somewhat relaxed for two days, the motions passed being moderate in quantity, but loose, rather offensive, and bright yellow in colour. She had occasionally complained of abdominal pains. During the whole time of her threes the child had snuffled slightly, and at first her throat had been a little sore, but there had been no cough. She had complained sometimes of frontal headache, but had not been delicious.

At my visit I found the child lying in bed with her face turned away from the window, as the light, she said, burt her eyes. There was no sallowness of complexion. Her expression was placid, and not at all anxious or distressed. The tongue was a little furred on the dorsum, and rather red at the tip and edges. She was thirsty, but had no desire for food. The abdomen was soft, without tenderness or distention. The spleen was very undistinctly felt; it seemed to be slightly enlarged. There was no rash of any kind on the body, nor any cedema of the legs. The urine was not albuminous. The heart sounds were healthy. There was no rhonehus, nor any other abnormal sign about the lungs. Respiration regular, 24; pulse

regular, 108; temperature, 101 (at 4 P.M.).

This case, which was seen on the seventh or eighth day of the illness, when the ordinary eruptive fevers could be excluded, might have been acute tuberculosis, typhoid fever, or acute gastric catairh. The occurrence of fever, with a history of previous delicacy of health, was quite in keeping with the ordinary course of tuberculosis. There was, however, no family history of any such complaint, and this important fact, together with the complete absence of distress or anxiety in the expression of the child, and the absence also of any redema of the extremities, was held sufficient

evidence to exclude the presence of this formidable disease.

Between typhoid fever and acute gastric catarrh the distinction was more difficult. The temperature, it is true, although always elevated, had not followed the course of the temperature in a typical case of enteric fever, but in children this fever is often mild, and frequently deviates from the or linary type. Again, the absence of cruption did not exclude typhoid fever, for the eighth day is early for the rash to appear, and in children typhoid spots are sometimes absent altogether in undoubted cases of the disease. On the other hand, the state of the spleen was doubtful. Some slight enlargement was suspected; if this was so, the fact pointed distinctly to typhoid fever.

In tayour of acute gastric catarrh was the slight snuffling, the mild screethroat, the complete absence of delirium or of apparent discomfort, and the arregularity of the fever. Altogether, the symptoms pointed, perhaps, more decidedly to gastric catarrh than to the more serious disease, but it was impossible to exclude typhoid fever; therefore, a guarded opinion was expressed as to the nature of the case. The temperature fell on the following (eighth or minth) day. This early termination seemed to decide the question in favour of catarrh, for it is only in very exceptional cases that

typhoid fever subsides before the fourteenth day.

When gastric catarrh, instead of occurring in one solitary attack, as in the above instance, recurs repeatedly at short intervals, the diagnosis is more easy. This recurrent form is well illustrated by the following case

which was sent to me by Dr. Lister, of Croydon.

A little girl, aged seven years, pallid in appearance and ill-grown, but been wasting slowly for eighteen months. During the whole of this time she had suffered every two or three weeks from attacks of fevershness. In these illnesses the symptoms were the same. The temperature rose to 103 and 104°. The child looked sallow in the face, and was very irritable and languid. She was thirsty, but refused her food. Sometimes she vomited, but in the earlier attacks the bowels were never relaxed. She got thinner and weaker, and looked ill. A few months previously she had had a severe attack at Lowestoft, in which she had been slightly joundiced. Six weeks before her visit to me she had had a still more violent attack, which had left her completely jaundiced. This had been followed for the first time in her experience by diarrhoa; and for a fortnight the motions were green and slimy, and sometimes contained clots of blood. They were passed with straining and some pain. At the time of her visit, the looseness had in a great measure subsided, but the child still had a faint yellow tint of the skin. Her heart and lungs were healthy, and there was no sign of enlargement of the bronchial glands. Between the attacks of illness the child was said, as a rule, to be fairly well. On the subsidence of the fever her appetite would return, and she would begin to regain flesh. Unfortunately, before her strength could be said to be thoroughly restored, it would be again reduced by a new access of fever.

Jaundice in children after the period of infancy, is, in the large majority of cases, catarrhal. In this child, its occurrence with the two last attacks of fever helped greatly to explain the nature of these attacks, and the cause of the ill-health from which the child was suffering. Moreover, in the most recent illness, a new feature had been noticed in the diarrhoea which had followed the jaundice and still further delayed convalescence. In this diarrhoea, the characters of the stools, which contained mucus and blood, and were passed with straining and pain, pointed to a catarrh of the lower bowel. Explaining, then, the earlier attacks in the light afforded by the latter, it was evident that the child's sensitiveness to changes of temperature showed itself in the form of repeated attacks of acute gastric catarrh, accompanied by fever. This fact being once established, the treatment of the case was conducted upon the principles to be described, and the child

had no return of her feverish symptoms.

The non-febrile form of the disease may be recognised without difficulty. Frequently-recurring attacks of indigestion, a tendency to sculity and flatulence, restlessness and irritability after indulgence in sweets and other forms of fermentable food, are almost invariably the consequence of gastric catarrh. The complaint is so common a one that it should be always suspected in children who are habitually pale, thin, and nervous, with a sailow complexion, and who are subject periodically to fits of irritability and ill-temper. Continued loss of appetite from this cause often excites apprehensions that the child is becoming consumptive. The real cause of the wasting may, however, be detected by noticing that the cheat, on examination, shows no sign of disease; that his expression, although occasionally wearied, as after exertion or before going to bed, is not habitually distressed, and that the evening temperature is normal. On inquiry, too, it will be found that the wasting is not a constant feature, but that the child is better and worse, sometimes appearing to be almost well and to gain flesh,

at others, being languid, moping, and sallow-looking when indigestion is excited by a fresh attack of catarrh.

Treatment.—Whether the gastric catarrh assumes the febrile or the non-febrile form, its treatment is the same. Our object is, firstly, to put a stop to the existing derangement, and, secondly, to adopt such measures as will

prevent its recurrence.

To cure the existing catarrh, we must do our best to remove all sources of irritation which may be keeping up the disorder. The acrid mucus, a free secretion of which is one of the ordinary phenomena of the catarrhal state, is a constant source of fermentation and acidity. It very quickly induces an acid change in the more fermentable articles of food. Therefore, if the stemach be oppressed by sour matters, shown by uneasiness at the epigastrum, a sour smell from the breath, and a feeling of nausea, immediate benefit will be derived from an emetic dose of ipecacumha wine. Afterwards, a draught composed of tincture of nux vomica (III i, iii,), with bicarbonate of soda (gr. iv.-vi.), in water sweetened with spirits of chloroform, taken two or three times a day, will soon restore the gastric mucous membrane to a healthy condition. Strong purgatives are to be avoided, but as there is usually constitution in these cases, an occasional mild aperient will be required, such as compound liquorice powder or castor-oil. If there be fever which does not subside after the action of the emetic, the child may be allowed to take fluids from time to time in moderate quanti-The best are unsweetened barley-water, flavoured, if desired, with orange-flower-water, and fresh whey.

During the treatment, as long as any signs of acidity of the stomach persist, care should be taken to exclude from the diet all matters capable of favouring the tendency to fermentation of food; and even for some time afterwards, readily fermentable substances, such as starches and sweets, should be taken sparingly, lest the derangement be encouraged to return. At first nothing should be allowed but freshly-made broths, with dry toast, and when milk is once more permitted, it must be guarded with a fourth pirt of lime-water, or with saccharated solution of lime, in the proportion of twenty drops to the teacupful. While the derangement continues, no fruit, cake, sweets, light puddings, or potatoes should be permitted. When the appetite begins to return, a little fish, chicken, or mutton may be allowed, but the child must not be pressed to cat; indeed, until his digestive power be completely restored, the utmost care must be taken not to

overload the stomach with food.

The above measures will effect a considerable improvement in the condition of the child, but at this point the treatment may be said only to have begun. The patient is in a weakly state from successive attacks of gastric catarrh. We have therefore to adopt measures to strengthen the digestive power, and take such precautions as will insure him against a relapse

To give tone to the atomach and strengthen digestive power, preparations of iron are required. It is a common practice in such cases to administer the preparation of the phosphates of iron and lime known as "Parrush's chemical food." This syrup is a very favourite remedy with mothers, who, musted, perhaps, by the name, give it largely, and with the worst results. Theoretically, no doubt, it is an active tonic, but practically it is highly pernicious. The reason is that the syrup in which the phosphates are dissolved supplies material for fermentation, and each dose is soon followed by acidity and flatulence, so that the medicine really aggravates the mischief it is intended to allay. The better plan is to give the dialysed iron, or, if there be any tendency to acidity remaining, the ammonio-citrate, with a few grains of bicarbonate of soda, sweetened with spirits of chloroform. After a time a change may be made to the solution of strychnia, with the perchloride or pernitrate of iron, given directly after food. All this time, the quantity of fermentable material taken at meals much be restricted, as already recommended. During the same time, a mild aperient should be given every few days, whether it seems to be required or not, to insure proper relief to the bowels, and prevent the retention of any excess of mucous secretion.

In spite of this treatment, however, the child will not be secure against relapses unless special precautions are taken to guard the body against chills. The catarrhal state, whatever be the organ affected, tends constantly to repeat itself under the influence of slight causes, and there is little doubt that it induces an extreme sensitiveness to changes of temperature. Children who suffer from attacks of catarrh of the stomach and bowels, should wear a broad flannel bandage applied tightly to the abdomen, so as to reach from the hips upwards to the arm-pits; and the medical practitioner should look upon it as his first duty in these cases to see that it is properly applied. The binder should be considered as part of the child's ordinary dress, and be cast off at night with the rest of his clothes. In many cases it is necessary, in addition to the above precautions, to fortify the resisting power of the child by cold bathing. Some caution, however, is often required in recommending this step to parents. Mothers are apt to take fright at the very mention of cold water; and it is true that, in the case of weakly children, reaction is difficult to establish, so that a cold bath given in the ordinary way would not be attended with benefit. If, however, the bath be given according to the method advocated on a previous page (see page 17), and the skin be first stimulated by vigorous friction so as to enable the body to resist the shock of the cold douche, and the shock itself be lessened by making the child sit in a few inches of hot water, the bath will have a highly invigorating effect and be followed by immediate reaction. The continued use of this bath, besides having a remarkably tonic effect upon the system generally, confers great resisting power against changes of temperature, and considerably reduces the child's susceptability to chills.

By means such as have been indicated, the most obstinate gastric catarrh may be treated with success. But it must be borne in mind that success depends upon equal attention to all the points that have been insisted upon. A finned binder will be of little vidue if the tendency to fermentation is encouraged by the immoderate use of starches and sweets; and even cold douching may not be sufficient to neutralise the ill-effects of rapid changes of temperature acting upon a body imperfectly protected from the cold. In all cases, it is advisable to avoid the use of syrups are not well horne by young subjects, and often do more harm than good. It is far better to sweeten the child's physic with glycerine, or a few drops of spirits of chloroform.

In cases where habitual pain after food is complained of, the treatment found useful in similar cases in the adult should be resorted to. The diet should be arranged on the principles already indicated. Both sauces and highly-spiced or fermentable food should be forbidden, and the child should take bismuth and sods, or small doses of dilute hydrocyanic acad with an alkali.

CHAPTER III.

CONSTIPATION.

Compare of all ages are subject to constipation. Usually, it is a temporary designment, which quickly subsides under suitable treatment. In other cases it amounts to a positive infirmity, and is exceedingly obstinate and discult of cure. The term constipation is a relative one. In itself, it impressingly to the health from retention in the alimentary canal of matters which ought to be discharged. The condition is therefore compatible with a axis evacuation, if the relief afforded to the system is incomplete. In infants who require the bowels to be emptied several times in the day, a axis stool in the twenty-four hours is a sign of costiveness which should be neglected.

All forms of mechanical obstruction to the passage of the intestinal contents give rise to arrested or imperfect evacuation as a prominent symptom, The variety of constipation is not here referred to. The form under confidention in this chapter is due to deficiency of expulsive action, and not harrowing of the channel, or other kind of mechanical hindrance.

Gouten,—One of the commonest causes of constipation is an unsuitable dictary. This is especially the case in infants. A child brought up be land, and fed with excess of farinaceous food, is often troubled with an obtinate form of costiveness which is a source of continual discomfort. In frequent passage along the bowels of undigested starchy matter keeps the annous membrane in a state of constant hyper-secretion. A slumy nucleis thrown out which coats the lumps of undigested food so that the annual roat of the bowel in its contractions can have little hold upon their shapery surface, and they are forced forwards with difficulty.

Still, all cases of constipation occurring in hand-fed babies cannot be attained to this cause. Often, the most careful examination of the stools an detect no excess of mucus. On the contrary, the motions are hard and many, and seem to be drier than natural. This very dryness of the evacuations appears in many cases to constitute a cause of infrequent relief to the bow is. We know from cases of diabetes in the adult, where the example of the form the kidneys diminishes intestinal secretion, how amonly constipation results from this want of moisture. In the young that a similar deficiency of secretion, however induced, may cause dryness of the fiscal contents and diminish the facility of their passage. Special reless of diet have a constipating effect upon certain children. In some, the interferes with the regular action of the bowels. In others, eggs may be a like sluggishness. I have known troublesome costiveness continue the long as the yolk of an egg was allowed every day, and disappear at once the number of eggs was reduced to two in the week.

Atony of the bowel, or actual deficiency of expulsive power, is a not unpurpose cause of constipation even in young subjects. In badly-nourished budgen, the muscular coat of the intestine must share in the general malnutrition; and as, in this condition, the lower part of the colon and rectumare apt to be over-distended by accumulation of undigested food, the difficulty of carrying forwards the fareal masses is increased. In some cases, the difficulty is added to by a peculiarity of infancy upon which Dr. Jacobi has laid much stress at a cause of constipation in very early life. In the newborn infant, the length of the large gut is proportionately greater by always one-third than it is in the adult. This excess of length is due, not to the ascending and transverse colon, which are rather shorter at this age than they become in after years, but to the descending colon and significant flexure. Consequently, the flexure is thrown into many curves, and is often beat upon itself so repeatedly as seriously to retard the passage of its contents.

Suggishness of peristaltic action, if not complete atony of the bowel, may be a sequence of certain diseases. After chronic diarrhesa, a state of constipation commonly prevails which is very difficult of cure. Typical fever often leaves a similar condition behind it, and after an attack of acute rheumatism the same mactivity of the bowels is often noticed. Again alceration of the intestinal nucous membrane, when not accompanied by catarrh, almost invariably induces deficient fecal excretion, and sometimes, in these cases, excrementitial matters may be long retained. In typhoid fever. constipation of a week or longer is frequently met with, and indeed, in many cases, no effort at expulsion appears to be made until the bowels are excited to contract by a copious enema. In these cases, no doubt, the normal peristaltic action of the bowels at the seat of ulceration is paralysed by the inflummatory process there existing; but a similar sluggisliness of the mtestinal mucous membrane may be induced by disease in a distant part of the body. Thus, disease of the brain or its membranes is usually accompamed by constipation as a prominent symptom, and in another part of this volume reasons are given for supposing that Bright's disease in the young child may produce the same result.

There is one cause of constipation in infants which must not be forgotten. This is the sluggishness of the bowels which is induced by opium Hand-fed babies are apt to be very peevish and troublesome at night, and an unscrupulous nurse will often drug the child with "soothing syrup" or other opiate in order that her own sleep may be undisturbed. This practice induces a very obstinate form of constipation, and, unless detected, may be a cause of much perplexity to the medical attendant. It is therefore

important in obstinate cases to examine the child's pupils.

The causes which have been referred to may influence the state of the bowels at all periods of childhood, but there are other causes which largely prevail after the period of infancy has passed. Habitual neglect of the calls of nature is as common a cause of constipation in young people as a is in their clders. The lower bowel, when it finds its warnings neglected soon becomes accustomed to the presence of its feeal contents, and request something more than the ordinary stimulus to excite its action. from necessity or convenience, school-children of both sexes often suppress the natural desire for relief; but if the favourable moment is allowed to pass, efforts made at another time are often ineffectual, and a habit of constipation is thus acquired which may be very difficult to overcome during infancy, constipution may be made worse by this means. Children of ten or twelve months old, who have been subjected to much pain from distention of the sphineter by hard faceal masses, will often resist, as long as possible, the desire to empty the bowel, in order to spare themselves unnecessary suffering. In such cases, if measures are not taken to enforce due evacuation, serious accumulation may ensue.

Want of exercise is another cause which is often found to prevail amongst young girls, especially if they are much confined to the house and pressed too quickly forward in their studies, and very obstinate constipation

may result from their sedentary life.

Symptoms.—In injuncy, deficient excretion from the bowels is usually indicated by a pasty, dull complexion, fretfulness, and agitation, especially at night. The child's sleep is not the sound, unbroken sleep of health. He often starts and twitches, and is roused up by the least noise. Flatulence is an early consequence. The child seems to suffer from occasional twinges of pain, for he often cries suddenly without evident cause, and draws up his lower limbs uneasily. His upper lip looks purple; the fluscles of his mouth twitch, and if the pain is severe, his whole complexion may become ghastly white. If the constipation is obstinate, the stools are voided with great difficulty; and in cases where several days pass without any rehef, defection is only effected with much straining and pain. The infant often makes violent efforts to unload his bowel of its accumulated burden, and will strain until his face is purple, his bowel prolapses, and his navel starts. Tinging of the faced masses with blood from rupture of small vessels about the anus is often accu, and umbilical hernia not unfrequently owes its origin to this cause.

The belly is generally swollen from flatulence, and sometimes the gas accumulates in such quantity as to cause a fit of violent colic, in which the child gives signs of extreme suffering, screaming and writhing and drawing up his legs. Actual convolsions may be induced by this cause. In cases where irritation of the bowels is excited by the retention of excrementifial matters the temperature may become elevated for a time, but it subsides at once when the accumulation has been removed. In many children, the torpor of the bowel is accompanied by languid circulation so that the hands and feet are habitually cold. If the state of constipation continue, the general health usually suffers; the flesh gets flabby, and the child is prevish and fretful, with a tendency to vomit. Palpation of the abdomen will often discover hard masses in the descending colon. These are well-defined lumps, are painless, and can be indented by firm pressure with the finger.

In older children, we see hitle more than dulness of complexion, a furred tongue, and some want of sprighthness and activity. The child may complain of discomfort after foo I and of occasional headaches. His breath is often unpleasant, and there may be aphthic on the tongue and lips, or red patches on the tongue from which the epithelium appears to have been thrown off. Sometimes the bowels act only at rare intervals, and if proper measures are not resorted to, may remain confined for a week together, or even longer. Such children are subject to sick-headaches, and have habit-

unlly a posty-looking, unhealthy tint of skin.

If the constipation proceed to actual impaction of fæcal masses in the bowel, more striking symptoms are noticed. The impaction usually takes place in the rectum itself, and consists of a quantity of hard lumps which it is very difficult to break down and bring away. The presence of the hard masses causes irritation, which shows itself by more or less pain in the lower part of the belly, by tenesmus, and often by difficulty of micturition. The child is generally sallow, listless, and weakly-looking. The appetite may be unaltered, but is usually poor. The tongue is often quite clean, although the breath is field. The belly is distended and sometimes tender. Distribute may be a consequence of the intestinal irritation. The motions are sently and thus; they usually contain a few small scybala, and are passed with nuch pain and tenesmus. Instead of loose, they may be very small and solid, with excess of mucus.

In some cases, in addition to irritation, positive injury may be caused by the presence of the fieral masses. Dr. T. Chambers has reported the case of a girl, aged eleven years, who had suffered for three months from a persistent diarrhora which was the consequence of a vast accumulation of faces in the rectum. The mass by its pressure had caused absorption of the triangular cushion which constitutes the perineum, and had reduced the

recto-vaganal septum to a mere membrane.

These cases, if not judiciously treated, may actually prove fatal. Dr. Bristowe has referred to the case of a little girl, eight years old, who had long suffered from a tendency to constipation, and had occasionally gone for three weeks without relief to the bowels. When she came under observation she flad had no passage for seven weeks. The child was pale and thin, with a strumous look. Her belly was large and tense, although painless, her tongue clean and her appetite poor. She grew weaker, and looked haggard and anxious. Her belly became more distended, and occasional colicky tains were complained of. Towards the end, her tongue became foul; she often vomited, passed high-coloured urine in small quantity, and eventually sank from exhaustion. The vomiting was never stercoraceous. After death, the intestines were found greatly distended and their courts hypertrophist. They were full of olive-green, semi-solid faces, which were of thicker consistence in the rectum than elsewhere; and immediately above the axis was a hard conical plug of faced matter which completely prevented the escape of the contents of the bowel.

If impaction take place at a higher point in the bowel—in the escum or at a bend of the colon-symptoms of complete occlusion may arise, and inflammation is often excited in the intestine. Over the seat of obstruction there is pain, which may extend to the whole abdomen, and be violent and paroxysmal; there is tenesmus, and the bowels are obstinately confined. The child vomits repeatedly, throwing up at first bile and macus, afterwards feculent matter. Hiccough may be distressing. The abdomen is distended. The tongue is thickly furred, and perhaps dry and brown. The pulse is rapid, small, and thready; the temperature is often high, and the prostration is extreme. On examination of the belly, a hard swelling may be detected through the muscular wall, and can often be indented with the finger; or, if inflammation have occurred, there is some tension of the parietes, and an intensely tender swelling can be discovered at the seat of obstruction. Inflammation of the cacum (typhlitis) is the most familiar instance of this inflammatory form of the disorder. Firm impaction of the colon with faces is a variety of obstruction which, if not relieved by the adoption of suitable measures, may be as fatal to the patient as any other form of intestinal occlusion, but it is eminently curs-

ble if the nature of the impediment be recognised in time.

Diagnosis.—In ordinary cases, the want of regularity in defecation, and the infrequent passage of hard, scanty stools, is a sufficient token of the existence of constipation. But often the indications are much less precise. In infancy, as has already been remarked, a single stool in the four-and-twenty hours constitutes a state of constipation which requires attention. Even in older children a daily evacuation may occur and yet the rehef to the bowels be incomplete. Habitual sallowness of complexion, offensive breath, wakefulness at night and startings in sleep, are common indications of a loaded bowel, especially if the symptoms occur in a well-nourished child who presents no other indication of ill-health; and dyspeptic symptoms (discomfort and a feeling of heaviness after meals, occasional nausea and a furred tongue) will often be found to arise from the same condition.

It is very important in cases where the evacuations are very small, frequent, and watery, or loose, to remember that this condition is often a consequence of the accumulation of faced masses in the rectum. In such cases, we may expect to find distention of the belly and tenesmus, with some pain in the lower bowel in defecation; and the stools, on inspection, will be found to consist of offensive, thin faculant matter containing mucus and a few small, hard scybala. When these symptoms are noticed in a child of four or five years of age or upwards, it is of importance to examine the rectum; and often by this means the cause of the apparent looseness may be discovered at once. Still, even if we obtain evidence of faceal accumulation, caution is often necessary. We must not at once conclude that retained faceal matter constitutes the whole of the derangement, and that when this has been removed the child will be well. Ulceration of the bowels is often accompanied by this vary group of symptoms. This subject is considered elsewhere (see page 661).

If actual impaction of faces occur so as to offer an insuperable obstacle at any point of the intestinal canal, symptoms of occlusion of the bowel arms. The distinction between this condition and infussusception is ex-

plained in the chapter treating of the latter subject.

Treatment.—The regular action of the bowels is at all ages so much a matter of habit that the child as soon as he can walk, or even earlier, should be trained to regularity in this important particular. Every morning after breakfast he should be accustomed to go punctually to stool, and nothing should be allowed to interfere with this necessary duty. By this means the bowels become accustomed to regular relief at the same period of the day. The mother should herself see that the rule is enforced, for an inattentive nurse, from ignorance or carelessness, is very apt to neglect it.

In infants, constitution may be combated by careful regimen, by the adoption of special articles of diet, by enemata, and by drugs. In the first place, the dietary should be revise I and excess of starchy matter excluded. If the child is eight or ten months old, the first meal in the day may consist of a tenspoonful of fine outment rubbed up carefully with cold milk into a thin, smooth paste, and then stirred briskly while hot milk is added. Mellin's "Food for Infants," probably on account of the glucose it contains, often has an admirable effect in regulating the bowels of infants who are inclined to costiveness, and is a very useful resource. If the constipation is only temporary and occasional, a small lump of manna dissolved in a dessert-speenful of warm water, strained and added to the bottle of food, has a ready aperient effect; or fifteen to twenty drops of the liquid extract of rhannus frangula will be equally successful. In cases where the constipation is habitual, I have found a combination of the infusions of senna and gentian a remedy of unfailing usefulness. I usually combine these with the tinctures of bella lonna and nux vomica, as in the following draught. The quantity ordered is smitable to a child between eight and twelve months of age, and can be given at first three times in the day immediately before a meal:-

Ŗ.	Finct. nucis vomicæ	TIL HB.
	Finct. belladonne	TI V.
	lufusi sepnæ	
	Infusum gentianse comp	
3.5	Da James Anna	

M. Ft. haustus.

The value of this remedy consists in the fact that the patient does not become dependent upon the medicine. On the contrary, it has a strengthening effect upon the coats of the bowel, so that after a time it can be given twice in the day, then only once, and eventually be discontinued altogether.

CHAPTER IV.

DIABRHOEA.

Diagraphy in early life is a subject of the utmost importance, as to a large proportion of the deaths which occur in infancy are to be ascribed. The term itself is a vague one. It expresses merely an injurious manage in the alvine dejections, without reference to cause, and is applied equity to a triding derangement, and to a serious, or even fatal illines. It the fore embraces several varieties of intestinal disorder which are chiral distinct, although, anatomically, perhaps, they may present mere different in degree of the same pathological condition. For practical purposes will be convenient to describe three forms of bowel complaint. Such anon-inflammatory diarrhees (mild intestinal catarrh); acute inflammatic diarrhees (severe intestinal catarrh, or entero-contist, and choice and durition (infantile cholers). Of these, the first only will be treated of in the president process.

In simple non-inflammatory diarrhox, the mucous membrane of the basels is in a state of temperary irritation, resulting from a mild form of estant. The disorder is a mere derangement of function, is, as a rule, accompined by no great violence of purging, and is quickly arrested by suitable that ment. By many writers, this form of diarrhoxa is not separated form the more severe variety of muco-enterities, which will be described afterwards. Its clinical characters are, however, so different, and its symptoms so and less serious, that it is convenient to devote a special character to its occ-

sideration.

Causation.—Improper feeding is one of the most frequent causes of looseness of the bowels. Amongst hand-fed babies, the disorder is 1500 ally common, and unless quickly arrested, is very apt to run on into the 2flammatory form, and prove serious. The food may be excessive in man 29 or unsuitable in quality. Often it is both, and an infant of a few mercla old is supplied with an amount of farmaceous food far in excess of = powers of digestion. The food is consequently carried along the ilmotary canal, fermenting and irritating the mucous surface over with posses, until it is discharged. A common cause of looseness of the bases is the practice, which often prevails in badly-regulated nursenes of jeparing for the infant in the morning the whole day's supply of food. To mixture of milk and awestened farinaceous matter seldom remains as changed for many hours together, and often, after a short time, is preunfit for the child's consumption. But besides infants, children of an exare subject to temporary looseness of the bowels, from the critation & digested and fermenting food. In such cases, the alvine flow may be a garded as the natural effort of the bowel to relieve itself of an armona burden. The danger is, that in infants, and weakly children, the wall

catarrhal process may not cease with the expulsion of the offending sub-

stance, but may pass on into the more serious form.

A cause which is little less common than the above, is chilling of the surface. Children, and especially young babies, are very sensitive to changes of temperature, and part with their heat very rapidly. Unfortunately, it is at this susceptible age that the body is habitually less covered than at any other period of life. From the time that the child relinquishes his first long clothes, until his third or fourth year, he is exposed, with insufficient protection, to frequent changes of temperature. At all seasons, while indoors, his legs and arms are bare-often his neck and shoulders as well; and not seldom from the waist downwards he is covered by nothing but his short and scanty skirts. It is not, then, surprising that in a changeable climate the child should be subject to frequent chills, and that diarrhoen should be so common a complaint. In England, the derangement is especially prevalent at the end of spring and the beginning of autumn - seasons when the warmth of the day is rapidly succeeded by the cool of the evening. Moreover, it must be within the experience of most medical practitioners, that the sudden alternations which sometimes occur, even in the height of summer, from excessive heat to a cool, or even chilly temperature, are generally followed by an outbreak of diarrhea amongst the younger members of the community. Rickety children, probably on account of their profuse and ready perspirations, are especially hable to these attacks.

Whilst cutting teeth, young children are more than usually prone to looseness of the bowels. In such cases, the relaxation is popularly ascribed directly to the process of dentition, and the child is said to "cut his teeth with diarrhea." There is, however, no doubt that the teething process is concerned in the derangement only indirectly. During dentition, a child is often feverish, and pyrexia from any cause reduces the resisting power of the body, and renders it sensitive in an unusual degree to changes of temperature. In one case, the catarrh fastens upon the bowels, in another upon the stomach, in a third upon the lungs, according to the varying susceptibility of the organs; and strictly speaking, the child suffers not because he is teething, but because he is feverish.

Although looseness of the bowels from the above-mentioned causes is usually transient and trifling, it is liable at any time to become severe and even dangerous. An intestinal catarrh, unless quickly arrested, is apt to extend and grow violent, especially in weakly subjects; and an attack of duarrhose which begins mildly enough, may suddenly change its character

and assume very serious proportions.

Morbid Analomy.—As the derangement is not in itself of much moment, few opportunities of an examination of the intestine are afforded. Such, however, occasionally occur when the derangement has been present in a young child who is feeble and ailing from some more serious affection. In such cases, the mucous membrane may appear to be quite healthy, and if here and there a certain amount of arborescent redness is discovered, this is in all probability a post-morten change. Occasionally, an excess of shiny mucus may be found coating the lining membrane over a greater or less extent of surface.

Symptoms. In infants, the mild intestinal catarrh which constitutes the non-inflammatory form of diarrhea usually occurs suddenly. Sometimes it is preceded for some hours by slight griping pains, nausea, or even von-iting, a furred tongue, restlessness, previsioness, and other signs of disconfort; and occasionally, if a very indigestible substance has been avallowed,

by some fever. In a short time, a profuse discharge of thin feculent matter takes place from the bowel, and the pyrexia, if it had been present, subsides at once. At first, the evacuations are feedl, and contain lumps of undigested food. They have often an offensive sour smell, and may be frethy from evident fermentation. Usually, the early fa-cal stools are succeeded by thinner, smaller watery or slimy dejections, showing an excess of mucus, and tinted of a green colour. If the catarrh affect exclusively the lower part of the larger bowel, there is much mucus and perhaps streaks of blood from straining. In the first few hours the stools are usually frequent, but afterwards they become rarer, and five or six -seldom more-are passed in the course of the twenty-four hours. They are more numerous in the day than in the night, and are excited by liquid food, especially if this be taken warm and in large quantities at a time. The belly is not swollen or tender, and the motions after the first are usually voided without pain. If frequent, they have a noticeable effect upon the nutration of the child. He looks pale, and his flesh quickly becomes soft and flabby to the touch, although to the eye the body may not appear to be wasted. A thermometer placed in the rectum shows no increase of temperature. The duration of the derangement varies from twenty-four hours to two or even three days. If it exceed that period, it often passes into the more serious variety described in the next chapter.

If the diarrhosa be due to a chill, other signs of esturth may usually be detected. The child snuffles from slight coryzs, or coughs from a triling

cold on the chest.

After the age of infancy, the symptoms present little variety from those just described. The child may complain of discomfort in the belly, but preserves his spirits, often his appetite, and will not allow that he is til. He is usually thirsty, and his tongue is furred, but his general health, and even his nutrition, seem to suffer little, if at all, from the looseness of his bowels.

In children of five or six years of age and upwards a form of looseness of the bowels called "lienteric diarrhea" is common. This derangement consists in an exaggeration of the normal peristaltic movement, which appears to be at once excited by the taking of food. In these cases, the latter part of a meal is accompanied by an uneasy sensation in the belly which soon becomes a griping pain, and is quickly followed by an urgent desire to evacuate the bowels. Often the child has to burry away from the table, and the motions are found to consist almost entirely of undigested food and mucus. The bowels act in this manner after each meal, and often also in the morning before breakfast. The abdominal pain may be complained of at other times without being followed by a stool. The tongue is slightly furred, or is clean, red, and irritable-looking. If this looseness continue for several weeks, as it often does, it causes considerable impairment of nutrition.

Treatment.—If an infant be taken with diarrhea, the treatment will vary according to the period at which the child comes under observation. If he is seen early, and there are signs of abdominal discomfort, especially if the motions contain lumps of undigested curd and starch, it is always best to assist the discharge of the offending matters by a teaspoonful of castor-oil, or a small dose of rhubarb and soda (gr. iv.-v), of each with gr. j of powdered cinnamon). This the child will take readily if it be made into a paste with a few drops of glycerine. Afterwards an antacid can be ordered with a carminative. The following, slightly altered and modernised from

an old prescription by Boerhaave, is very useful:

	ipon. duri						
C	retae præp				 	 	gr. xx.
S	rupi tior.	aurantii	l		 	 	2 ij.
, A	q. menths	BELLYB.			 	 	g jij.
M A	. fænicul			• • •	 	 akt.	5 j.

Sig. A teaspoonful to be given every eight hours to a child between six and twelve months of age. To older children it can be given every six hours.

If, after the action of the laxative, the stools still continue to contain lumps of undigested food, or if the belly remain hard and distended, it is well to repeat the aperient until the dejections assume a more healthy character.

Even if the diarrhea appears to be occasioned by a chill, it should be treated in the same way; for there are in such cases acrid secretions which cause great irritation of the bowels until they are removed. At the same time, care should be taken that the abdomen is kept warm with a flamed binder, and that the child, if nursed, is restricted to the breast. If he be fed by hand, the milk should be diluted with barley-water, or with water in which a little gelatine has been dissolved, to insure time division of the curd, and should be alkalinised by the addition of ten or fifteen drops of the saccharated solution of lime.

In the large majority of cases, an attack of simple diarrhora is quickly arrested by this means, especially if care be taken that the child is confined to the house and guarded from further chill. If, however, the looseness continue, a powder composed of rhubarb (gr. iij.) and aromatic chalk (gr. v.) should be given at night-time; and in the day, a small quantity of laudanum should be prescribed with an antacid and warming aromatic:

B.	Sp. ammon. aromat	m xx.
	Tinct rhei	M xxiv.
	Tinct. opii	guttee iv.
	Sp. chloroformi	
	Aquam caruiad.	31.

Sig. One teaspoonful to be given every eight hours to a child of six months old.

Oxide of zinc (gr. j.); bismuth and chalk (gr. iij.-v. of each); and the old-fashioned but not the less useful chalk and catechu mixture, are all of service, especially if the stools are acid and frothy. So long, indeed, as signs of fermentation are visible, chalk with an aromatic should form part of the mixture, whatever be the combination adopted. If afterwards the evacuations become thin and watery, an astringent is indicated. Such cases, however, ought strictly to come under the head of inflammatory diarrhea, and full directions for their treatment will be given in the next chapter.

If the diarrhose occur in the course of teething, there is often hesitation as to the course to be adopted. Some authorities have been of opinion that the purging should not in such a case be hastly arrested, lest the fever and local inflammation be thereby aggravated. There is, however, no foundation for such apprehensions. I have never seen ill effects follow from the suppression of the intestinal flow. On the contrary, if the infant be weakly and the bowels habitually irritable, the continuance of the relaxation may cause such depression of the strength as to place the child's life in immi-

nent danger. The wisest course to follow is, first to remove irritating scoretions by a mild aperient, such as the thubarb and soda powder, or easteroil, and afterwards to prescribe one of the antacid mixtures given above. Boerhaave's aromatic soap draught is very useful in these cases.

After the age of infancy children must be treated for the mild form of diarrhose upon precisely similar principles to those laid down above. They should be confined to the house, and restricted in acid-making articles of food, such as fruit and sweets. A dose of rhubarb and magnesia, followed by a draught, several times in the day, containing spirits of sal volatile with chloric ether and a few drops of laudanum, or chlorodyne in some aromatic water, will soon restore the alimentary inucous membrane to a healthy condition.

Lienteric diarrhosa must not be treated with astringents. The looseness is quickly arrested by small doses of amenic and hux vomica. For a child of six years old one drop of Fowler's solution of arsenic may be given, with two drops of functure of nux vomica, three times a day, before food. One or two drops of laudanum may be added if the looseness does not quickly yield.

CHAPTER V.

INFLAMMATORY DIARRHOEA.

INPLANEATORY diarrhora (severe intestinal catarrh or entero-colitis) is a much more serious disorder than the preceding. The purging may be severe from the first, or may begin as a mild looseness of the bowels, which quickly becomes more violent, and is accompanied by very evident impairment of the strength and interference with the general nutrition of the patient. In teeble children and infants it is often rapidly fatal, and even robust subjects may die collapsed after a few days. In some cases it passes into a chronic stage, and if not fatal to life, may reduce the child to a state of extreme emacation and weakness.

Causation.—The causes which have been enumerated as giving rise to the simple non-inflammatory form of diarrhoa may also induce the more serious variety of intestinal catarrh. The severity of the process excited by these agencies is probably often dependent upon constitutional tendency, or upon some special state of the system prevailing in the child at the time

of the attack.

Chilling of the surface and improper feeding are, no doubt, answerable for many of these cases. Besides these, the drinking of contaminated water, or the efflueum from decaying organic matter given out by the putrefying refuse of large cities is, no doubt, a frequent cause of the prevalence of severe and often fatal dearthea during the summer months. Not unfrequently several of these causes are found in operation at the same time. If an infant born of poor parents, and living in a badly drained and crowded house, be fed in hot weather from an ill-cleaned and sour-smelling bottle, it may be considered certain that acute infammatory diarrhea of a violent character will very shortly follow. In bottle-fed infants, indeed, the chosense is especially common, and is answerable for a large part of the mortality which occurs in cities during the first twelve months of life.

Severe inflammatory diarrhoea appears to be almost confined to large towns; and the mortality from this cause is greatest during the months of July, August, and September. According to Dr. G. B. Longstaff, it is not so much heat alone, as heat combined with drought that gives its virulence to the disease; for the mortality is greatest in years with hot, dry summers, least in years when the summers are cold and wet. This observer regards the complaint as a communicable zymotic affection, and attributes its origin to a locally bred musma from the soil or sewer-air. It seems, indeed, likely that in many of the more serious cases of acute inflammatory diarrhoea there may be a strong septic element in the illness. Certainly we often find a degree of nervous prostration quite out of proportion to the amount of purging. Indeed, a state of exhaustion may continue after the diarrhoea has been arreated, and end in death, although days have passed without any excessive looseness of the bowels having been noticed.

Weakness of the child, as might be expected, favours the occurrence of

inflammatory diarrhose; but there are certain diseases which are connectly accompanied by catarrh of the bowel. Thus in typhord fever dearlose is a frequent symptom; and in measles and scarlatina purging may ferral very serious complication. Again, causes which promote congestion the portal system, such as cirrhoses of the liver, and diseases of the heart and lungs, which impede the passage of the blood from the right side of the heart to the left, and therefore interfers with the whole venous circulation may also help to determine the derangement.

Marbid Indong.—The catarrh of the intestine is seldom general smally it is very partial, and is limited to the large intestine and jopular. On opening the bowel we find the lining membrane coated at the utlet st part with a layer of thick mucus containing detached epithelial scales. The mucous membrane itself is red-lened, and often thickened, and its soling glands and the glands of Peyer's patches are swellen so as to project along the surface. Sometimes the mesenteric glands are a little swellen.

If the inflammation have passed into a chronic stage it is dark gray a dirty red in colour, and the enlarged follicles can be seen as small, pearly projections. In some cases patches of false membrane are seen on the surface especially in the large intestine. The mucous membrane then has the appearance of being sprinkled over with bran. The little patches course for exuded lymph containing epithelial scales. They vary in size and shape, mitually occupy the summits of the ridges of the mucous membrane.

If the catarrhal process has lasted long or been very serious we often find ulcerations. These are usually seen in the large intestine, especially towards the lower part, and in the lower part of the illium. The ulcerate seated at the follicles and result from suppuration and ulceration starter from the interior. They are at first circular but may extend their circum regularly. Not rarely we find intussusceptions of the bowel. These usual occupy the small intestine, and several may be present at the same treathey are evidently produced immediately before death, for the invarianted portions can be readily drawn out and show no sign of congestion or suching.

In many cases of severe intestinal catarch the liver is futty. As the frequent complication, according to Kjellberg, is parenchy matous replace. This physician states that in 143 cases of fatal intestinal catarch has find kidney disease in no less than 67. It is more common in infants that a older children, and is often partial, attacking only a portion of the cornel substance.

Symptoms.—The symptoms of acute inflammatory distribute vary to some extent according to the age of the child. As a rule, if the policite be profuse the dramupon the system causes symptoms of depression which come on earlier and are more severe in infancy than at a later period of childhood. Moreover, in infancy the intestinal disorder is apt to be acceptanted by symptoms dependent upon parenchymatous nephritis; are it the complication is not so often seen after the period of the first direction as come to an end. The derangement will, therefore, he first described a affects infants, and afterwards as it is met with in older children

In videals inflammatory diarrhosa usually begins like the mode? with symptoms of discomfort about the belly and some boseness of the bowels; but the purging soon becomes more severe. If there be any tric catarrh, the child often vomits; and both the matter ejected from the stomach and that discharged from the bowels is acid and sour such their character and become thin and watery. They are brownish or greated

in colour, and give out a most offensive odour. Unless the lower bowel be affected there is little mucus visible to the eye, and the stools are passed without straining or signs of pain in the belly. In number they vary from ax or seven to fifteen or twenty, or even more, in the twenty-four hours. Their character is found to change from time to time, partly according to the frequency of their passage. Thus, if they follow rapidly upon one another they usually consist of dark-coloured watery fluid, which deposits thick feculent matter on standing. If separated by a longer interval, they become theker and more distinctly fæcal, and may contain small lumps of curd. Often they vary in character, and are at different times light and pasty, or frothy and dark, or green and very liquid. They are almost always very offensive. Under the microscope Dr. Lewis Smith has detected undigested particles of casein, fibres of ment, crystalline formations, epithelial cells—single or arranged in clusters—mucus, and sometimes blood. According to Nothnagel, of Jena, nucus, invisible to the naked eye, but perceptible under the microscope, indicates a catarrh of the smaller bowel.

The general symptoms are very severe. The infant rapidly wastes, and becomes so weak that he cannot sit up. His eyes get hollow; his face is very pale; the nasal line encircling the corners of his mouth becomes deepened into a distinct wrinkle, and erythematous reduess appears upon the buttocks and inner parts of the thighs from the irritation of the discharges; the skin is dry, and the amount of urine is greatly diminished. Often the tongue is quite clean and red, although less moist than in health, and there is great thirst. If there is much gastric catarrh, the tongue may be furred upon the dorsum, and vomiting is often a distressing symptom. The pulse is rapid and feeble. The temperature varies. Sometimes it remains unaltered or may even be subnormal; in other cases it reaches to 102 or 103, rising and falling irregularly, but never dropping to the level

of health

After a few days, the earlier in proportion to the profuseness of the drain, the child falls into a state of profound depression, with quick, feeble pulse, and rapid, shallow breathing. The eyes are hollow, the purple lids close incompletely, and the face, especially round the mouth, is livid. The Contanelle is deeply depressed. The tongue often gets dry and brown, and thrush may appear upon the cheeks and lips. Often, although the hands and lect feel cold, the internal temperature of the body is very high. A thermometer placed in the rectum will sometimes mark 107", or even higher. although the child's general appearance is that of collapse. Thus, a little box, aged nine months, had suffered from diarrhea for a week, and was occasionally sick. When seen the motions were light coloured, watery, and offensive. His temperature (in the rectum) was 105.6°; pulse, 176; respirations, 64. On the following morning the temperature was 103'; but In the evening it rose to 107.8°, and the child died a few hours afterwards. Just before death the thermometer marked 106°. Another infant, ten months old, had diarrheea for about a fortnight, the bowels acting five, six, or seven times in the day. At this time the temperature was normal. It then began to rise, and for a few days varied between 101° and 102°. Then it rose rapidly to 107.4°, and the child died with all the signs of collapse. In neither of these cases was permission obtained to make examination of the body, but no complication could be discovered during life to account for the elevation of temperature.

When the catarrh is scated in the larger bowel, especially if it affects principally the descending colon and rectum, the symptoms are more dysenteric in character. Indeed, this form of inflammatory diarrhosa is often

improperly spoken of as "dysentery." The infant usually cries before the passage of a stool from griping pairs in the belly; and the evacuations are discharged with great effort and straining. Often the bowel prolapses and the motions contain streaks or drops of red blood. The stools themselves consist of slimy matter from admixture with mucus, and lumps of coagulated mucus can be distinctly perceived in the feed matter. Sometimes the straining continues for a considerable time after the passage of the motion, and the prolapsed bowel protrudes like a bright crimson ball from the anus. Often it can be returned only with great difficulty, and when replaced is shot out again directly by the straining. In this form the stools may be as numerous as when the small intestine is affected, the vomiting as distressing, and the prostrating effect upon the system of the constant purging quite as pronounced. Indeed, if the tenesmus is urgent and the protrusion of the inflamed bowel almost constant, the case is very likely to end fatally.

If the derangement be complicated with parenchymatous acphritis, the signs of general collapse, into which the infant in fatal cases almost invariably sinks, are diversified by others pointing to the kidney. According to Kjellberg's description of such cases the tongue is dry, the skin upon the abdomen is cool and dry, and its elasticity is completely lost, so that when pinched up it remains wrinkled, lying in loose folds; the legs are stretched out and stiff, often ordematous, the urine is very scanty, albuminous, and deposits a sediment containing epithelial and hyaline casts and small round cells. The chill vomits occasionally, sometimes shricks out, and may be convulsed. In the very acute cases the infant is resiless, with a very rapid pulse and hot skin. He flexes his thighs on his belly, and although drowsy and stupid, screams at times with purp, and appears to feel

acutely the slightest touch upon his body.

In the more protracted cases the infant often falls into a comatose state, which from its resemblance to the third stage of meningitis has been called "spurious hydrocephalus." The child lies in a drowsy condition, from which, however, he can at first be roused. His eyelids are hilf closed; the pupils are sluggish and may be unequal; the pulse is rapid, and often intermittent; the breathing is irregular and sometimes sighing; the fontanelle is deeply depressed; the features are purched and shurp; and the complexion is livid or even lead-coloured. The temperature taken in the rectum is subnormal. While in this state the stools—small, watery, and often greenish—may continue, and be passed involuntarily, or the purging may cease, but without being followed by any signs of improvement. Unless energetic measures of stimulation are adopted, the child continues in the same state for twelve or twenty-four hours, or even several days, growing weaker and weaker, and death may be preceded by a slight convulsive seizure.

Spurious hydrocephalus may be the consequence merely of sluggish circulation through the brain of impoverished blood. Often, however, it appears to be owing to the occurrence of thrombosis in the cerebral sinuses. Parrot has suggested that it may be sometimes due to unemic poisoning

from deficient renal secretion.

When the disease occurs after the age of infancy, the child is usually able to resist the exhausting effects of the diarrhea for a longer period than is possible at the earlier age; but he rapidly loses flesh and strength, and if the purging is severe and is accompanied by vomiting, the features boon look pinched, the eyes get hollow, and the expression is languard and distressed. Unless the lower bowel is affected, pain in the belly is usually

insignificant; but if the descending colon is the seat of the derangement, there is much tenesmus and griping pain, and the bowel may prolapse. The temperature in these cases is usually moderately elevated during the earlier period of the attack, but often falls to a lower level than that of health when the purging has produced much depression of strength.

The stools are very watery and offensive, usually dark in colour, and if much milk is being taken, may contain lumps of curd. Sometimes, especially in very hot weather, they may be yellow or green from excessive secretion of bile. The urine is comparatively scanty and high-coloured. According to Nothinagel, if the small intestine is the seat of catarrh, the excretion of indican is in excess. When death takes place it is usually by asthema; but spurious hydrocephalus is uncommon after the period of infancy has passed, and, according to Kjellberg, kidney complication after that age is equally rare.

At all ages the symptoms of prostration come on earlier and are more pronounced if the child is already reduced in strength when the attack begins, and therefore inflammatory diarrhosa occurring as a secondary complication in a child worn and wasted by previous illness is an exces-

sively serious derangement.

The chrone form of intestinal catarrh is a very obstinate and dangerous disorder, and unless treated judiciously is almost cortain to end fatally. It may succeed directly to an acute attack, or may begin insidiously. If it occur as a sequel of the acute variety, the stools gradually become fewer and the more urgent symptoms subside. The child, however, does not regain flesh or strength, but remains feeble and pallid. His bowels act three or four times a day, and the evacuations consist of thin, dark, offensive fluid, or of equally offensive pasty matter and mucus.

The insidious beginning of the chronic disorder is very common. If detected early and treated with judgment, it is readily arrested; but if it continue unchecked, it becomes a confirmed derangement and is much more difficult of cure. Still, even in bad cases the disorder may be usually

garded to a successful issue if proper measures are adopted.

A child of eighteen months or two years of age is noticed to be looking pale, and his flesh is found to be flabby. Then he shows less than his usual pleasure at being on his legs, and if the power of walking have been only lately acquired, often refuses altogether to put his feet to the ground. These symptoms occasion great perplexity to the attendants, for the child's appetite continues good—often unusually keen—and his bowels are regularly relieved. On inquiry it will be found that the motions are more numerous than natural, often three or four in the day; that they are large, offensive, and sour-smelling, and that in appearance they rescouble a mass of soft putty. If only one or two stools occur in the day, they are often curiously copious; and the mother will declare that the quantity of fool consumed by the child, considerable as it may be, is quite insufficient to account for the enormous amount of matter passed from the bowels.

For weeks, perhaps, these symptoms go on unchanged. The wasting continues, and all power of digesting what is swallowed seems to be lost. Occasionally for two or three days together the bowels are relaxed, the stools being frothy and sour-smelling, or thin and dark-coloured like duty water; but the drarrhers soon ceases and the motions again become large, soft, and pasty, as they were before. The attacks of acute catarrh repeatedly return, the intervals between them grow shorter, and eventually the losseness becomes a confirmed condition. Often, however, a considerable time may clapse before this stage is arrived at. The child for months may

remain pale and listless, with curious alternations of voracity in feeding and disgust for nourishment of every kind. He is not feverish but sweats copiously. There is no actual diarrhora, perhaps even no increased frequency of stool. No pain is complained of The mother will say that she cannot think what is the matter with the child, but that he is wasting away.

When the diarrhoea becomes persistent, the stools vary in character from time to time. In any case, they have an intolerable stench; and may be dark coloured and watery; or thicker, but still fluid, like thin paste; or may consist of green matter, like chopped spinach, diffused through a dark brown liquid. If they show a shreddy deposit, mixed with small black closs of blood, ulceration of the bowels may be confidently predicated, even al-

though no tenderness of the abdomen can be detected.

The wasting now proceeds rapidly. The child gets hollow-eyed, wrinkled, and old-looking. His belly swells from flatulent distention. His lambs often become ordenatous. He is excessively feeble, and hes quite motionless, taking little notice of anything. His appetite may be good, even at this stage, but often it is capricious or altogether lost. The water is diminished in quantity, if the purging is severe, and may contain from time to time, a little uric acid sand. Eventually, the child sinks into a state of exhaustion, and dies from asthenia, or is carried off by an attack of inflammation of the lung. All the symptoms which have been described as spurious hydrocephalus, may be noticed before death, and the diarrhosa may quite cease during the last few days of the illness.

These insidious cases are more common during the second year of his, than at any other period, although they may also occur later. When the complaint arises as a result of an acute attack, chronic diarrhosa is often met with during the first year, and is especially frequent in infants who

have been weaned early and fed afterwards on unsuitable food.

Diagnosis.—Inflammatory diarrhosa, if accompanied by pyrexia, may be confounded with typhoid fever. The distinguishing points between these

two diseases are pointed out elsewhere (see page 83).

The severity and danger of the attack may be detected from the first, by noticing that the temperature in the rectum is raised. In simple diarrhoa, the temperature is normal after the first stool. It is a question of considerable interest to ascertain the exact seat of the catarrh. The presence of jaundice would, of course, indicate that the duodenum was involved; and tenesmus, with or without prolapsus am, would point to the rectum. From a series of careful and laborious investigations, carried out by Prof. Nothnagel, who submitted to microscopical examination more than one thousand specimens of catarrhal stools, considerable addition has been made to our knowledge of the distribution of the lesion in cases of intestinal catarrh. According to this authority, mucus is passed in considerable quantity in other forms of catarrh besides that affecting the lower bowel, and can be detected by the microscope when not visible to the naked eye. The amount of mucus, and its more or less intimate admixture with the frecal matter, furnishes important evidence; so, also, from the presence or absence of bilestained mucus and epithelium, much information can be derived. The results of Prof. Nothnagel's researches may be thus briefly summarised.

If the catarrh affect the jejunum and ilium, no mucus can be seen by ordinary inspection of the stools; but when a specimen is placed under the microscope between two thin plates of glass, islets of mucus are distinctly visible. We can then affirm positively that the catarrh is scated in the small intestine, and that the colon is healthy. If the mucus is tinted with bile pigment, it also indicates jejunal and ilial catarrh; but, in addition, it

shows that there is increased peristaltic action of the colon and the lower part of the ilium. In these cases, the stools are always liquid, for if retuned in the colon sufficiently long to acquire firmness, the bile pagment is always transformed, and the play of colours in Gmelin's test can no longer be obtained. Besides bile-stained mucus, cells of cylindrical epithelium, leucocyte-like corpuscles, and fat-globules, all tinted with bile, can be observed. In addition, on examining the urine, the indican' excretion is found to be in excess.

When the larger howel is affected, no bile-tinted mucus globules can be perceived. The stools are of a pulpy consistence, and the mucus they contain is distinctly visible to the unassisted sight. The nearer the affected part of the bowel is to the execum, the more intimate is the admixture of the mucus with the general facal mass. If pure mucus is passed in large quantity, we may conclude that the sigmoid flexure or the bowel below it is the part involved; and scybala embedded in mucus, point distinctly to the rectum.

Spurious hydrocephalus does not present much difficulty in diagnosis.

The history of exhausting disease, the depressed fontanelle, the low temperature, and the signs of general prostration, sufficiently mark out this

condition from the ordinary forms of cerebral disease.

Prognosis. - Inflammatory diarrhora is so fatal a complaint in weakly children that it is very important to estimate the chances of a favourable ending to the derangement. Much will depend upon the age of the child, the sanitary conditions under which he is living, and the state of his previous health. The disease is most dangerous in babies who have been weaned early, and fed afterwards on excess of farinaceous food, or with portions of their parents' meals. Such infants are weakly and ill-nourished at the time of the attack, with irritable bowels from their unsuitable dist. A severe scute catarrh coming on under such conditions, rapidly reduces their remaining strength, and very commonly ends fatally. Older children, having greater vigour, are often able to battle through a complaint which would kill a younger and weaker subject. Therefore, after the age of infancy has passed, the prognosis is more favourable than at an earlier pemod; but even in these cases, if the attack is violent and the purging severe, the danger is not slight, and the derangement may resist all our efforts to arrest its course.

At all ages, the case is more serious if the temperature is high than if it be only moderately elevated. Also, great frequency in the stools; violent vomiting; early collapse; unusual drowsiness or stupor; stertorous breathing; convulsions, or other sign of cerebral complication, and any sudden marked increase in the pyraxia—all these are signs of very serious import. On the contrary, a fall in the rectal temperature is of good omen. If the internal heat of the body be found to have become normal, we may entertain hopes of improvement, although the general symptoms appear to have undergone no change.

In the chronic form, the progness is also more serious in children under the age of two years. Another very important matter is the persistence of the diarrhosa. If the purging is a confirmed derangement, our chances of success are much fewer than if intervals occur, however short,

^{*}To test for indican:—Add to the urine to be examined, an equal quantity of funing hydrechloric acid, and then with a pipette, pour down a few drops of strong solution of chismle of time. If no indican be present, the colour of the urine so treated becomes relievished from the action of the test on some unknown constituent. If indican be contained in the urine, the colour of the fluid becomes dark green or blue.

in which the stools are merely soft and pasty without being relaxed. If ulceration of the bowels has occurred, we should look forward to the termination of the illness with very serious apprehension (see Ulceration of the Bowels).

Treatment.-In all cases of severe diarrhorn in the child, especially in the infant, our first care should be to place the patient at once upon a surable diet. This subject is of the first importance; for it is indispensable to improvement that all food be withheld which is capable of fermenting and giving rise to acidity. Our object is to furnish the child with a thet which will supply nour shment to the system without leaving an undigested residue to irritate the bowels, and so aggravate the derangement we are endeavouring to cure. Milk, in particular, must be prohibited unless the patient be an infant at the breast. If he be suckled, it will sometimes be found that restricting the child entirely to his mother's breast is followed by improvement. Often, however, even this diet will not agree, and other means will have to be adopted. A hand-fed baby must be fed with wher and cream, or whey and barley-water in equal proportions, or with weak veal or chicken tea diluted with whey or barley-water. The food should be given cold, and in small quantities at a time. If the child is weakly, and in any case if he show signs of becoming exhausted, white wine wher is of great service. This must be given cold in suitable quantities at regular intervals. Thus, a feeble infant will take a tablespoonful every hour with advantage at first. Afterwards, as the need for stimulation grows less pressing, other foods may be alternated with the white wine whey; or this may be given only two or three times in the day.

Koumiss has been used largely in these cases, and sometimes appears to agree. My own experience of this food, however, has not been quite satisfactory. In giving koumiss to a young child, the gas should be first expelled by pouring the fluid several times from one vessel to another. The quantity allowed to be taken at each meal must be proportioned to the severity of the purging. If this be insignificant, the child may take the whole contents of his feeding-bottle. If, on the contrary, the looseness be frequent and exhausting, koumiss, like other fluids, must be given sparingly, and the quantity taken on each occasion must be very carefully restricted. The addition of Mellin's food to any of the first-named fluids is useful, and

in most cases answers well.

Older children should be fed, while the temperature is high and the purging severe, with plain whey, barley-water, and weak veal or chicken broths, given in small quantities; or if the strength is failing, with the wine whey, or brandy-and-egg mixture, and strong meat essence. When the first violence of the disease has abated, the patient may begin to take milk, but it should be well-diluted with barley-water to insure fine division of the curd, and be alkalinised by the addition of the saccharated solution of lime, fifteen or twenty drops to the teacupful. Whatever be the age of the patient, any sign of exhaustion must be combated by energetic sumulation. Brandy must be given internally, and the skin must be irritated by warm mustard baths.

After regulation of the diet, the next matter is to see that the belly is kept warm. The whole abdomen should be covered with a thick layer of cotton wadding, and this must be kept in place by a broad flannel binder. If there is any tendency to coldness of the feet, they must be warmed by a

hot bottle.

Purity of the air is another point which is not to be neglected. The window should be opened—care being of course taken that the child is

not exposed to draught—and a free circulation of air through the room can be insured by a small lamp placed in the fire-grate. Few persons should be allowed in the sick room; and all soiled linen should be removed at

once to another part of the house.

In all cases of severe intestinal entarch, a careful watch should be kept over the temperature, and any great increase in the bodily heat should be at once reduced by tepid bathing. In tropical climates, the treatment of inflammatory diarrhora by baths has been found very successful. A point of great practical importance in applying this method, is to remember the depressing effect of the illness, and to be careful that the application of cold is not carried to the point of inducing prostration. The more weakly the child, the more careful should we be so to regulate our measures, as to avoid a shock to the system which might be too severe to awaken any responsive reaction. The use of the bath at once reduces the temperature, and even in cases which eventually prove fatal, its immediate effect is often encouraging.

A little girl, aged twelve months, with twelve teeth, was seized with severe duarrhoea. The stools were buff-coloured and watery, without lumps, and were passed very frequently in the day. After about a week, the dejections became frothy, and had a dark green tint. There was much tenesmus, and the bowel sometimes prolapsed. On an average, there were about fifteen stools in the twenty-four hours. The child was very weak, and had

no appetite, but was thirsty. She never vomited.

When first seen on the twelfth day of the purging, the tongue was red, with some fur on the dorsum. The skin was inelastic. The abdomen was distended, but unless the child strained, the purietes were flaccid, and there was no tenderness. The eyes were hollow, the mouth livid, and the masal line was well marked. The fontanelle was depressed. The temperature was 103.4°.

The child was ordered to be fed with veal-broth and barley-water in equal proportions, and to take as medicine, powders of bismuth and aromatic chalk. After each motion she was bathed in cold water. After six of these baths, each of which had greatly reduced the temperature, the bodily heat remained normal, the stools were reduced to three in the twenty-four hours, and the child's appearance was much improved. She looked brighter, the eyes were less hollow, and there was less hvidity about the lips. The stools were green and slime, and were evacuated with straining. Unfortunately, after a few days of this improvement, although there was no increase in the diarrhea, the child seemed to sink from exhaustion, and died on the mnetcenth day of the illness.

In this and similar cases, the child was placed in cold water, and bathed for a minute or two with a sponge. When the child is very weak, it is advisable to make use of water warmed to the temperature of 70°, and to bathe him in this water for a few minutes, or until sufficient evidence of reduced temperature is obtained. Afterwards, he should be placed between blankers in his cot, with a hot bottle to his feet. A stimulant is usually required after the bath; and may be given with advantage, also, when the

child is taken out of his cot to be placed in the water.

The above measures are all of great importance, and constitute in themselves the main treatment of the disease. The use of drugs, although often of signal service in the conduct of the case, cannot be expected to lead to any good result unless the other matters have been first attended to.

If the case is seen early, it is well to begin the medicinal treatment with a gentle laxative, such as castor-oil, or rhubarb and soda. Afterwards, if the temperature is only moderately elevated, not passing above 100° in the rectum, the aperion should be followed by an astringent mixture containing

onium. For a child of six months old, two grains of the extract of hometoxylon may be combined with five drops of the tincture of catecha, and half a drop of laudanum in a chalk mixture, and given every ax hours in the day and night. If the case resist this treatment, it usually goes on. and appears to be little influenced by astringents, however ingenious viter may be varied and combined. The cases we meet with in children s bospitals, have usually been treated with a variety of the ordinary landing reaedies, but the diarrhoa continues apparently unaffected by changes in the physic. After seeing many of these cases, we are led to rely less upon the pharmacopicia than upon attention to diet and the other means by which the disorder may be controlled. Of astringent remedies I prefer the entracts of hiematoxylon (gr. ij.-v.), and rhatany (gr. ij.-v.), or the therm of catechu (M r.-x.), to gathe acid, sulphuric acid, and lead. In my hann dilute sulphuric acid has appeared to be almost inert unless given in ster ly concentrated form; gallic acid is often disappointing as a cure for hisrhose, and lead I believe to be inadmissible for infants, as it has seemed to

me to be not unfrequently a cause of convulsions.

In cases which resist the ordinary astrongents, the old prescriptor of dilute nitric acid with opium is often of special value. For a child of ca months old, two drops of the dilute acid, with half a drop of tinet, out may be combined with a quarter of a drop of truct, capaci, or two of tack zingiberis, and given in a tenspoonful of water sweetened with given: three times a day. When the diarrhora is accompanied by a high temper nture, astringents are seldom of much service until the pyrous has sub-In these serious cases, the temperature must first be reduced by mel x tepid bathing; and for medicine, the child may take a few drops of estate oil (M iij.-vj., according to his age), with one or two drops of laudance. several times in the day. Another remedy, from which the best results was times follow, is ipecacuanha. The value of specacuanha in small and apeated doses in the bowel complaints of children, has long been known Certainly, there are few drugs which have a more striking effect upon the mucous membrane of the intestine. The dose of specacuanha should away be combined with an aromatic. One-tenth or one eighth of a grain may be given with a few grains of aromatic chalk powder in muchage every three or four hours. Even in these small doses, the remedy may sometimes reercise a depressing effect upon the system; it is well, therefore, to combut with each dose a few drops of chloric other or sal volatile. Another for in which the remedy may be administered is the time-honoured combinate of Dover's powder with mercury and chalk. I have known obstinate comof inflammatory diarrhosa, which had resisted other methods of treatment to yield quickly to small and repeated doses of this compound powers. In a child of aix months old, I order a quarter of a grain of each (Dover's pasder and gray powder) every three hours. Ipecacuanha is also useful a somewhat larger doses, so as to produce a slight emetic action. Times a quantities of half a grain or a grain to a child of six monthsold twice in Se day, it will often produce vomiting without much retching; and if the stools have been previously pasty and sour-smelling, will cause a very rapid improvement in their character. When the lower bowel is affected and there is great tenesmus, ipecacuanha is especially indicated. In such cast it may be administered suspended in thin starch (gr. v. to 🗦 ij) as an ingetion twice a day. The castor oil and opium mixture is also useful above the lower bowel is the soat of catarrh, and has great influence in allows: the pain and tenesmua. One-eighth of a grain of powdered ipecs-uses may be usefully combined with this mixture. If the stomach is very an

table, and the diarrhosa is accompanied by excessive vomiting, ipecacuanha is of the utmost service. This drug, although an emetic in large doses, in feeble doses is a sedative; and if given very frequently in small quantities, has a very striking influence in improving the condition of the patient. In fact, fully to exhibit the value of this remedy, we should select a case in which the vomiting is frequent and the tenesmus distressing, and give one or two drops of ipecacuanha wine in half a teaspoonful of water regularly every hour. Antimony, which has a similar action to ipecacuanha, is also useful in like cases. Two drops of the wine, combined with half a drop of opium, and two or three of tincture of ginger, form a very satisfactory remedy given every four or six hours. In all cases where the lower bowel is inflamed, an injection of tinet, opin in thin warm starch (M inj.-v. to 5 sa.) is most useful in relieving the tenesmus and checking the purging. It may be administered every night. Dr. Tyson recommends chloral to be used in the same way, and prescribes half a drachm of the chloral hydrate to two ounces of thin starch. Of this, one drachin is to be used at a time. A drug which is often useful when other astringents fail, is bismuth; but to be efficacions, the dose of this drug must be large. For a child of six months old, it will be useless to give a smaller quantity than ten grains every four hours. I usually combine the bismuth with a few grains of the aromatic chalk powder, and have often met with very good results from this remedy.

Directly a reduction in the temperature and an increase in the consistence of the stools show that the first acute violence of the disease is subsiding, astringent remedies are called for, and the case must be treated as

already described,

If the lower bowel is acutely inflamed, and prolapses as a crimson ball which cannot be returned, or is replaced with great difficulty, the protruded gut should be first fomented with warm water; next, half an ounce of thin, warm starch, containing four drops of laudanum and five grams of powdered ipecacuanha, should be thrown up the rectum; lastly, a thick poultice of boiled starch should be applied over the fundament. The enema may be repeated twice a day, but the fomentation and poultice should be renewed after each action of the bowels. If prolapsus occur later, as a consequence of relaxation of the sphineter and irritability of the mucous membrane at the lower part of the rectum, the bowel should be returned by pressure with the oiled finger, and if necessary may be retained in place by a pad. Astringent and tonic remedies internally, such as pernitrate of iron and nux vomica (for a child of six months old : liq. ferri pernitratis, in iij. ; tinct. nucis vonnce, in \(\frac{1}{2} \); aquam ad , \(\frac{1}{2} \)j. ; to be taken three times a day), and enemata of infusion of rhatany after each protrusion, will usually quickly put an end to the prolapse. Ordinary cases of prolapsus ani in children, the consequence of repeated catarrhs of the lower bowel, without any great frequency or urgency in the dejections, may be readily cured in most cases by the application of an efficient flannel binder to the belly. The occurrence of fresh catarrhs being thus prevented, the relaxed mucous membrane soon recovers its tone.

In cases where the symptoms known as "spurious hydrocephalus" are noticed, or in any case where signs of prostration are visible, the child should be placed for ten minutes in a warm mustard bath, and should be afterwards wrapped in flamel, with hot bottles to his sides and against his feet. The brandy-and-egg mixture can then be given every hour or half hour in doses of one tenspoonful, or if the patient be a young infant white wine whey may be used instead. In all cases of inflammatory diarrhora, the quantity of food to be taken at one time must be carefully regulated

according to the strength of the child. If the purging be severe, and especially if it be accompanied by distressing vomiting, liquid food should be given in quantities of one spoonful every half hour. Sometimes no more than one teaspoonful can be borne at one time.

In the chrone form of inflammatory distributes, the treatment consists mainly in a careful regulation of the food. Milk in such a case is an irritant poison which must be strictly forbidden; and starches are digested

with difficulty, and must be very sparingly allowed.

In the insidious beginning of the disorder, when large pasty stools are being passed, the child, if an infant, should be fed with weak veal-broth and barley-water in equal proportions; whey with cream; the yolk of one egg beaten up with broth or whey; and Mellin's food mixed with whey or barley-water. The meals should be frequently varied during the day, and the quantity allowed must be strictly proportioned to the infant's powers of digestion. For medicine, he may take a powder of rhubarb (gr. ij. iii) and aromatic chalk (gr. iij. v.) every night for three nights; and in the day, a mixture composed of half a drop or a drop of laudanum with four or five grains of the bicarbonate of suda in some aromatic water. If the stools still continue pasty in character, although reduced in quantity, a couple of grains of pepsin may be given two or three times a day in water and glvcerine, before food. In such young children, if the derangement have not passed beyond this early stage, it is usually readily arrested by this means. The infant should be warmly clothed, with a flannel bandage round his belly, and should be taken out frequently into the open air.

In older children, if the derangement have persisted for a considerable time, digestion and nutrition are less easily restored. The same plan must

be adopted of forbidding milk, and greatly restricting the quantity of starchy food. The child should take the yolk of an egg for his breakfast, with a slice or two of thin, well-tousted bread and fresh butter. For dinner, the lean of an under-done mutton-chop, with well-boiled cauliflower, and fried bread crumbs. For his evening meal, strong broth, meat jelly, or meat-escance. It is best, in obstinate cases, to accustom the child to take mult biscuits, or multed rusks, instead of ordinary bread and toast, as the former are much more readily digested. Sometimes the pancreatic emulsion scens to be beneficial, but apart from the disagreeable taste of this preparation, which renders it exceedingly unpleasant to the patient, it often causes musea and discomfort, and has to be discontinued. Pepsin (gr. ii). v.) is, however, very useful, and the extract of mult often proves a valuable aid to digestion.

Still, maltine must be given with caution, as, if it contain excess of glucose,

it may encourage looseness of the bowels.

I have found raw meat of immense service in cases where the stools continue pasty and offensive in spite of the most careful regulation of the diet. It is prepared by mineing a piece of raw rump-steak or mutton-chop, pounding it finely in a mortar, and then straining through a fine sieve. Meat so prepared may be caten as it is, or diffused through meat-broth or meat-jelly, or spread upon bread and butter. It may be taken in large quantities. If possible, the child should be induced to swallow from a quarter to half a pound in the course of the day. Before each meal of raw meat, a dose of pepsin should be administered. Children soon take a liking for this food. At first it is only partially digested, and the decomposing residue gives a most offensive smell to the stools; but after a few days, especially if pepsin be taken, the meat ceases to be visible in the motions. By the above measures, strictly carried out, the most obstinate cases can be arrested. The child rapidly regains flesh and strength, and after a time

his power of digesting milk and starch returns. Very careful watching, however, is required in order to carry the illness to a successful issue. The stools must be inspected every day, and any sign of looseness, offensiveness, or hyper-secretion of mucus will require to be promptly attended to. Offensiveness of the motions is due to the presence in them of undigested and decomposing food. This is often the consequence of abnormal briskness of peristaltic action, which forces the contents of the bowel too rapidly along; or it may be due to mere weakness of digestive power. In the first case, one drop of landamum should be given three times a day to quiet exaggerated peristaltic action. In the second, the diet must be revised, especially in the matter of farinaceous food, and no starch unguarded by malt should be allowed to be taken. Excess of mucus may usually be quickly moderated by the easter-oil and opium mixture previously recommended, or by a few drops (v.-x.) of liq. hydrargyri perchloridi, given every two or three hours during the day. Slight looseness of the bowels is readily arrested by aughtly doses of powdered rhubarb (gr. iij.-v.) and aromatic chalk-powder (gr. v. -vii); or the latter may be given with a drop of laudanum, and ten or lifteen of truck catechu, three or four times in the day. The flannel binder in all these cases is as important for older children as it is for infants, and should be fitted closely to the abdomen, as already directed.

If, when the child is first seen, the derangement has become a confirmed diarrhea, the above plan of treatment, as regards duet, must still be the same. The belly should be covered with cotton wadding under a flaunel binder, and the child should be strictly confined to two rooms. The purging must be controlled by hematoxylon, rhatany, and opium, given several times in the day in the doses recommended on a previous page; and if the motions are sour-smelling, a few grains of aromatic chalk may be added. If the purging is obstanate, especially if ulceration of the bowels is suspected, nitrate of silver is a most valuable remedy. It is suitable to both infants and older children, and should be given with dilute nitric acid and tinet, opin in glycerine. For a child of six months old, one-eighth of a grain may be administered every four hours. For an older child, the quantity of the nitrate may be increased to one-fifth or one-fourth of a grain. The treatment of severe cases when ulceration of the bowel is present, is fully

considered in another place (see page 666).

The raw meat diet is very useful in obstinate cases, and, if the diarrhosa be copious, should form the staple of the child's nourishment. Stimulants will usually be required, and should consist of the brandy-and-egg mixture given as often and in such quantities as may seem necessary.

When the purging has been arrested, the case must be treated as described for the early insidious form of the complaint. Afterwards, quinine and iron may be given, and the child should be sent, if possible, into a bracing air. A valuable tonic in these cases is the following, suitable for a child of three years old:—

Ŗ.	Pepsini porci	gr. iij.
	Liq. strychuiæ	刑士
	Quintae	gr. 88.
	Acidi nitro-muriatici dil	M iij.
	Aquamad.	3 ij.

M. ft. haustus.

To be taken before each of the three principal meals.

Cod-liver oil is also a useful remedy, and should never be neglected in obstinate cases.

CHAPTER VI.

CHOLEBAIC DIARRHEA (INFANTILE CHOLERA).

Change are diarrhose is the most dangerous form of intestinal flux to which children are liable. It occurs only during the summer months, runs a very rapid course, induces in a few hours a startling change in the appearance of the patient, and often ends fatally. The affection has derived its name of choleraic diarrhose from its resemblance in many of its symptoms to Asiatic cholera; but it is not, like the latter disease, an epidemic malady, and appears to be essentially distinct in its nature, although in many re-

spects so apparently similar.

Causation.—Choleraic diarrhosa is especially a complaint of warm weather, and summer heat must be looked upon as a powerful predisposing cause of the disease. Other agencies, however, must come in as exciting causes, for the affection is not common in country places, and indeed is rarely seen out of cities. Injudicious feeding, had drainage, and the effluvium arising from decaying organic matter are probably auxiliary causes which have a notable influence in exciting this as well as the other forms of gastro-intestinal disorder. Infantile cholera, as its name implies, is a disease of early childhood, and is more common during the first aix months than at a later period of infancy. It is said not often to be mot with after the first dentition is completed; but older children are subject, like adults, to attacks of cholerine or summer cholera, which have all the characteristics of choleraic diarrhesa in the infant. Boys are said to be more subject to it than girls; and robust children are attacked by the com-

plaint as often as the ailing and the feeble.

Marbid Auutomy.—An examination of the intestinal canal in fatal cases of infantile cholera reveals little to account for the clarming character of the symptoms by which the progress of the disease had been accompanied. A patchy redness of the mucous surface may be visible, but often this is very slight and incomplete. Indeed, it may be absent altogether, and instead of red, the mucous membrane may be paler and more bloodless than natural. The glands of Peyer's patches, and the solitary glands of the large intestine, often stand out from the surface like little trunslucent projections, and sometimes the mucous membrane is softened. The softening appears, to be a secondary lesion, and to occur as a consequence of the profuse serous transudation, which is one of the main features of the illness The same softened state of the mucous membrane is often seen in the stomach. If the course of the disease is very rapid, extensive destruction of the crithelial coating has been noticed in the gastro-intestinal canal The organs generally are anomic. The brain is especially bloodless, and is said to give evidence of fatty degeneration and cedema. The kulneys are congested, and, according to Kjellberg, may be sometimes the seat of neute parenchymatous nephritis.

Symptoms.—The outbreak of the disease may be sudden or gradual

Sometimes it bursts out as a violent attack of vomiting and purging, which quickly assumes alarming proportions, and the child speedily passes into a atute of collapse. In other cases it begins as an ordinary purging, but after a few days vomiting occurs, and the stools assume the peculiar watery

appearance which is so characteristic of this fatal malady.

However it may have begun, the disease when established has very peculiar features. There is obstinate vomiting and very persistent diarrheea. The child first throws up the contents of his stomach, and all fluid or medicine swallowed instantly returns. Next, the ejected matters consist of mucus, thin watery fluid tinged yellow, or even pure bile. The stools, which are at first feculent, thin, and offensive, soon lose almost all trace of fecal matter, and consist of a copious flow of serous fluid, which soaks into the diaper, and when evaporated, leaves nothing but a faint vellowish stain upon the linen. The quantity of fluid discharged from the bowels is sometimes extraordinary. When thus serous, the stools are not especially offensive; they have not the horribly fortid odour which is noticed in many cases of inflammatory diarrhoea—an odour which seems to cling to the diaper. and can be with difficulty washed away. The number of the stools varies. Sometimes twelve or fifteen are passed in the twenty-four hours. In other cases the bowels act less frequently; but usually, if the stools are separated by a longer interval, a larger quantity of fluid is discharged on each occasion, so that the abstraction of water from the body is very much the

As a consequence of the profuse drain both from the stomach and bowels, the patient's body wastes and dwindles with a rapidity which is surprising. After only a few hours, the eyes grow hollow and the nose sharp, the checks fall in, and all the features look pinched and drawn. If previously well nourished, the child's ficsh loses all elasticity, and feels soft and doughy to the touch. The abdominal parietes are flaccid and sometimes abrunken. The skin is inclustic. Owing to the loss of water, the thirst is extreme. The child, if he can speak, asks constantly for drink. If an infant, he fixes his eyes upon any cup or vessel containing fluid, sucks his lips, and whines in a manner which is sufficiently expressive. In most cases, however, anything which may be swallowed is immediately returned.

The urine is excessively scanty, and if the diarrhea is profuse, may seem to be almost suppressed. The tongue may be clean, or covered with a thin fur. Towards the end of the disease it is often dry and brown. The pulse is rapid and very feeble. It often reaches 150, but is regular in rhythm. The temperature is generally high. The heat of the surface may be natural, or even sub-normal, and often the extremities feel cold to the hand; but a thermometer placed in the rectum registers a high level, the mercury using to 104, 105°, or even a point still more elevated. The child is excessively restless. As long as he has strength to do so, he moves his arms and legs uneasily and whimpers or cries feebly. Often he draws up the corners of his mouth as if to cry, but no sound is heard. He sleeps little, but lies in a drowsy state with eyelids only partially closed. The fontanelle is deeply hollowed, and in extreme cases, owing to the shrinking of the brain from abstraction of water, the bones of the skull can be felt to over-lap.

In a very short time, unless some amendment occur, the child passes into a state of collapse. He lies perfectly quiet, as if dosing. His eyes are only half closed; his features are sharp, and his face livid and old-looking. The vomiting usually ceases at this stage, but the diarrhosa generally continues, although with diminished violence. The come becomes

more and more complete; the conjunctive cease to show any sign of sensitiveness, and the child dies quietly, or in a faint convulsion.

In the comparatively rare cases which terminate favourably, the first sign of improvement usually noticed is a fall in the temperature; the next a cessation of the vomiting, so that fluids can be retained upon the stomach. Then the stools begin to present a better appearance. The serous discharge becomes again tinged with facal matter, and the craving for drink is less noticeable. The diarrhæa may then cease, or thin feculent stools may continue to be passed in small quantity for some days. In other cases the improvement in the stools is the earliest sign of amendment, and the vomiting continues for a time, even after the purging has ceased.

The duration of the illness is terribly brief. Often it may be measured by hours. Always at the end of the fourth or fifth day, the patient is either dead, or is evidently advancing towards convalescence. Death may take place in five or six hours from the first onset. In other cases the civil survives for a longer period. Usually he dies in the course of the third

day.

Diagnosis.—There is no difficulty about the detection of the disorder. The uncontrollable vomiting and diarrhora, the intense thirst, the rapid shrinking of the tissues, the copious serous stools, the scauty secretion of urine, and the early collapse—all these form a group of symptoms which is

very characteristic, and, indeed, can hardly be mistaken.

Prognosis.—When the disease is established, the prospect of recovery is faint. Early cessation of the vomiting is a favourable sign, and any return of feculent matter in the stools allows room for hope, however unfavourable the general condition of the child may appear. Also, a fall in the internal temperature, although the symptoms may not have visibly improved, is a sign of amendment which is not to be disregarded. If the child sink into a state of collapse, he almost invariably dies. At any rate, I have never known an infant to recover from such a condition. Indeed, in any case, during the first few months of life, the ratio of recoveries is

excessively small.

Treatment.—On account of the persistent vomiting, which is one of the marked symptoms of the complaint, attempts to supply nourishment and support the strength of the child against the exhausting and continuous drain from which he is suffering, often meet with little success. Indeed, as long as the vomiting is frequent and distressing, and the purging severe. it is better to abandon all attempts to introduce food into the stomach. We should content ourselves with allowing the child to drink as much iced water as he shows an inclination to swallow; for stinting of liquid in these cases has been shown to be not only cruel, but injudicious, As soon as any diminution in the vomiting allows us to hope that food may be retained, we may begin by giving a tenspoonful of white wine wher (iced), and repeating this quantity every twenty minutes or half hour. If this be vomited, a less quantity should be given; but if this, too, be rejected, it is better to postpone, for the time, any further attempts to supply nourishment and return to the iced water. If the stomuch can retain the whey, the child may be allowed to take it in considerable quantities. sucking it through the bettle like any ordinary food. If after a few hours there is no sign of sickness, a dessertspoonful of cream may be shaken up in the hottleful of whey. Milk in any shape, even breast-milk, must be strictly forbidden in these cases.

Koumiss has been strongly recommended as a food in this disease. Dr. Archibald M. Campbell, of New York, speaks highly of its value in arresting the vomiting, subduing the thirst, reducing the number of the stools, and improving their appearance. He recommends that it should be given at first in quantities of half or a whole teaspoonful every ten minutes or quarter of an hour, and that the quantity should be gradually mereased. While it is being taken, icod filtered water can still be used to quench thirst. If the white wine whey be employed, no other stimulant is required, but if kommiss be used, the child will require an occasional dese of pure brandy, of which five or ten drops may be given at one time.

On account of the early occurrence of collapse, the case should be watched with the utmost attention, and any sign of exhaustion requires to be combuted by energetic stimulation. The child must be placed for five or ten minutes in a warm mustard bath; and afterwards brandy (ten to thirty drops) must be administered, and repeated at short intervals, until the warmth of the extremities is restored. It must be remembered that a high internal temperature is compatible with considerable coldness of the surface; and that it is of extreme importance to encourage the heart's action and improve the general circulation. Often the dose of brandy will have to be repeated every few minutes for a time. It is astonishing how large a quantity of spirit must be given in many cases to produce a sufficient effect even upon a young baby.

If the child is seen early, before exhaustion has come on, and the temperature is found to be high, it is well to reduce the pyrexia by placing the child in water of 75° or 80° Fahr. If, however, there is great feeble-

ness, the mustard-bath must be used as already described.

Medicines given by the mouth are very disappointing in this disease. French authors speak highly of the value of nitrate of silver. If this salt be employed, it may be given in quantities of gr. 1 to gr. 1 several times in the day. A common prescription is a combination of bismuth with aromatic chalk powder. If used, the dose of bismuth should be a large one (gr. v.-x. for a child of three months old), but the medicine is usually rounted; and if retained, has never seemed to me to have the slightest effect in allaying the irritability of the stomach or arresting the purging. The use of the salicylate of lime has been proposed by Mr. Walter Kilner, and the value of the remedy has been very warmly praised by Dr. Hutchings, of Brooklyn, New York, in the treatment of these cases. This physican administered the drug in doses of from three to five grains every two or three hours. If a small dose was given without effect, a larger one was substituted; and the influence of the salt in controlling the purging, checking the vomiting, and reducing the temperature was very decided. The medicine was found, in most cases, to arrest the stools without modifying their character; although, in exceptional cases, a simple diarrhosa continued for a short time during convalescence. Another drug to which great value has been attached, is the bromide of potassium. It is said in some cases to produce a rapid improvement in the number and frequency of the stools.

Enemata are sometimes very serviceable. For a child twelve months of I three or four drops of laudanum in a tablespoonful of thin starch, with a quarter of a grain of sulphate of copper, may be thrown up the bowel. The injection can be repeated three times in the twenty-four hours, and will be sometimes followed by signs of evident amendment.

In my experience, by far the most valuable remedy is morphia administered hypodermically. The sulphate of morphia, as being less likely to be converted into apo-morphia in the blood, is recommended by Dr. W. Hard-

man for this purpose. The quantity employed need not be large; in fact, a small dose appears to be nearly as effective as a large one. For a child of a year old, one-thirtieth of a grain may be used, combined with five or six drops of ether; and the injection may be repeated in an hour's time if the symptoms continue. This treatment is best suited to cases which are seen early, before symptoms of exhaustion have set in. In such cases the effect of the sedative so introduced is to arrest the vomiting and purging almost immediately, without producing any signs of narcotism. The child afterwards requires energetic stimulation to help him out of the state of weakness into which he has fallen. An infant should be fed with white wine whey. An older child can take the brandy-and-egg mixture in frequent doses; and it is very important to keep the extremities warm. In many of these cases, after the arrest of the more pressing symptoms, very vigilant and intelligent nursing is required to enable the child to resist successfully the depressing effect of the illness. Often there appears to be a tendency to failure of the heart's action. After making a step or two towards recovery, the patient may fall back again into a state of asthema, and die, without any return of the gastro-intestinal symptoms, or the occurrence of any inflammatory complication to explain the unfavourable change. This tendency must be combated by mustard-baths, stimulating frictions to the skin, and brandy given in frequent doses. A strong mustard-poultice, placed for a few minutes over the heart, is often of service; and the subcutaneous injection of ether may prove a valuable attinuant. In addition to the above measures, the belly must be covered with cotton wadding, and the air of the room should be kept pure, and frequently renewed.

In the attacks of choleraic diarrhosa or summer cholera which occur in older children, the use of morphia hypodermically is equally valuable. A sixteenth or twelfth of a grain may be used, and improvement follows very

quickly.

A little girl, aged seven years, was seized at 1 a.m. with violent romiting and purging. The bowels acted very frequently, without any straining, and the stools consisted, after the first few evacuations, of thin serous fluid. The vomiting continued. The child looked pinched and blue, and was excessively feeble. When seen at 4 a.m., the surface was cold, and no pulse could be felt at the wrist. The stools had the appearance of faintly-

tinged water. The thirst was intense.

One-sixteenth of a grain of morphia was at once administered subcutaneously, and the child was put to bed with a hot bottle to her feet. The diarrhosa then ceased, and although the vomiting recurred three times afterwards, it was each time excited by the swallowing of nulk. At 9 x x the temperature was 100.4°, and a few hours afterwards—eleven hours after the injection—it was noted: "Condition greatly improved: much stronger; some blueness about mouth; eyes sunken; tongue slightly furred, not dry; still excessively thirsty; complains of no pain; pulse fairly good, 138." After this note, the child only vomited once or twice, and the bowels only acted on two occasions, the stools each time being thin and offensive. The patient was soon convalescent.

The diarrhesa which sometimes succeeds to an attack of infantile cholera, must be treated as directed under the head of Inflammatory

Duarrhoea.

CHAPTER VII.

DYSENTERY.

Dyserver must not be confounded with the scute catarrh of the sigmoid flexure and rectum which is so common in children, and also gives ruse to severe tenesmus and pain. The affection, when it runs its ordinary course, is not, strictly speaking, a diarrhea. Facal matter is passed rarely, and then only as small hard scybalous masses enveloped in mucus—stools which bear no resemblance to the slimy feculent motions which constitute a familiar symptom of inflammatory intestinal catarrh. True dysentery is a specific disease which often occurs in epidemics, although sporadic cases are occasionally met with. It is rarely seen in England, except in the chronic form—the result of a previous scute attack in chil-

dren who had been resident abroad.

Causation.-Dysentery is common in tropical climates, especially in places which are badly drained, and therefore damp, and where the air is loaded with the emanations from decaying vegetable matter. On account of being thus endemic in ague-breeding districts, the disease has been thought to have some affinity with intermittent fover; but it has been shown that dysentery is not necessarily generated in mularious spots, and that it may occur in places where ague is unknown. Foul air, impure water, bad drainage generally, and rapid alternations from extreme heat to coolness of the atmosphere are the causes to which the disease is especially attributed. In a case which was under my care in the East London Children's Hospital—a little boy of five years old, in whom, after death, the mucous membrane of the whole large bowel was found to be converted into a purplish-black slough—the illness had begun suddenly during very hot weather, and was attributed to foul emanations arising from the emptying of the dust-bins of the street in which he was living. It is well known that amongst the poor these receptacles are charged with refuse of every kind, and are often most offensive from the presence of decaving organic matter. Faulty nutrition and chronic digestive derangements appear to be predisposing causes which may incline the child to be more readily affected by the injurious influences surrounding lum. The disease is therefore said to be more common in hand-fed babies than in infants at the breast. The affection, when it occurs in epulennes, has a tendency to propagate itself. The emanations given out by the dejections of a dysenteric patient are said to possess peculiarly noxious properties, so that any one incautiously inhaling the effluyium is likely to take the

Morbid Anatomy.— In the earliest stage of dysentery the mucous membrane of the colon and rectum is congested, and is swellen from inflammatory infiltration into its substance and the underlying arcolar tiesue. The colour of the membrane becomes rosy red, or may pass through the various shades of purple to slate gray of a very deep tint. At the

same time the solitary glands project from the surface, and are enlarged to the size of a millet seed or a small shot. The inflammation sometimes occurs in patches, which are separated by more or less healthy-looking membrane, and these run together so as to cover a considerable extent of surface. A false membrane may be found adhering to the inflamed area. This can be separated as a thin opaque film which dips down into the follieles of Lieberkühn. It consists of an inflammatory hyperplasia of the

follieular epithelium.

If the disease pass beyond this stage, superficial ulcerations are seen. Sloughs form upon the surface, and separate, exposing ragged, irregular ulcers with swellen, abrupt edges. Dr. Parkes was of opinion that the ulcers began in the distended follicles. Dr. Maclean believes that they are produced by sub-nuccus purulent effusion which detaches the nuccus membrane. This becomes gangrenous and is thrown off. The sloughs tary in size. If the process is rapid, large sloughs may be detached, and sometimes casts of the intestinal tube are eliminated unbroken. Their tint is yellow or ash-coloured, or even almost black. The ulcers are circular or irregular in shape, and are large or small according to the extent of mucous membrane destroyed. The floor of the ulcer is usually formed of the sub-nucous tissue, but the lesion may extend to the muscular coat, or may even perforate the bowel as in typhoid fever.

The destructive process is most intense in the lower part of the colon and in the rectum; but the inflammation may involve the whole colon, and even pass the ilio-excell valve into the lower part of the ilium. If the child survive, createssation may occur. A fibrinous exudation is thrown

out on the floor of the ulcer, and becomes gradually organised.

Lesions may be found in other organs. The mesenteric glands may be swollen, the abdominal organs may be congested, and abscess of the liver may occur. In a little girl, aged three years and a half, who died in St. Bartholomew's Hospital under the care of Dr. Andrew, two abscesses were found in the liver. The child had never lived out of Eugland, but had suffered for two months from an attack of dysentery, succeeding to prolonged diarrhora of ten months' duration. One of the abscesses was situated in the right lobe, and was as large as an orange. The second, no larger than a filbert, occupied the left lobe. In the neighbourhood of the abscesses the structure of the liver was healthy. The whole of the large intestine was extensively ulcerated.

The chronic form of dysentery is not always the consequence of unhealed ulcers. Still, in many cases ulceration is present. In advanced cases the intestinal tube may be atrophied, with complete disappearance of its glandular structures, and extreme thinness of its coats. In a less advanced stage, the arcolar tissue, and even all the coats of the bowel, may

be greatly thickened.

Symptoms.—The illness begins with slight fever, loss of appetite, and sometimes nausea. The child complains of uneasness in his belly of a colleky character, but his sufferings do not seem to be very severe. Then a sudden feeling of tenesmus urges him to evacuate the bowels, and the contents of the rectum are discharged, more or less coated with tenacious mucus. The passage of the motion, however, produces little or no relief. The desire quickly returns, so that the child almost constantly requires the stool, and sits straining with extreme violence. Nothing, however, is voided but offensive mucus, with occasional minute scybala. The mucus may be streaked or mixed more or less intimately with blood. In bad cases, it resembles a rose-coloured jelly. All this time the griping

continues. The child often screams with pain, and may be found resting on his knees in his bed, with his head buried in the pillow. Still, there is little or no tenderness of the belly. The face is pale, with a distressed expression. The child cannot sleep. His tongue is white, and his skin dry. He seldom complains much of thirst, but cats little, either from loss of appetite, or from the increase of abdominal pain, which he soon finds is provoked by the taking of food. Sometimes, for the first few days, the stools may continue to be feculent. Then, as the griping pains and tenesinus increase, the dejections become more scanty and frequent, and

consist of fural matter mixed with gelatinous mucus.

The disease does not always begin thus mildly. It may be ushered in by a severe rigor, or an attack of convulsions, with high fever, distressing griping pains, and almost constant tenesmus. There is burning pain at the anus, and the child, if permitted, will remain, as long as his strength allows, almost constantly seated on the night-stool. As in cases of acute inflummatory diarrhoea, the straining may induce prolapse of the rectum. The mucus passed from the bowels is bloody almost from the first; and sometimes pure blood, bright or dark and clotted, may be evacuated, However it may have begun, if the disease last beyond a week without improvement, sloughy matter begins to be discharged from the bowels. The stools, instead of consisting merely of offensive bloody mucus, begin to contain dark-coloured, shreddy matter, mixed with reddish, dirty water. The odonr of these stools is intolerably feetid, and grows more and more insupportable. The particles of slough generally get larger in successive dejections, and sometimes cylindrical portions of dead and putrelying mucous membrane may be discharged unbroken. It is comparatively seldom, however, that this stage is reached in the case of a child. The drawase is so exhausting a one that death usually takes place before much sloughing of mucous membrane has had time to occur. Sloughing is rately found in children under twelve years of age.

The abdomen usually becomes distended as the disease progresses, and there is often some tenderness on pressure over the colon. The weakness now becomes very great. The child lies back with a pinched, haggard face, sleeps little, and is very restless. His hands and feet are apt to be cold, although the internal temperature is high. He is thirsty, but cares little for food. He may be troubled with vomiting. His water is scanty and high-coloured; sometimes it is passed very frequently, but retention of urine is apt to occur, and require the use of a catheter. His tongue, very furred on the dorsum, becomes red at the tip and edges, and often dry.

In favourable cases the distressing symptoms gradually subside. The temperature becomes normal; the tenesmus grows less and less, and disappears; the stools lose their blood and contain much grayish mucus; they begin again to show signs of feculent matter; the insupportable dysenteric ordour diminishes; the tongue cleans, and the appetite and

spirita improve.

In fatal cases the abdomen is distended; the pulse is very rapid and feeble; the prostration is extreme; the face is dusky and haggard; the extremities are cold; the child grows delirious, or sinks into a state of stupor, in which he dies. Towards the end paralysis of the sphincter may occur, so that the outlet of the rectum is seen wide and gaping. In exceptional cases ordena of the lower extremities is noticed; and Dr. S. C. Busey states that this is sometimes associated with discolouration of the skin of the feet and legs.

A certain variety in the symptoms can be noticed in different cases,

The tenesmus is distressing in proportion to the degree to which the rectum may be implicated. If, as may happen, this part of the colon is only slightly involved, the straining may be insignificant, or even altogether absent. In such a case the dejections are more feculent, and contain altered bile mingled with the mucus and blood. The number of the steels is very variable. There may be from two or three to ten or twelve, or even more, in the hour. In the latter case, even if the quantity of mucus discharged on each occasion be scanty, the whole amount passed in the day and hight may be very considerable. The temperature is elevated. The mercury in the evening is often found to rise to 102° or 103°, but sinks in the morning to below 100°.

If the child die, death usually takes place from exhaustion, the patient being worn out by pain, want of sleep, and the profuse discharge of a highly albuminous fluid from the bowels. Sometimes, however, the fatal termination may be reached in a different manner. The disease may appear to take a favourable turn, and the dysenteric symptoms may have even subsided, when the child is suddenly seized with convulsions, then sinks into a state of coma, and dies in a few hours. Dr. S. C. Buscy has connected these cases with thrombosis of the cranial sinuses—a complication which is always to be feared in the infant, when his strength is pro-

foundly impaired by exhausting disease.

After the subsidence of the acute symptoms, dysentery often passes into a chronic stage. The child remains pale and thin, and continues to lose flesh. His bowels are open several times in the day, and the motions, which consist of scybala and fleshy-looking humps, are passed with stransing. His tongue tends to be dry, and is often glazed, or is fissured with transverse cracks. He complains of frequent pains in the belly of a colicky character, and these are usually excited by taking food. The child is habitually thirsty, and is sometimes feverish at night. Such cases may go on for months, or in older children for years. Even in the most favourable cases, convalescence is usually slow, the bowels being costive and troublesome for a considerable time after the disease is at an end. The colon often remains torpid, while the irritability of the rectum continues; so that, although the apparent need of evacuation is urgent, and the stranning distressing, small stools consisting of scybala embedded in mucus are alone discharged.

Diagnosis.—As long as the stools continue to be feculent, the inflammatory process may be judged to be as yet in an early stage. Afterwards, when gelatinous mucus, clear or blood-stained, is passed unmixed with true faces, or containing merely hard small scybala, we may conclude that the inflamed area is still limited to the rectum and the lower part of the colon. If later, when the tenesinus and griping pains are severe, the mucus is again containinated with thin feculent matter, it is probable that the inflammation has extended higher and has involved the upper

part of the colon, and, perhaps, a portion of the ilium.

In the earliest stage there appears to be nothing special in the symptoms themselves to indicate that the disease is anything more than an ordinary attack of severe intestinal catarrh. Afterwards, when the affection has become more fully developed, the characteristic fector of the dejections at once reveals the nature of the illness. Intussusception of the bowel is also marked by the passage of blood-etained, non-feculent mucus, combined with great straining and severe colicky pain. The distinguishing points between the two diseases are elsewhere described (see page 674).

Prognosis.—The danger of the case is in proportion not only to the averity of the attack, but also to the time at which the patient comes under observation. Dysentery is a disease in which early treatment is of the utmost importance. If the child be seen during the first few days, or even before the end of the first week, he will probably recover under judicious treatment. Absence of severe depression of strength and spirita, placidity of expression, and a fair pulse are all signs of favourable import; and an early return of feculence in the stools, if combined with a diminution in the colicky pains and tenesinus, may be taken as an indication of approaching convalescence. On the contrary, early prostration, a haggard facies, a feeble, frequent pulse, great restlessness, hiccough, a dry tongue, a gangrenous odour from the stools, and, especially, delirium—all these symptoms should occasion the utmost anxiety.

If, after the consistion of the ordinary dysenteric symptoms, the child remain prostrate and stupid, lying in a drowsy state with eyes only partially closed, his pupils sluggish, his breathing irregular or of the Cheyne-

Stokes type, we should fear the occurrence of cranial thrombosis.

Treatment.—If the child is seen early, he should be put into a bath of the temperature of 95°, and he kept there for ten minutes, or a less time if he feel faint. He should be then put into bed with hot fomentations to his belly, and take a draught composed of castor-oil in conjunction with rhubarb and laudanum, in some aromatic water. This combination is believed to have originated with the late Dr. John Scott, examining physician to the H. E. I. Company. It was kindly communicated to me by Dr. Chevers, who, in his own large Indian experience, has been accustomed to rely greatly upon this remedy if given sufficiently early in the disease, To a child of ten years of age the draught may be given in the following proportions:

B.	Tinct. opii	III, v.
	Olei ricini,	
	Tinet, rhei comp	मा प्रो.
	Aquam cassusad.	7 88.
	ft. haustus.	

If after this draught the bowels act more than twice in the next twelve hours, an enema contuning ten drops of isudanum in half an ounce of tarch- or gum-water, may be thrown up the bowel. In the case of children, opium should be used with especial care, on account of the early prostration which is so apt to occur in this disease. If given at the first, its use should not be continued too long. Dr. Morehead speaks warningly against too prolonged use of opium, which he says makes the dejection pasty

and scenty, and is injurious to favourable progress.

If the practitioner fear the use of opium by the mouth, ipecacuanha is useful a remedy in the young subject as it is in the adult. Six grains have be given to a child ten years of age; two, three, or four grains to a bounger child. The dose must be mixed with as little fluid as possible, in the tobe repeated every day at sufficient intervals for the child to be able to take nourishment; for the ipecacuanha must not be given until two hours have clapsed after food. Usually, twelve hours may be permitted to pass between successive doses of the drug. The diet should consist of meat-broths, thickened, if necessary, with boiled sago or arrow-toot; and of boiled milk diluted with barley-water, and alkalimised with a few drops of the saccharated solution of lime. The child must be kept

as quiet as possible in his bed, and painful teneamus must be treated with injections of opium and starch, and by hot applications to the belly and anus. All through the acute stage the child should be rigidly contined to his bed. The air of his room should be kept pure by open windows and the proper use of disinfectants; and all excreta should be disinfected before removal from the sick-chamber.

If the case is seen early, or is of a comparatively mild character, the above treatment will be usually effectual in checking its further development. In the very severe cases, or those which are seen after the end of the first week, when pangrenous aloughs are being passed, the belly should be covered, as in the former case, with hot applications or turpentue stupes. Inecaccuanha should be then given in one full dose (gr. vj -vij, to a child of ten years of age), and the quantity can be repeated in eight or ten hours. If thought advisable, a few drops of laudanum can be given half an hour before the inecaccuanha. After taking the latter the child should be kept perfectly quiet, and must take no food or fluid. If he be very thirsty, however, he may be allowed to suck small lumps of ice. Dr. Maclean speaks very highly of the value of the remedy so administered. According to this physician, the straining and colic subside, the blood and slime disappear from the stools and are replaced by feculent matter, the skin becomes moist, and the patient falls into a quiet sleep.

The value of mercury in the treatment of dysentery is a question upon which very opposite opinious are held. While some writers warmly advocate its use, others as warmly denounce its employment. The tendency of the present day, however, appears to be to neglect mercurials in favour of ipecacuanha. Dr. Morehead was accustomed to presente a combination of calomel or blue pill, ipecacuanha, and opium, every four, six or eight hours; and to give, in addition, a small, occasional dose of castor-oil. This treatment he considered especially applicable to the first few days of the disease, although it is also suitable at a later period. He relates the case of a child, three years of age, who had been ill with dysenteric symptoms for eighteen days. Two grains of ipecacuanha, three of extract of gentian, and one each of Dover's powder and blue pill, were given every three hours, with great benefit. When, after a few days, feculent matter reappeared in the stools, the opium was omitted from the prescription, and the other remedies were given for some days longer.

Whether mercury be given according to this method, or the child be treated with ipecacuanha alone, as is the more modern practice, an occasional dose of castor-oil is often indicated. If the abdomen becomes full and tense, and the dejections are scanty, a dose of the oil (two teaspoonfuls to a child ten years of age) may be given with advantage. If the tenesmus is distressing, an enema of starch and opium, in the proportions already recommended, may be used at sufficient intervals. If, towards the end of the disease, the child appears much enfeebled, the brandy-and-egg mixture should be given.

In the case of an infant, the treatment varies in some degree from that found useful in older children. Ipecacuanha is not to be recommended for patients under twelve months old; for, according to Mr. Scriven, infants of this age do not bear well the nausea and starvation which this treatment involves. For these patients calomel is a preferable remedy. To a child eight or ten months old half a grain of calomel may be given morning and evening, and an enema containing one or two drops of laudanum twice in twenty-four hours. Mr. Scriven speaks highly of lancing the gums in all cases of dysentery in teething infants. He disapproves of

farinaceous foods; and even milk—unless the child be at the breast—he considerably restricts in quantity, preferring to rely for nourishment upon beef-tea and chicken-broths. As in the case of other forms of bowel complaint, these meat-broths may be advantageously combined with an

equal proportion of barley-water.

In no instance should the ordinary astringent remedies be used while the illness is scute; but when the disease passes into the chronic stage, they may be judiciously resorted to. In such cases, large doses of bismuth with aromatic chalk may be given; rhatany and catecha are often of service; and the pernitrate of iron is an especially valuable remedy. Enemata of weak nitrate of silver (half a grain to the ounce) are often of considerable value, the bowels having been previously cleared out by a copious injection of warm water. These injections should be large, and must be given very slowly. For a child ten years old a couple of pints may be used. Instead of a nitrate of silver injection, simple warm water may be employed, or a solution of alum (gr. xv. to the ounce) as recommended by Mr. Seriven. While these remedies are being made use of the child should take a daily dose of Dover's powder, if the straining and abdominal pain continue.

Cases which have resisted treatment by astringents will sometimes yield readily to ipecacuanha in doses of one grain three times a day, with an occasional injection of laudanum and ipecacuanha in warm starch if the tenesmus is distressing. At the same time the food should consist of strong meat-essence, well-boiled rice, pounded under-done meat, and boiled milk, if it agree. Eggs are often not well borne in these cases.

A remedy which is very useful in the chronic stage of dysentery is the perchloride of mercury given in quantities of ten or lifteen drops several times in the day. It may be usefully combined, as Dr. Ellis has suggested, with the tincture of cinchona. Sometimes the perchloride has been found to be more useful in very small doses frequently repeated, as five drops every two or three hours. In any case, if the dose is small it must be repeated more frequently in the day.

In all cases of chrome dysentery, great care should be taken that the belly is duly protected from alternations of temperature by a broad flamed bandage, that every attention is paid to promoting the action of the skin, and that the surface of the body is kept perfectly clean. A complete change of climate to a bracing sea-air is of the utmost service in complete

ing the cure.

During convalescence from dysentery the child's appetite is often enormous. Great watchfulness must be therefore used that he do not cat a quantity of indigestable substances, such as new potatoes, unripe fruit, or great excess of farinaceous matters and sweets. He should live principally upon meat once cooked, eggs, fresh-made broths and milk, and wine, in the shape of port or sound claret, may be allowed him with his dinner.

CHAPTER VIII.

GASTRO-INTESTINAL HAMORRHAGE.

Hamoreman may occur in the young subject both from the stomach and bowels. In gastric hamorrhage the blood may be vomited directly from the stomach, or may pass down the alimentary tube and be voided dark, and more or less altered in appearance, with the stools. The presence of blood in the evacuations is, therefore, no proof that the source of bleeding is in the bowels. Nor, indeed, does blood ejected from the mouth always come from the stomach. Even blood which is brought up by evident retching, and intimately mixed with curdled milk, may not, and often does not, owe its origin to the gastric mucous membrane. Infants at the breast not unfrequently vomit blood which is drawn with the milk from the breast of the mother. Cracked nipples are often very irritable, and bleed easily. In such cases, the act of sucking may determine a hamorrhage from the fissure, and a large quantity of blood may be swallowed by the child. At the end of the meal this is often vomited with part of the milk which has been taken, and is a cause of great alarm to the parents.

In older children who suffer from epistaxis, the blood which flows down into the throat from the posterior nares is almost invariably swallowed. If this be large in quantity it is sometimes vomited, and appears then to have been thrown out by the stomach. So, also, ulceration of the back of the throat and of the gums, such as is seen occasionally in scrofulous and badly-nourished children, may be a cause of bleeding. If at the same time the child be suffering from disordered stomach, and vomiting be frequent, the efforts of retching may determine a flow of blood from the ulcerated surface. The blood mixes with the contents of the stomach is these pass through the mouth, and gives the appearance of his morrhage from the deranged gastric membrane. I have known such a case to occur

and be a cause of great perplexity.

Causation.—Real gustro-intestinal hiemorrhage may be due to many different conditions. There is a special form of hiemorrhage which is occasionally seen in new-born infants as a consequence of causes which have not even yet been fully made out. Melana neonatorum occurs usually within a few hours of birth. It is said to be more common in girls than in boys, although this is not the experience of all observers and sturdy, well-nourished children are as amenable to it as the feeble and the frail. The occurrence is fortunately very rare. Sometimes it has been known to follow a tedious labour, in which the child's head had suffered great compression. In other cases the respiratory function after birth had been established with difficulty. Often, however, the bleeding can be attributed to no such reason. Sometimes it appears to be the direct result of ulceration of the stomach and duodenum. Such a lesion has been occasionally discovered in the new-born babe, and has been ascribed to follicular gastritis by Billard; to an embolism of the umbilical ven

near the liver, and extending for some distance into its branches, by Landan; and by Steiner, to a fatty degeneration of the blood-vessels. An example of such a gastric ulcer was shown by Dr. Goodhart in 1851, at the London Pathological Society. A new-born infant had died from hæmatemesis thirty hours after its birth. The child's appearance was healthy. On examination of the body, after turning out the blood-clot with which the stomach was distended, a small, oval ulcer, one-eighth of an inch in length, was seen at the cardiac end of the stomach and close to the greater curvature. This sore was clean-cut, sharp-edged, and firm in texture. In its floor was a dark speck, which proved, on close inspection, to be an open vessel. It is, however, uncommon to find any distinct breach of surface. In the large majority of cases the hæmorrhage appears to be capillary, and nothing but a congested state of the vessels of the

stomach is discovered on examination of the body.

Some writers, especially Grandidier and Ritter, have attributed the bleeding to a condition allied to hamophilia; and certainly in cases where death results from profuse capillary harmorrhage in the new-born child, some special and unusual tendency to bleed from slight causes must evidently prevail. In one of four cases published by Dr. Halliday Croom, a marked bemorrhagic tendency existed in the father. In another, although no family predisposition could be detected, the child himself had an evident tendency to bleed, for the pressure of the forceps with which the infant was delivered had produced an extensive ecchymosis on either side of the head. In a child possessing this unfortunate tendency, any cause which interferes with the establishment of respiration will increase the pressure on the veins, and may thus determine an effusion of blood from the capillary system. Still, with regard to this supposed constitutional infirmity, it must be remarked that melena neonatorum is said not to have been especially observed in families subject to true hemophilia; and that of infants who survive, few show in after life any particular tendency to biemorrhage.

In older children gastro-intestinal hamorrhage may be due to either

general or local causes.

Of the general causes, hemorrhagic purpura is perhaps the most common. In this disease the bleeding occurs not only from the stomach and bowels, but also from the nose, mouth, and kidneys, and into the subcutaneous tissue. The tendency to hemorrhage is only a temporary phenomenon, and ceases when by treatment or otherwise the condition of the patient has become improved.

In homophilis the tendency is permanent, and persists to the end of life. As in the former case, the bleeding is not confined to the gastric or intestinal mucous membrane, but may occur from any mucous surface and

into the subcutaneous tissue.

In the malignant forms of all the emptive fevers general hemorrhage may also occur. In such cases the symptom indicates a profound con-

tammation of the system, and is of most unfavourable augury.

The usual form of gastro-intestinal homorrhage met with in the child arises from purely local causes. Ulceration of the bowels, such as occurs in typhoid fever, in cases of long-standing intestinal catarrh, and as a consequence of tubercular or scrofulous disease, is a common source of bleeding. The same symptom is seen in the ulceration arising from dysentery. In intussusception a prominent feature is the passage of blood and blood-stained mucus from the bowel. The irritation of worms will sometimes induce bleeding from the mucous membrane; and intestinal derangements

which give rise to straining, especially if the bowel prolapse, are a common cause of admixture of blood with the stools.

There is one other cause of hæmorrhage which must be mentioned. This is polypus of the rectum. Polypi are said not to be uncommon under the age of ten years, and to occur more frequently in boys than in gals. These fibro-cellular growths spring from the sub-nucous tissue, and are covered by the nucous membrane. They are more vascular in the claid than in the adult, with a greater tendency to bleed, and are attached by a slender pedicle which readily gives way. The polypus varies in size from a pea to a marble, and may be sometimes seen within the bowel, if near the sphincter, looking like a bright red cherry. It bleeds easily, both during the passage of a stool and also independently of defacation, and if its seat is near the outlet, the effused blood may be mixed with mucua

Symptoms.—In the case of the new-born baby, the hamorrhage which is special to this period of life begins usually within a few days of birthin the majority of instances within the first twenty-four hours. It may, however, be delayed. Of tifty cases collected by Dr. Croom, the bleeding took place:—in thirty, between the first and sixth day; in eight, between the sixth and eighth; in four, between the eighth and twelfth; and in eight, between the twelfth and eighteenth day. The blood is sometimes ejected from the stomach as well as passed from the bowels. Sometimes however, mekena occurs without hamatemesis; and less commonly, humatemesis without mekena. Of eight cases seen by Ledever, four had hamorrhage from both stomach and bowels; three from the bowels alone;

and one exclusively from the stomach.

The appearance of the blood may be preceded by great restlessness and pallor, a sunken belly, and sudden prostration. When the blood appears externally the infant seems to suffer no pain. He passes apparently an ordinary stool; but this, on inspection, is found to consist either of dark treacly matter from admixture with meconium, or of dark pure blood. If, at first, dark and contaminated with the contents of the bowels, the blood soon becomes red and unaltered. In quantity it is often sufficient to seak the linen and the diapera. The dejections succeed one another rapidly, and after each passage the child is left cold and motionless, and seeingly exhausted. In rare cases, if the discharge is sudden and copious, he may be convulsed. After a time he revives somewhat, and cross feeby; but if the flow be profuse, soon falls into a collapsed state. He has quietly, with pallid face, cold extremities, an almost imperceptible pulse, and a sunken fontanelle.

After continuing for about twenty-four hours, the hamorrhage, if the child survives, usually stops. In most cases blood ceases to be ejected from the mouth before the flow from the bowels is at an end. Sometimes, after a temporary intermission, the bleeding returns, and may continue, in diminished quantity, for several days longer. When the bleeding begins for the first time after the fall of the cord, hamorrhage may also occur from the umbilious. Pale watery blood oozes from the navel, and the flow persists in spite of all efforts to arrest it. In some cases the effusion of blood is confined to this region, but more commonly it is quickly followed by hamorrhage from the bowels, and, in some cases, from the ears, the gums, the vagina, and into the skip.

If the harmorrhage be profuse the child may not recover from the state of collapse into which he has fallen. In the favourable cases he gradually improves, but remains weakly and pallid for some time after-

wards, with a tendency to intestinal catarrh.

In later infancy and childhood, gastro-intestinal hamorrhage, arising from the causes which have been mentioned, usually occurs in the form of medicia. The bleeding is, as a rule, more profuse when it is excited by causes acting through the system generally than when it occurs in consequence of a purely local lesion. In hamorrhagic purpura large quantities of blood may be passed per anum, bright red and clotted, or more or less altered and blackened. In this disease, as also in hamophilia and in the malignant forms of the specific fevers, the tendency to hamorrhage is a general one. The nose and gums bleed easily, the skin is spotted with potechia, or larger hamorrhagic stains, and the urine is often discoloured.

When the bleeding occurs from local causes the effusion is scanty, as a rule, and is evacuated from the bowel, pure, or mixed with the ordinary freeal dejections. In typhoid fever bemourhage is the exception in young subjects. In this and the other forms of intestinal ulceration the bleeding, when present, is seen in the form of small black clots at the bottom of the chamber-pan. In dysentery, and in cases of invagination of the bowel, the blood is brighter, and is passed pure, or mixed with mucus. It may amount, in the latter disease, to several ounces, but is rarely seen in so large a quantity. Usually only a few teaspoonfuls are passed at a time, and the discharge is only effected with excessive straining and pain. The irritation of worms is not often accompanied by bleeding, but in rare cases a bright red clot may be passed per anum. Catarrh of the lower part of the colon, especially if the bowel prolapse, may give rise to slight hemorrhage. The blood is usually in the form of light-coloured streaks, but sometimes small red lumps may be evacuated.

In polypus of the rectum the blood is also bright red, and may be in considerable quantity—a tablespoonful or more—pure, or mixed with mucos. If the growth be small and above the sphineter, the discharge of blood is accompanied by no pain; but if it be large, and especially if it be caught within the sphineter, it may give rise to much straining and discomfort. In such cases there may be frequent desire to go to stool, without the appearance of a dejection; much mucus is passed from the bowel, and the frecal masses may be growted from the pressure of the growth during their passage. If the disease is allowed to go on long unchecked, the child becomes pale and cachectic-looking from constant loss

of blood.

Durgnosis. The special form of hemorrhage of the newly-born (melena neonatorum) is so rare a complaint that in every case where blood is ejected from the mouth or passed from the bowel in a very young infant, we should rather suspect the blood to be furnished from some extraneous source; and if the child be at the breast, our first care should be to examine the apple of the mother or nurse for fissures or signs of erosion. A true hemorrhage in a young baby is at once indicated by pallor of the face, surking of the fontanelle, and depression of temperature. If, after bringing up a quantity of bright blood, the child seem contented and happy, without loss of colour or any aign of depression or distress, it is unlikely that his own body is the source of the bleeding. If, on the contrary, blanching of the face, coldness of the extremities, and signs of general depression accompany or precede the pussage of blood, there can be no doubt that the hæmorrhage is no misleading phenomenon. Still, it is often far from easy to ascertain its source. If the bleeding occur at only a short interval after birth, and succeed to a prolonged and difficult labour, or arise in a child in whom the respiratory function has been with difficulty established, we may suspect the phenomenon to be symptomatic

of a congested state of the viscera, aided, probably, by a special humorrhagic tendency in the child. If it occur some days later, and have been preceded by signs of uneasiness after taking the breast, some difficulty of deglutition or frequent vomiting, the effusion of blood is possibly due to a gastric or duodenal ulcer; but a positive diagnosis of this lesion cannot be ventured upon. If hemorrhage occur solely from the navel, and be accompanied by an icteric tint of skin, the case is probably one of congenital deficiency of the bile-ducts. If previous infants in the same family have died after presenting similar symptoms, the probabilities are strong that this distressing malformation is present. This subject is considered

elsewhere (see page 717).

In later infancy and childhood we should inquire about epistaxis, and examine the throat and gums for ulceration and signs of recent bleedings If the apparent brematemesis be due to epistaxis, blood will be often seen trickling down the back of the pharynx. If the case be one of hemorrhagic purpura, we notice the petechize on the akin, and can detect the general disposition to ready effusion of blood. In cases of hæmoplalia the same tendency is probably a well-recognised peculiarity in the family. and information as to its existence is usually forthcoming. In the malignant forms of the specific fevers the accompanying symptoms are usually sufficiently characteristic of the nature of the illness; and, moreover, the existence of an epidemic in the neighbourhood is probably well

In cases where the hemorrhage is due to a local cause, the source of the bleeding may be discovered from the symptoms by which the passage of blood has been attended. Small black clots lying at the bottom of a thin, dark-coloured water or pea-soup-like fluid, usually indicate ulceration of the bowel. Small red clots or streaks are commonly dependent upon catarrh of the lower part of the colon, with tenesmus. Red blood in larger quantity, pure, or mixed with mucus, and passed with great straining and pain, may be possibly due to an invagination of the bowel, or may be the consequence of a polypus of the rectum. In cases of intussusception other characteristic symptoms are present. If the blood be due to a polypod growth, this may be often seen at the end of defocation caught in the grap of the sphincter, and looking like a bright red ball. If the tinger is introduced into the rectum, the polypus can be distinctly felt attached to the posterior wall of the bowel by a slender stalk.

Prognosas.—When hamorrhage occurs in the new-born infant, the danger is always great; but the probabilities of a favourable issue depend partly upon the degree of strength of the child himself, and partly upon the opinion we have formed as to the source of the bleeding. A wellnourished infant of robust constitution can often bear an extraordinary loss of blood without sinking under the hemorrhage. A weakly infant succumbs quickly. If we have reason to suspect an ulcer of the stomach or duodenum, the prognosis is exceedingly unfavourable. Also, if convulsions occur, if the bleeding continue beyond the first twenty-four hours, and if it return after apparent ressation, we have reason to fear the worst. Of Lederer's eight cases, five died. Of twenty-three cases collected by Rilliet and Barthez, eleven ended in death. Dr. Croom estimates that, taking all forms of the disease together, the mortality is about sixty per cent. In older children the danger of intestinal hemorrhage depends upon the cause to which it is owing, and the severity of the condition of which it is the consequence. Rectal polypi are readily removed; indeed, sometimes they separate spontaneously and are discharged with a stool.

Treatment.—In cases of meliana neonatorum, the child must be fed with his mother's milk given with a spoon, or failing this, with ass's or goat's milk, diluted with an equal quantity of barley-water, with whey and cream, or with white wine whey. Pancreatised milk, prepared according to the directions given in the chapter on Infantile Atrophy, is also very putable. Whatever may be the food, it should be given cold and in small quantities at a time. The infant must be kept perfectly quiet. An ico-bag should be applied to his belly, and his feet must be kept warm. He may take internally a grain of gallic acid, or a couple of grains of the extract of krameria, every two or three hours; or one or two drops of oil of turpentine may be given every hour. In addition, four or five ounces of the infusion of krameria may be thrown up the bowel. The strength of the child must be supported by white wine whey, or by a few drops of hramely given at short intervals.

In older children bemorrhage must be treated according to the condition which has given rise to it. Polypus of the rectum is removed by sering the growth with a forceps and passing a silk ligature tightly round the pedicle. But in early life the slender stalk often snaps when stretched, and the mere action of drawing the polypus below the sphineter often detaches it from the mucous membrane. Its separation is followed by no

bleeding, and hemorrhage ceases from that time.

CHAPTER IX.

ULCERATION OF THE BOWELS.

Tux subject of ulceration of the intestinal mucous membrane must, necessarily, be referred to in describing the various diseases in the course of which such ulcerations are liable to arise. Still, it seems desirable, in addition, to devote a special chapter to its consideration. It is not uncommon to meet with ulceration of the bowels in children who have not recently suffered from acute disease, and in whom no special cause for the intestinal lesion can be discovered. Such latent cases are not always easy of diagnosis, for ulceration of the bowels is not necessarily attended with diarrhos. Purging, when it occurs, is dependent not upon the ulcerative process, but upon the intestinal catarrh which accompanies the breach of surface. When the catarrh is at an end the purging ceases, although the ulcers may be still unhealed. Typhoid fover in early life often runs its whole course without any looseness of the bowels, and this in instances where, from the length and severity of the attack, there can be little doubt that ulceration has been present. So, also, in cases of scrofulous or tubercular ulceration of the intestinal mucous membrane, the occasional attacks of purging are often separated by considerable intervals during which the bowels are sluggish, although, on post-morten examination of the body, extensive breaches of surface are discovered in the intestinal tract.

Ulceration of the bowels may be acute or chronic. The acute form is seen in cases of typhoid fever, dysentery, and inflammatory conditions of the bowel which give rise to lesions of the mucous membrane, either by the separation of superficial sloughs or by ulcerative inflammation of the glandular follicles. If life be prolonged the ulcerative process may pass, in certain cases, into a chronic stage, and lead to serious interference with the nutrition of the patient. The chronic form of the lesion will alone be considered in the present chapter. It occurs in two principal varieties in the child, viz.: the simple ulceration from prolonged intestinal catarrh, and the scrofulous or tubercular ulceration, which so often accompanies a sim-

ilar condition of the lungs.

Merhal Anatomy.—Simple ulceration of the bowels is seen principally in infants and the younger children. The part of the bowel affected is the large intestine and lower part of the ilium. The ulcers are very shallow, and can best be detected by inspecting them sideways. They may be seated on the summit of the longitudinal folds of mucous membrane, and are then elongated or sinuous. Others are seen between the folds, and are small circular breaches of the surface, which can often only be detected by careful scrutiny, as their bases are of the same tint as that of the mucous membrane surrounding them. The process by which they are formed appears to be as follows:—The follicles become enlarged and elevated above the surface like little pearly beads. Their contents then become purulent, and the follicles still further increase in size. Lastly, the roof of

the follicle is detached and the contents escape, leaving a clean-cut ulcer. Mixed up with the ulcers are other follicles large, elevated, and semi-transparent—the contents of which have not yet become purulent. The ulcers are roundish or irregular in shape, and vary considerably in size. Their edges are well defined and congested, their floor uneven, and of a

reddish or gravish colour.

Tubercular or scrofulous ulceration of the bowels is more common in children of three or four years old and upwards than in infants. form of lesion is usually associated with scrofulous or tubercular disease of the lung, and almost invariably with cuscous enlargement of the mesenteric glands. The ulceration appears to be chiefly of a scrofulous nature, the presence of the gray granulations being only an occasional and secondary consequence of the caseous degeneration of the follicular structures. The sent of the disease is usually the ilium, and the glands affected are the follicles of Peyer's patches and the solitary glands, especially those in the neighbourhood of the the excel valve. Primarily, the destructive changes are limited to these parts. Thus, the follicles swell up from great multiplication of their corpuscular elements. They then undergo cheesy degeneration, soften, and form a number of closely-set ulcers, which unite at their borders and give rise to more or less extensive areas of ulceration. Their edges are soft, red, and uneven, and their floor red or grayish in colour. The ulcerative process does not confine itself to the area of Peyer's patches, but extends laterally along the course of the smaller arteries and veins by a similar process of caseation and softening, so as often to encircle the gut completely. The infiltration advances into the neighbouring tissues, and causes gradual disintegration and destruction. At the same time the ulcer deepens, but seldom passes beyond the muscular coat. As a secondary process gray granulations may appear, and mihary nodules are then seen in the tumca adventitia of the smaller vessels, especially the arteries and lymphatics. The serous surface at the site of the ulcer is opaque and reddened, and may also contain gray granulations. times adhesive peritonitis is set up, and neighbouring portions of intestine become glued firmly together. If in these cases rupture of the floor of the ulcer take place, the intestinal contents are extrawaated, not into the general peritoneal cavity, but into a limited pouch formed by the adherent bowels.

The simple form of ulcer may cicatrise and leave little trace; but this termination is less common in the more severe form which is due to a tubercular or scrofulous cachexia. Still, even in these cases cicatrisation may take place here and there, and on account of the transverse extension of the breach of surface, may lead to serious contraction of the channel of

the gut.

Symptoms.—Ulceration of the bowels may be attended by few symptoms, and if, as sometimes happens, diarrhea is absent, the nature of the illness may be completely overlooked. As a rule, the special symptoms of the intestinal lesion have been preceded by a prolonged attack of purging, which has caused serious interference with nutrition, and greatly reduced the general strength. Abdominal pain is not necessarily present, but often attacks of pain of a colicky character are complained of, and these are usually found to precede the passage of a stool. There may be no obvious tenderness on pressure of the abdominal wall, but, in many instances, deep pressure in the course of the colon seems to give rise to uneasiness. Still, even in cases where tenderness appears to be completely absent, once tension of the abdominal parietes will be noticed. Indeed, this

symptom is nearly always present, and careful pulpation of the abdomen will rarely fail to detect it. The tension is not necessarily general. Often it is hunted to the side upon which the ulceration exists, as if the muscular parieties contracted instructively to protect the sensitive part from injury. The belly is usually more or less distended from fistulent accumulation, but this symptom varies in degree. Still, although fuller than natural, it appears normal to the eye; and there is no loss of the natural markings such as is seen in cases of peritonius. If the mesenteric glands are enlarged they may be often felt on deep pressure, and the superficial veins

of the abdomen are then unnaturally visible.

The appearance of the stools is very characteristic. The bowels may not be relieved many times in the day. Sometimes they are even costive. In the latter case the stools vary in character. They may consist for the most part of light-coloured lumps, often covered with mucus, and sometimes showing a streak of blood. But every now and again a loose motion will be passed which at once discloses the nature of the case. The motions which are characteristic of the lesion are of two kinds. The first consists of a dark reddish-brown water, intonsely offensive and putrid-smelling. It deposits a sediment of shreddy, flaky matter, often containing little black spots which are minute clots of blood, and sometimes small, pule, hard faccal lumps. The second is a pale yellow homogeneous fluid of the consistence of cream or thin paste. It often has a curious muculaginous appearance as the vessel containing it is tilted from side to side. This form of stool has, like the first, an offensive smell, but not, like it, an odour of putrefaction.

Hiemorrhage from the bowels is seldom copious. Usually it occurs as black clots, like little particles of soot; but sometimes larger black lumps may be seen. If there be an ulcer at the lower part of the rectum the blood is redder in colour, and may be in larger quantity. The number of the stools varies from one or two to twenty, or even more, in the twenty-four hours. Their passage is sometimes preceded by slight colicky pain; and if the lower part of the rectum is the seat of ulceration, there may be some straining at stool, and the bowel may prolapse. It is not common for an ulcer to occupy this part of the rectum; but should it do so, some serious consequences have been noted. The irritation excited by the lesson just within the internal sphineter may cause spasmodic closure of the lower outlet, so that much difficulty is met with in evacuating the bowels. As a result of this obstruction, great enlargement and hypertrophy of the rectum may occur, and we find tympanitic distention of the belly, and

many of the symptoms of impaction of faces.

A child who is the subject of intestinal ulceration is not necessarily very thin. The degree to which nutrition is interfered with depends upon the amount of intestinal catarrh and consequent diarrhora. If the purging is severe, wasting is rapid; but if the bowels are not much relaxed, nutrition may go on well, and the child progressively increase in weight, although the character of the stools indicates that the ulcers are still unheated. The appetite is often good, and the tongue clean; and except for a certain pinched look of the face and distress in the expression of the child, he might be thought to be suffering from a very trifling complaint. Even in cases where the ulceration is of a scrofulous nature the same rule holds good, provided the lungs are healthy. Cuseous enlargement of the mescenteric glands does not necessarily produce wasting; and if the ulceration is not extensive, the temperature lugh, or the purging severe, the lesson may produce no noticeable impairment of the child's nu-

trition. The heat of the body is not always increased. I have known cases where characteristic stools, containing shreddy matter and blood-clots, continued to be passed for months, and where caseous glands could be distinctly felt in the abdomen on deep pressure, run their whole course and end in recovery, with a temperature which seldom rose above 99°.

Ulceration of the bowels is sometimes complicated with peritonitis. In cases of scrofulous or tubercular ulceration of the bowels, tubercular peritonitis is a common secondary lesion. But a simple ulceration may also be accompanied by inflammation of the scrous lining of the abdomen

without perforation of the bowels having taken place.

A box, aged six years, was struck on the abdomen with a heavy piece of wood. The accident made him feel faint, and he vomited several times on that and the following days. On the day after the injury he complained much of pain in the belly, and from that time suffered from frequent colicky pains in the abdomen, and diarrhosa, which often obliged him to keep his bed. He was admitted into the East London Children's Hospital six months after the accident. At this time the boy was pale, but not very thin (he weighed thirty-two pounds twelve ounces). He complained of pun in the right side of the belly and over the epigastrium, and there was considerable tension of the parietes in these situations. The abdomes was rather distended, but was not tender. There was no fluctuation or duluess in the flanks, but much gurgling could be felt and heard on palpaturn. His tongue was furred in two lateral bands. The bowels acted four times in the day, the stools being pale, small, and solid. The boy had a purched, distressed expression, and seemed languid and dull, but expressed numself as quite comfortable except for the occasional pains in the belly. There was no albumen in his urine. The lungs and heart were healthy. His temperature at 6 p.m. was 99.4°.

A few days after the lad's admission his temperature rose; he began to vomit, and the bowels became much relaxed. The stools consisted of dark brown liquid, or of fluid like pea-soup, with small hard facal masses. The counting continued, and the belly became swollen, tympanitic, and very tender. The child then rapidly wasted and became exceedingly prostrate. Dehrum came on, and he sank at the end of a fortnight. During the last

week his temperature varied between 99° and 102°.

On examination of the body there were signs of old peritonitis, due probably to the accident. In addition, much recent lymph was found coating the intestines. In the ilium several of Peyer's patches were found to be the seat of alceration. The alcers were shallow, with a grayish, uneven floor and thickened edges. There were no gray granulations anywhere.

This boy's condition when he entered the hospital illustrates very well the symptoms often found in cases of ulceration of the bowels, for there is no reason to suppose that he was then suffering from peritonitis. Abdominal pain of a colicky character going on for months, especially if combined with tension of the purietes, and a history of more or less persistent diarrhoa, is suggestive of intestinal ulcer, and the pinched, distressed look of the boy's face quite excluded the idea that these symptoms were due to any unimportant derangement, however persistent. It is an invariable rule, which should never be forgotten in clinical investigation, that in a child a haggard face means serious illness. However insignificant the symptoms and signs may appear, if a child look ill the case is not one to be neglected or bridty regarded. The intestinal lesion in this boy was probably the consequence of a chronic catarrh of the bowels of many months' standing; for from the time of the accident he continued to suffer from persistent

looseness of the bowels, with attacks of colicky pain. The return of the catarrh followed upon the action of an aperient which relieved his bowels of a large quantity of hard feeal masses, and the irritation thus excited no doubt induced the second attack of peritonitis from which he disck.

If there is any reason to suspect ulceration of the mucous membrane of the bowels, aperients are not to be recommended. Our whole efforts should be directed to promote the healing of the ulcers by quieting persetaltic movement. Therefore, however important it may seem to remove freed accumulation, we must remember that an aperient only sets up fresh irritation, and that its action may be followed by very serious consequences.

As a rule, the lower down in the colon the ulceration is seated, the more numerous are the evacuations and the more distressing the tenesmus and the pain. Still, even if an ulcer occupy the sigmoid flexure or rectum, there is not always diarrhoa; indeed, sometimes the faceal matter presents itself only in the form of hard scybala mixed with very offensive muco-purulent fluid. In these cases, if hiemorrhage occur, it is usually more copious, and the blood more natural in colour, than when the ulcers eccupy any other portion of the bowel. Constipation is most liable to be found in cases where the lesion is seated in the small intestine, the colon being healthy; but even in this form of the disease, any additional irritation which sets up catarrh and increases the peristalsis of the larger gut may give rise to diarrhoa. An ulcer of the duodenum would probably excite distressing vonuting and pain at an interval after food. Such a lesion in

the child has never come under my notice.

Inamous. - If the symptoms of ulceration are well marked, there is little difficulty in ascribing them to their true cause. An abdomen full, without great distention or loss of the natural surface markings; increased tension of the parietes, with tenderness on deep pressure; diarrha-a, with colicky pain, the stools consisting of dark, putrid-smelling, watery fluid, depositing brown or yellow shreddy matter and small black blood-clots - this group of symptoms, when combined with a distressed expression of face. is very characteristic of intestinal ulceration. The chief difficulty in such a case would be to exclude tubercular peritonitis; for this additional lesion might be present without excessive tenderness, without fluctuation, and without any caseous lumps being detected on palpation. The belly, however, would be more distended and glabular; the natural markings of the surface would be absent; the temperature would probably be decidedly febrile; and in most cases, if the child were laid on his side so as to allow of the fluid accumulating in one flank, some evidence of its existence would be perceived on turning him rapidly on to his back and immediately palpating or percussing the part which had been dependent. It is, however, fortunately, uncommon to find cases of chronic tubercular peritoritis in which the symptoms are so obscure. Usually semi-fluctuation is readily discovered, and caseous masses, or unequal resistence of the abdominal contents, can be noticed on examination.

If the ulceration be accompanied by constipation or solid stools, the case may be mustaken for one of facal accumulation. The conclete pains and small lumpy evacuations are very suggestive of this condition, and even if the stools are occasionally loose, the symptom is not unknown in cases of impacted rectum. A little reflection will, however, convince us that there is more in the case than a loaded bowel is capable of explaining. We find in most instances a lustory of previous continued diarrhers; if tenderness be absent, there is still some tension of the abdominal wall; and the distressed expression of the child's face assures us of the existence

of scrious disease. Moreover, an examination per anum detects no accumulation in the rectum, and a copious enema, although it may remove solid

facal lumps, in no way improves the condition of the patient,

If we are satisfied as to the presence of the ulceration, we have still to decide whether the lesion is of a simple character, or is the consequence of a scrofulous or tubercular cachexia. The older the child, the greater the likelihood that the ulceration is not simply catarrhal. After the age of three years, the manifestations of the scrofulous diathesis become common; and at this age, chronic catarrh of the bowels seldom runs a sufficiently persistent course to set up ulceration unless aided by some vice of the constitution. If, however, the child have scrofulous or tubercular tendenmes, a much less prolonged writation of the mucous membrane will give rise to caseation and softening in the glandular follicles. The presence of calarged mesenteric glands, chrome lung disease, or other sign of the crofulous constitution, allows us to infer that the intestinal lesion is of a similar pathological character. The temperature is not greatly to be relied upon in these cases; for it is not necessarily elevated in cases of scrofulous niceration, while it may be raised from accidental causes in the simple form of the lesion. Nor is the state of nutrition of much value as a guide; for this depends less upon the nature of the ulcer than upon the degree to which catarrh of the bowels may have reduced the strength, and interfered with the digestion and absorption of food. If the child show no sign of the scrofulous cachexia, if his lungs appear to be healthy, and if tubercuhar peritoritis can be excluded, we may infer the ulceration to be of a simple character, although his general strength be poor, and his nutrition unmistakably impaired.

If the electation be tubercular from a secondary formation of the gray remulation around the elect, and in other parts, nutrition is at once protounlly affected, and wasting goes on with rapidity. In such a case, all the symptoms of general tuberculosis are present, and the child often dies from tubercular meningitis. Still, it must be confessed that cases sometimes present themselves in which all the symptoms of acute tuberculosis are noticed without a single gray granulation being discovered in the body ofter death. The case may even terminate with head symptoms indistinguishable from those of tubercular meningitis, although the interior of the crumium appears to be healthy, and the most thorough search discovers no gray tubercle in the meninges of the brain. It is difficult to explain these

cases. Fortunately, they are very exceptional.

Prognons.—In a case of simple ulceration from prolonged intestinal catarri, recovery will often take place under judicious treatment if there be no complication, and if addema have not occurred. The latter symptom, although it is far from indicating that the patient will certainly die, is yet of unfavourable import, as it shows a state of great weakness, and weakness

in itself renders a child less responsive to the action of remedies.

If the electron be ecrofulous, the prognosis is still less favourable; but ibere, if the strength is not greatly reduced, and if other organs are healthy, recovery may take place. Caseous culargement of the mesenteric glands does not appear to add to the danger of the case; but if serious lung mischief is present, the concurrence of the two lesions leaves us little room for hope. If secondary tuberculosis occur, with formation of the gray granulation in the neighbourhood of the ulcer and elsewhere, death is certain.

A case presenting these deceptive phenomena occurred some time ago in the Victoria Fark Hospital, and was published by Dr. S. West, in the Lancet for September 30, 1882.

Treatment.—The utmost care is required in the treatment of these cases if the illness is to be conducted to a favourable usue. Our endeavours must be directed to quiet irritation; to prevent the occurrence of fresh entarch; to reduce peristaltic action, so that the healing of the ulcers may not be interfered with; to support the strength of the patient, and to fur-

ther cicatrisation by suitable medication.

The child should be kept in bed in a well-ventilated room, and his belly should be protected by a broad layer of cotton-wool confined by a suitable bandage. All discharges and soiled linen should be at once removed, and every means be employed to keep the air of the room fresh and pure. The diet must be regulated so as to convey nourishment without supplying material for fermentation. As long as catarrh persists, fermen'ale fool is to be avoided; and even when the charrhose has been arrested, the capacity for digesting such a diet still continues small. Milk must be positively forbidden; and starchy matters can only be taken, if at all, in very small quantity. An infant must be fed with weak real or chicken-broth and barley-water in equal proportions; whey, plain, or if the child be feeble, made with sherry (white wine whey), and cream, wolk of egg beaten up with whey or veal-broth; and Mellin's food dissolved in either broth or whey, and mixed with barley-water. The meals must be small and frequent; and it is advisable to make constant changes, so as to furnish a sufficient variety. If the purging be severe, no more than one tablespoonful, or even less, can be given at one meal; and all food must be

given cold.

After the age of eighteen months, raw mutton or beef forms a very valvable remedy. This should be prepared as directed in the treatment of chronic diarrhea, and may be eaten plain or diffused through broth or jelly. Uncooked meat so prepared is very nutritious and digestible; and even if not completely digested, the residue appears to be perfectly unrritating to the bowels. Still, it is well immediately before the meal to give a dose of pepsin (gr. iij .- v.) dissolved in a few drops of dilute hydrochloric acid, in order to aid the process of digestion. If the child be between the ages of one and a half and two years, and the purging be severe, little other food besides the raw meat, meat-jelly, and broth should be allowed for a few days, until the violence of the catarrh is reduced. Afterwards, or in older children at first, yolk of egg, well-boiled cauliflower or Spanish onion pressed through a fine sieve, and thin well-toasted bread may be allowed. In some of these cases, where the power of digesting starch seems reduced to a minimum, a good substitute for brend is the malted child's biscuit made by Messrs. Hill & Sons of Bishopsgute Street. If these are objected to, a loaf may be baked expressly for the child in which a proportion of finely-ground fresh malt is introduced-one part of mult to two parts of flour. It is well, also, in addition, to give a spoonful of Hoff's extruct of malt directly after the meal. When the intestinal catarrh has been arrested, milk may be returned to, but should be given cautiously. In most cases, it is the curd of the milk which is digested with such deficulty; and I have found the pancreansed milk prepared with Bengers pancreatic solution, as directed elsewhere (see page 600), to be well borne when ordinary milk could not be taken. In other cases, skimmed milk seems to agree better than milk from which the cream has not been removed. Whatever be the age of the child, so long as he is taking milk a careful watch must be kept upon the digestive process; and any sign of flatulence or acidity, and especially any return of the purging, should be a signal for reducing the quantity of the milk, or even for omitting it for a

time altogether from the diet. If the child is weakly, or appears to be exhausted by the purging, stimulants must be given as required. White wine whey for infants, and brandy-and-egg mixture for children of all ages, are the most valuable.

With regard to medicines: -As long as there is purging, astringents with opium are indicated. It is well in these cases not to rely too much apon one form of remedy, for we shall often be forced to make frequent changes in the prescription in order to guide the disease to a favourable ending. If the stools consist of the homogeneous, pasty liquid matter which has been described, intrate of silver is pre-eminently useful. Oneeighth to one-fifth of a grain should be combined with a few drops of dilute nitric acid, and one or two drops of laudanum, in water sweetened with glycerine. This dose can be given three times a day. If from tenesmus, pain in the right iliae fossa, or the appearance of bright blood in the stools, there is reason to believe the large bowel to be the seat of the lesion, internal administration of the drug may be supplemented by the use of the salt locally. For a child two years of age, the lower bowel should be first cleared out by a copious injection of tepid water, and afterwards two grains of the nitrate dissolved in four ounces of water must be thrown up the bowel through a long tube. If tenesmus is urgent, five drops of bu lanum may be added to the medicated injection; or, after the return of the nitrate, the hudanum, mixed with half an ounce of thin warm starch, may be thrown into the bowel. The astringent injection can be repeated for three or four nights in succession, and can then be given only on alternate nights, if the symptoms still persist. Instead of the silver salt, sulphate of copper (half a grain to the ounce of water) may be used for the injection, and is often of service. This treatment by injections is useful not only by applying the astringent directly to the affected part, but also by clearing away hardened lumps of facul matter, which are very apt to be retained and keep up irritation even when the stools generally are loose and frequent,

Another useful remedy is the extract of hamatoxylon. Three to five grams may be combined with one or two drops of laudanum, and two to four drops of ipecacuanha wine in the compound chalk mixture, and given three times in the day. A combination of the extracts of hamatoxylon and rhatany (gr. iij. of each) is often found of signal efficacy if the purging is obstinate, or gallic acid (gr. ij -v.), with a few drops of aromatic sulphuric acid, may be used. Opium should be always added to the astringent, whatever this may be, in order to reduce irritability of the mucous membrane, and quiet peristaltic movement. Sometimes we find cases, which have resisted all other treatment, yield to bismuth given in large dos s. For a child of two years old, fifteen grains of the carbonate of bismuth may be given with five grains of the aromatic chalk powder, every four hours; and a few doses of this combination is followed by really surprising improvement in many cases. If thought desirable, a drop of landanum may be added to each alternate dose of this remedy, or a small

injection of starch and opium may be given every night.

When purging has been arrested, the healing of the ilders may be promoted by perfect rest, and the administration of the pernitrate of iron (M inj -v.) with Lindaminn (M j.-ij.) in a teaspoonful of water sweetened with glycerine; or quinine may be given with pepsin and strychnia, as recommended during convalescence from inflammatory diarrhoa. For a considerable time it will be necessary to pay strict attention to the dict, and limit the quantity of farinaccous and saccharine foods; and long after convalescence is established, the child should continue to wear a finnel

bandage round the belly as a necessary part of his dress.

CHAPTER X.

INTESTINAL OBSTRUCTION (INTUSSUSCEPTION).

Occusion of the intestine in the child is rarely due to any other cause than intussusception or invagination of the bowel. Although any form of mechanical obstruction met with in the adult may conceivably arise in the young subject, such lesions are so uncommon in early life that when discovered they have been placed upon record, less for their practical usefulness, than for the interest they may possess as pathological curiosities. Thus, the bowel has been known to be strangulated by peritoneal bands, or by the veriniform appendix; to be obstructed by curemomatous or lymphatic swellings; or to be narrowed by congenital strictures. The temporary impaction of freeal matters which is sometimes found, is treated of elsewhere (see Constipation). A description of intestinal obstruction in the child practically resolves itself, then, into a description of intussusception, and the present chapter will be confined to this subject.

Cawation—Invagination of the bowel, although an uncommon accident at any period of life, is more often seen in the young child than in the adult. Babies seem to be especially prone to it, for a large proportion of the cases occur during the first twelve months of life. This comparative frequency of the lesion in infancy is attributed by Rilliet to the losser connections of the esecum in the iliac fossa at this age, and also to the imperfect development of its muscular bands, which lessens its resistance to

the penetration of the small intestine into its interior.

In infancy, intussusception consists either of an invagination of the small intestine into the larger, or of one portion of the colon into another portion. At a later period of childhood, the intussusception may involve the small intestine alone, without the larger gut being concerned in the

invagination.

Infants and children in whom this accident occurs, are usually sturdy and well nourished; and the illness takes places suddenly, as a rule, without being preceded by a period of feebleness or a state of ill-health. Boys are more subject to it than girls. The causes which give rise to it are not always easy to determine. Drastic purgatives, indigestible food, violence of cough, external injury, and even rapid motion, as when a child is danced quickly up and down in his parents' arms, have all been quoted as exciting causes of the lesion. It is certainly curious to find that in many of these cases the symptoms of obstruction were immediately precoded by a fall or other accident. In a case which lately came under my own notice—an infant of ten months old—the first symptoms followed a fall from his mother's bed on to the floor. Indeed, the child, when first seen, had a severe bruise on the temple and check, testifying to the severity of the accident. Still, if causes such as these were alone capable of determining involution of the bowel, the accident would be surely more commonly met with than it is. In some recorded cases, intussusception has been preceded by intestinal catarrh; and it is conceivable that any sudden increase of peristaltic action may help to induce it.

Morbid Anatomy.—In intussusception, one portion of the bowel is forced or invaginated from above downwards into another portion immediately continuous with it. At the point of invagination, therefore, a swell-

ing is seen which consists of three thicknesses of gut disposed one over another. Firstly, the external investing tube; secondly, a portion continuous with this, which has been doubled inwards, or inverted within the first, lastly, the contained portion of the bowel whose entrance into the first constitutes the lesion. Of these, the middle layer, which is of course reversed or turned inside out, has its mucous coat, now on its exterior, in contact with the mucous coat of the investing portion of the gut; while its peritoneal coating, now innermost, is in contact with the peritoneal covering of the contained or invaginated portion of the bowel.

The intussusception is formed not only by the intestinal tube, but also by the portion of mesentery in connection with it. This being drawn in with the invaginated portion, presses the latter to one side. Consequently, the foremost opening of the contained segment is not in the middle line, but is twisted so as to rest against a part of the investing sheath. When once started, the invagination tends to increase by peristaltic action, the increase being always at the expense of the outermost portion, and may

vary in degree from an extent of a few inches to several feet.

The consequences of the intussusception are occlusion of the intestinal canal, and obstruction of the circulation in the double layer of bowel which forms the invaginated portion. The two inner tubes become dark purple from congestion, and swollen; and some effusion mixed with blood is poured out between the opposed mucous surfaces, and also into the canal beyond the point of obstruction. Lymph is afterwards exuded, and the opposed serous surfaces become adherent. In some rare cases, the inflammation extends beyond the seat of disease, and causes general peritonitis; in others, alceration and perforation take place in the investing sheath, owing to irritation of the end of the contained portion; and this is sometimes seen to protrude through the opening thus formed, into the cavity of the peritoneum. If the strangulation of the invaginated portion is complete, it becomes gangrenous, and, in favourable cases, may be detached, piecemeal or in mass, and discharged through the anus. Should this happen, if the adhesions already formed remain firm, the sheath or invaginating segment, being united at its free end with the part of the bowel immediately above the point of intussusception, still forms with it a continuous tube, although the intervening portion has been removed. Sometimes, however, the adhesions give way, and then extravasation may take place into the peritoneum.

In infancy, it is usually the small intestine which becomes invaganated into the colon. The end of the ilium, with the ilio excal valve, is forced into the excum. This, as the intussusception increases, penetrates farther and farther into the colon, drawing behind it the dium, and doubling first the excum, then the ascending colon, and afterwards more and more of the large, bowel the farther it extends. At last, it may reach the rectum, and be felt by a finger introduced through the anus. In such a case, when the ablomen is opened, the larger bowel seems in great part to have disappeared, and a tumour is found occupying, usually, the left side, often the that fossa. This is of a slate-gray colour, is elongated in shape, and doughy to the touch. By truction, the invaginated portion can be drawn out, although it is usually soft, and is apt to tear in the process. Before penetrating into the colon, the illum may or may not pass through the valve; usually, it does not do so, and if a portion pass between the lips of

the valve, it is seldom more than a few inches.

Sometimes, even in infancy, more often in older children, the intusausception occurs in the course of the small intestine, the colon taking no part in the invagination. When this displacement occurs in a healthy child, it of course gives rise to symptoms of obstruction. It may, however, take place without producing symptoms. In examining the bodies of children, especially if they have died of intestinal catarrh, or of some form of brain disease, it is not uncommon to find portions of the boxel invaginated, often in several places, without any symptoms of this accident having been noticed during life. This form of intussus-ception usually occurs in the small intestine. It is supposed to take place immediately before death; for the bowel is merely invaginated, and is not swellen or congested, or altered in appearance in any way. Moreover, it can be readily drawn out by a very slight effort.

Symptoms. There is some variety in the symptoms, according to the age of the child and the seat of the invagination. In infants the intersusception is almost always at the expense of the larger bowel. In older children it may be confined to the jejunum or ilium, without involving the colon. The symptoms noticed in infants, and those arising in older

children, must be therefore considered separately.

In the case of an infant the ordinary history given by the mother is that the baby was in his usual health, when suddenly he gave a scream, turned excessively pale, and then cried violently, writhing and drawing up his legs as if in great suffering. The pain is not constant, for the child, after a time, ceases to cry, and lies back, looking pinched and pale; but in a short time the paroxysm returns, and he screams and writhes as before. When the pain first comes on, the infant vomits his last meal, and the vonnting is usually repeated, especially if food or medicine be given to lam. In most cases, an aperient is at once ordered, and is returned directly it has been swallowed. The state of the bowels is important. If they are empty below the point of obstruction, they remain obstructly confined, and the straining efforts, which are usually made, merely expel mucus and blood. If the lower bowel contains any facal matter, this is discharged in a thin, loose state, shortly after the occurrence of the intusausception. The stool may contain blood, and the action of the bowels is usually followed, after a short interval, by further straining and the evacuation of mucus and blood. At this time, the temperature is not clevated; the belly is painless-indeed, during the paroxysms of colic, gentle frictions to the belly seem to afford relief; the abdomen is neither full nor tense, and between the attacks of pain, the child may be often found in his cot lying upon his belly. Sometimes the secretion of urine is greatly diminished, but this is a very variable symptom, and apparently has no reference at all to the seat of obstruction. Often, at this period, the most careful examination of the belly detects no localised swelling; but after a time, if the abdomen be carefully palpated during an interval of rest from pain, a distinct swelling may be perhaps detected by the fingers pressed deeply into the left that fossa. There may be some tenderness at this point if some hours have elapsed since the occurrence of the accident. Later, the mass can often be reached by the finger introduced into the rectum, for its tendency is to travel farther and farther down the bowel. The child sleeps but little after the invagination has occurred. If, at the first, he sleeps between the attacks of pain, he soon ceases to do so, and remains wakeful and restless, constantly whining and crying until exhausted The temperature varies. Sometimes it is little altered from the normal level. In other cases, it begins to rise after a few hours, and may reach Directly symptoms of collapse are noticed, the tempera-102° or 103 . ture usually falls below the level of health.

The course of the illness is apt to vary according to the degree of strangulation of the invaginated segment, and the more or less completeness of the obstruction to the passage of the contents of the bowel. In rare cases, the passage is not completely occluded, so that faceal matter can still make its way, although, of course, in small quantity, through the narrow channel. The constipation is then not obstinate, but the stools are scanty, and consist more of mucus and bloody fluid than of the ordinary constituents of an evacuation,

The symptoms continue without improvement. The pains return at intervals. The child, in some cases, turns away from his bottle; in others, he sucks greedily to assuage his thirst; but, whether he swallow willingly or not, the effect is the same, and he usually vomits almost immediately. If he vomit at other times, the ejected fluids consist of bile-stained nucus, and very rarely of fracal matter. The face gets pale and more haggard; the eyel is close incompletely, and the eyel alls are sunken. Occasionally he strains, but only blood and mucus escape from the rectum. His belly is often tender over the seat of the tumour, and may become fuller and more tympanitic, with some tension of the parietes. Sometimes the

sphineter is relixed and open.

The symptoms of collapse come on early if the obstruction of the bowel is complete, and usually, on the third day, the child is found in the state described. Unless general peritoritis occur, there is seldom much pyrexia, indeed, the child, as a rule, feels cold and damp; and even if the internal temperature is higher than natural, the extremities feel cold. In this state, he remains until he dies. A convulsive seizure may precede death, and sometimes convulsions occur in the course of the illness, and are repeated several times. Before death, the invaginated mass may be perhaps seen to protrude for an inch or two outside the anus, as a dark-coloured, elongated hump. This, however, is not common. When the strangulation is complete, the disease seldom lasts longer than a week, and death often occurs in three or four days. If the obstruction is not complete, the progness of the case is longer; scanty loose motions may be passed at internals, and the child often lingers for a fortnight or more.

If, by any means, the invaginated portion of the bowel can be returned, the counting ceases; the bowels discharge a copious, semi-fluid, offensive stood, and the child sleeps. On waking, he takes the bottle or the breast, and seems cheerful and contented, although necessarily languid and

fuchle.

In older children, the symptoms correspond, in the main, with those already described, but certain differences are noticed. Thus, the distention of the belly is usually greater after the age of infancy, and comes on earlier. It is sometimes extreme, and the coils of dilated intestine can be made out through the abdominal parietes. Also, vomiting is generally persistent, and is apt soon to be feculent. The child will take no food, but is excessively thirsty. The discharge of blood from the anus occurs less frequently the more advanced the age of the child. If the invagination occupy the large intestine, the strangulated portion of the bowel is approached near to the outlet, and hiemorrhage from the ruptured vessels is likely to take place. If, however, the intussusception is higher up, and is contined to the small intestine without implication of the colon, no harmorrhage at all may be noticed. There is then, in most cases, obstinate construction. When the stage of collapse comes on, the tongue becomes dry, and is covered with a brown fur; the belly is tympunitic; the eyes are sunken, and the face of the child is ghastly and death-like.

If separation and elimination of the gangrenous portion of the bowel takes place, this favourable change is usually noticed in the course of the second week. In these fortunate cases, the dark-coloured gangrenous segment of the intestinal tube is passed with much straining, and often a quantity of dark, offensive feculent matter comes away with it. The amount of this varies, and is often very considerable. The discharge is followed by symptoms of great relief. The child usually falls into a profound sleep from which he wakes greatly refreshed. His thirst is diminished, his appetite begins to return, and his whole aspect betokens great improvement. The gangrenous portion may not be expelled in one piece, but sometimes comes away in patches and shreds, mixed with foul-smelling fæces and blood. After the separation and discharge of the slough, recovery usually follows with great rapidity.

In the fatal cases, death results more often from collapse than from peritonits. The child becomes weaker and weaker, and dies from asthema

Sometimes death is preceded by a convulsive seizure.

The above is the course of the disease in infants and older children. Of the symptoms, the sudden occurrence of severe abdominal pain, the vomiting, the constipation, the discharge of blood from the bowel, and the discovery of a swelling by palpation of the belly or exploration for anim, are the most characteristic.

The pain is of an excruciating character, as is shown by the child's agonising cries, his restless, jerking movements, and the death-like pallor which spreads over his face. In a case recorded by Dr. Wilks, the infant actually fainted from the intensity of his suffering. The pain comes on in paroxysms, but these do not occur at regular intervals. Often after the first access, the colic suddenly ceases, and the child appears to be easy. He may remain free from pain, showing no sign of illness, for some hours, but sooner or later the paroxysms return. This is most often the case with infants.

Vomiting is always present, and may vary from more regurgitation to violent retching. It is often accompanied by hiccough. The vomited matters consist of food and medicine, or, if nothing has been taken, of mucus and bile. Occasionally, blood is thrown up from the stomach. Mr. Maclood has recorded the case of a male infant, aged six months, in whom this symptom was noted before death. The intussusception had occurred in the

usual situation for this age.

Constipation is not a constant symptom. If the bowel below the point of obstruction contains facul matter, this is invariably expelled early. There is then no alvine discharge for the remainder of the illness. In less common cases a certain amount of diarrhum may be present, if the strungulation of the bowel is not complete; for the swelling of the invaginated segment becomes reduced after a few days, and the calibre of the canal

may be partially restored.

A discharge of blood and mucus is one of the most constant symptoms. The amount varies. In some cases, it may be scanty, nothing more than a stain of blood being seen upon the disper when the napkin is changed. In other cases, the quantity may reach several ounces. It appears early. It may be seen at the time of the first effort of vomiting, and is seldom delayed longer than twelve hours. In infants, this symptom is almost invariably present, and may be taken to indicate a degree of constriction of the bowel stopping short of actual strangulation and complete arrest of circulation. In older children, as has been said, it may be wanting.

A distinct swelling in the course of the bowel, when discovered, is a valuable diagnostic sign; but often it is not present. The tumour gener-

ally has in the left ihad region, and gives a firm, doughy sensation to the finger. It is movable, and varies from a walnut to a hen's egg in size, or may even be larger. When detectable by palpation of the belly, the tumour can often be reached by the finger introduced into the rectum; especially if at the same time pressure is made upon the invaginated mass by the other hand placed upon the abdomen. A rounded lump, feeling very much like the cervix uteri in a vaginal examination, may then be felt by the point of the finger. Sometimes the mass can be seen to protrude beyond the anus, but this is exceptional. Out of forty-nine cases collected by Dr. Lewis Smith, the protrusion occurred only in six.

Tenesmus is usually present, and is often distressing. It may cease as

the child's strength becomes reduced.

more advanced childhood.

The amount of fever varies. At first, the temperature is normal, but as inflammation occurs in the intussusception, the bodily heat increases, although it is rarely excessive. The symptom is said to be less marked in infants than in older children. The pulse, after the first few days, is very rapid, and as the strength declines, becomes excessively frequent and fee-ble.

The duration of the illness varies, as has been said, according to the completeness of the strangulation of the bowel, and also according to the age and strength of the child. In infants, it rarely lasts longer than a week, and death often takes place as early as the fourth or fifth day. In older children, the course of the disease may be equally rapid; but often it is more protracted, and cases have been recorded in which the lesion has become chronic, lasting several months. Separation and elimination of the gargenous portion is never seen in infancy, and is rare even in

Dispuss - When a child who has been previously in good health, or has suffered merely from looseness of the bowels, is suddenly seized with violent proxysmal colic and repeated vomiting, followed immediately, or after a few hours, by evacuations consisting of non-feed mucus and blood, discharged with great straining, we may conclude that he is suffering from occlusion of the bowels, due, in all probability, to intussusception. The discovery of an oval tumour, in the left side of the belly, will confirm us in our opinion, and if we can succeed in touching the mass, by the finger intexcluded into the rectum, the sign is a conclusive one. The conjunction of all the above symptoms is of importance, and the absence of any one of them is not to be disregarded. Thus, if we are called to a child who has been taken suddenly with pain in the belly, and vomiting, and whose bowels are obstinately confined, we must not conclude too hastily that an intussusception has occurred. The pain may be extreme and paroxysmal; the romiting frequent and distressing; and the constipation may have resisted aperients and enemats, without obstruction of the bowels in any form being present. Peritonitis, which paralyses the bowel, and induces vomiting by retlex disturbance, may produce just such symptoms. On the other hand, a passage from the bowels may take place, although intussusception has actually occurred. The appearance of one loose facal stool, after the beginning of the illness, is common in intussusception, for the contents of the colon below the point of obstruction are usually expelled shortly after the occurrence of the invagination. If, however, the bowels continue loose, and fored matter is afterwards evacuated, whether by injection or otherwise, the symptom is not in favour of intussusception; for, even if the channel become pervious later, after swelling has partially subsided, it is rarely free during the first two or three days of the illness. In such a case we 433

should hesitate to ascribe the symptoms to invagination of the bowel, unless the other evidence in its favour points irresistibly to such a conclusion

Again, severe colic in a young buby is often accompanied by alarming symptoms, in which all the signs of the most violent pain may be followed by great prostration. In the attack, the child utters piercing screams and writhes his body exactly as he does in intussusception; indeed, in almost all cases of invagination of the bowel, we generally find that an aparent has been ordered, under the impression that the spasms of pain are the consequence of irritation of the bowels by undigested food, or flatulent distention. In every case, therefore, where intussusception is possible, we must weigh the evidence very carefully, as the recovery of the child may depend upon early and accurate diagnoses of his illness. In addition to susple colic and peritonitis, intussusception may be confounded with disentery, with impaction of hardened facal masses, and with intestinal historrhage from other causes.

In simple code the pain, although often excessively severe, is not paroxysmal, with complete remissions, and usually ceases with the expulsion downwards of a quantity of gas. The skin is often hot, and the belly hard and swellen. There is no vomiting or tenesimus, or discharge of bloody indeus from the bowels. It is very important to attend to these points, for the administration of castor-oil or other aperient, which quickly cures an ordinary cole, cannot but be injurious in a case of intussusception, increasing the peris-

taltic action of the bowels, and aggravating the invagination.

Between peritorates and actual obstruction of the bowels, the diagnosis is often very difficult. The form of peritomits which is most apt to simulate intussusception, is that in which inflammation occurs suddenly as a consequence of ulceration and perforation of the vermiform appendix, with extravasation into the peritoneal cavity. In these cases, symptoms similar to those of obstruction may come on quite suddenly, and be very severe. But in peritonitis, the temperature is always elevated from the first, the abdominal parietes are distended and tense, and pressure in the right ihac fossa is painful. In intussusception there is no pyrexia at the first; the abdominal wall is lax and undistended; there is frequent tenesious, and, after a few hours, blood and mucus are discharged from the bowel This last symptom, added to the signs of intestinal occlusion, is pathogno-The mistake is most likely to be made when the symptoms occur in a child after the age of infancy, and hemorrhage is not present, or is alow to appear. Still, even in these cases, the absence of fever, the laxness of the parietes, and the tenesmus should raise strong suspicions of the real nature of the disease. In all cases of doubt, a careful examination of the belly, while the child is under the full influence of an anasthetic, will usually enable us to detect the presence of a tumour in the abdomen if invagination has occurred.

It is possible to mistake intussusception for dysentery, for the mistake has actually been made. In the latter disease, the dejections are often small, and consist of thick mucus, mixed more or less intimately with blood. They are discharged with great straining and pain. Even in severe catairth of the lower bowel, which is often improperly called "dysentery," much mucus, and often streaks or spots of blood, can be observed. But these symptoms alone are far from being characteristic of intestinal invagination. We miss the abrupt onset, the frequent vomiting, and the lax, undistended condition of the belly. Moreover, the whole course of the two discusses is different, and true dysentery is usually an epidemic malady.

In cases of impaction of fiveal matter—an accident which constitutes a

real occlusion of the bowel—the symptoms of invagination may be closely simulated. Vomiting, colicky pain, tenesinus, and constipation may all be present, and on examination of the belly, a firm tumour may be detected through the abdominal parietes. But in feecal accumulation, there is usually a history of hard and scanty stools for a considerable period before the attack; the vomiting is much less severe, there is no bloody mucus exacuated from the bowels, and the tumour is more superficial, does not shift its place, and can be indented by firm pressure with the fingers. If this condition be suspected, a large purgative enems will cause the tumour and consequent symptoms to disappear.

Sometimes, in intususception, the amount of blood discharged from the bowel is very copious. Still, the other symptoms of invagination are present, and it is only necessary to be aware that hemorrhage may be occasionally profuse, to prevent this fact from casting any doubt upon the

correctness of the diagnosis.

If attention be paid to the symptoms which have been pointed out as characteristic of intussusception, we shall be able, in most cases, to arrive at a correct conclusion. An examination per anum should never be neglected; nor, in a doubtful case, should we omit to inspect the ordinary structures of rupture, for although strangulated hernia is rure in young

subjects, it does, occasionally, occur.

Prognosis. When we have satisfied ourselves of the presence of intustusception, the prognosis is excessively grave. In the young buby, in spite of a few recorded cases of spontaneous reduction of the invaginated portion of the bowel, and of others in which remedial measures promptly applied proved successful, any measures we may resort to must be undertaken with serious forebodings. The danger is in direct proportion to the urgency of the symptoms. If the acuteness of the case indicates tightness of constriction, the prognosis is most serious, whatever measures are adopted, and however quickly assistance is rendered. In almost all cases of successful reduction by taxis, inflation, or injection, the symptoms have not been very severe. To be successful, treatment must be early; but delay is less fatal if the constriction be only moderate, than when strangulation is complete. If the infant is seen after the end of the third day, and acute symptoms have undergone no alleviation, a fatal issue to the illness can bardly be doubted.

In older children, whose superior strength enables them to resist for a longer period the prostrating effects of the obstruction, recovery by sloughing and discharge of the invaginated segment is possible, and may even take place when the child is in extremo, and after all hope has been abandoned; but this is a result which in any individual case we can never dare to anticipate. Certainly, there are no indications by which so favourable an issue can be forefold. Even if the evacuation of the slough by stool shows that channation has actually been accomplished, we must still not be hasty in declaring the danger at an end; for the greatest care will yet be required during the period of convalencence to prevent the newly-formed adhesions

from being injured or detached.

Treatment.—Accuracy of diagnosis and especially early recognition of the nature of the complaint, are of great importance in this disease. If the real cause of the vomiting and colic are discovered at the beginning, remedial measures may be applied with greater hope of success. As it is, medical advice is seldom sought until the bowel has been irritated by one or more doses of aperient medicine, to the serious aggravation of the patient's condition and the lessening of his chances of recovery.

The only admissible remedy is opium. This should be given at once, and repeated as often as a necessary to full the pain, and keep the child under the influence of the narcotic. It is best given by subcutaneous injection, and may be usefully combined with atropine. It is well to begin with small quantities, although it will be generally found that the system, even in infancy, is singularly tolerant of the drug. For a child of twelve months old, one-twentieth of a grain of morphia and a sixth of a grain of atropine may be used every half-hour until some sensible effect is produced upon the symptoma. This not only relieves the suffering of the patient, but also tends to prevent any increase in the invagination and to check the vomiting.

If the case is seen sufficiently early, the question of endeavouring to reduce the invagnation by mechanical means must be considered. Mechanical interference is only allowable during the first few days of the illness, before exudation of lymph has caused adhesion between the serous surfaces; and will be useless if great tenderness on pressure of the invaginated mass indicates the presence of inflammation. The means employed may be taxis, insufflation of air, or the injection of water. Before proceeding to any of these measures, the child, unless a young baby, should be placed under the full influence of an amesthetic. Taxis consists in kneading and otherwise manipulating the abdomen with the hand. This method is generally employed in conjunction with either of the others. The child is laid upon his back with the nates raised so that the body is inclined at an angle of 45 degrees. A large quantity of tepid water is then injected very slowly into the bowel by a Davidson's syringe capped with a long tube. Every now and again the abdomen must be kneaded with the hand so as to work the fluid along the bowel upwards towards the obstruction, and this process of taxis may be continued for several minutes. As much fluid must be used as the bowel can be made to contain. The best proof that reduction has been effected is sleep. As a rule, directly the child's more pressing symptoms are relieved, he sleeps at once. The return of the invaginated bowel is also sometimes marked by a discharge of blood and mucus, followed by a copions, offensive, semi-fluid stool.

Insufflation of air is best suited to cases where the intussusception has descended into the rectum and an enema returns at once. The air may be supplied by a common bellows, to the nozzle of which a caoutchout tube has been attached, terminating in a long gum-clastic tube. Some but must be wrapped round the base of this tube to enable it to fit closely within the sphineter. Air must be injected slowly, and at times the belly should be manipulated as in the former case. The process should be continued until the large bowel is thoroughly distended with air, if this prove possible. In a favourable case, the mass will be felt to recede from the left that region, and then pass altogether from the reach of the finger. If this happen, we

may have great hopes of having achieved our object.

These measures can only have a chance of success during the first three days. Certainly, after the fourth we can do nothing but harm by distend-

ing the bowel with either air or water.

In addition to the above methods, attempts have been made to replace the bowel by a long sound passed into the rectum, and have occasionally succeeded. This method is, of course, only applicable to cases where the invagination is within easy reach of the outlet. An exoplageal bougie with a sponge fastened to its end forms a useful instrument for this purpose. If the above measures prove ineffectual, it becomes a question whether a surgical operation should be resorted to, or whether we should trust merely to complete rest and opium.

The operation of opening the abdomen and reducing the invagination with the fingers has been happily accomplished in some cases, and may offer a chance of success when other means have failed. Our decision as to its desirability will depend upon the opinion we have formed with regard to the tightness of constriction of the invaginated gut. As Mr Hutchinson has pointed out, the imprisoned portion of the bowel may be tightly strangulated, or merely irreducible, with comparatively little constriction. In the former case, the course of the disease is very rapid, and the symptoms are severe; gangrene quickly supervenes, and death is speedy. In the latter, where the channel often remains pervious, although much narrowed, the course is more chronic, and the symptoms are less pressing. It is in these slower cases that the operation is especially likely to be successful. Unfortunately, the difficulty of judging of the degree of tightness of the constriction is very great. The severity of the symptoms is not always, in children, a trustworthy guide. Much depends in such a case upon the nervous impressibility of the particular patient; for a degree of strangulation which in one child will produce violent vomiting and early prostration, will, in another, be attended by much less serious and urgent symptoms. In young babies, unless the operation be performed within the first three days, and before the occurrence of collapse, we can have little hope of its success; but as, in such cases, the death of the child, if left alone, is cortain, the operation is surely a permissible one. In older children, I am strongly of opinion that it should not be performed if, from violence of vomiting, severity of the general distress, and early occurrence of prostration, we have reason to believe the strangulation of the bowel to be complete. The gut would probably he found either gangrenous or adherent. In such cases there is always the last chance of sloughing and elimination, and this the operation would take away. On the other hand, if the general symptoms are comparatively mild, and especially if the intestinal channel is not completely occluded, the operation is distinctly called for after failure of other means of reduction.

In the early period of the illness, vomiting is often encouraged by repeated and unnecessary feeding of the child. At this time, it is best to give no food at all, and only to allow an occasional spoonful of barley-water to assuage the thirst. If old enough, the child may be allowed to suck lumps of ice. If the vomiting remits, some simple food—nulk and barley-water for a baby, given cold with a teaspoon; and for an older child, strong beeftea, essence of meat, and milk, also in small quantities at a time—may be allowed. When the strength begins to fail, brandy-and-egg mixture can be

given.

If climination of the gangrenous segment take place, the utmost care should be observed that for months afterwards the child eat sparingly of farmaceous and fermentable articles of food, so as to avoid injuring the young adhesion by flatulent distention. Potatoes, peas, and broad-beans should be forbidden. Farinaceous puddings and sweets should be greatly restricted in quantity. In fact, the child should be dieted much as if he had lately passed through an attack of enteric fever.

CHAPTER XL

TYPHLITIS AND PERITYPHLITIS.

The execum and its appendix are liable to disease on account of the tendency to retention of foreign bodies and irritating substances in this part of the alimentary canal. In perityphilits, the inflammatory process begins almost invariably in the execum, and spreads thence to the loose arcolar tissus around it. In most cases, it is the consequence of ulceration and perforation of the wall of the cacum or vermiform appendix.

Causation, etc.—The form of perityphlitis which is due to ulceration of the verinform process seems to occur more often in early life than in later years. Therefore, childhood may be considered to be one of its predisposing causes. It has been noticed in an infant no more than seven months old; but this is very exceptional. Usually, the child is between four and twelve years of age. It is said to be more common in boys than in girls.

The determining cause of typhilitis is, no doubt, in most cases, constituting what Rokitansky named "typhilitis stercoralis." It has, however, been also attributed to cold and external injury. I have known it to occur during

convalescence from typhoni fever.

Perityphhtis is commonly due to the passage into the appendix of a httle concretion, which is retained and sets up inflammation and ulceration. Hardened intestinal concretions are often described from their appearance as cherry- or date-stones, but on examination are almost invariably found to consist of the earthy phosphates combined with inspissited mucus and or-dinary feeal matter. They may be formed around small foreign bodies, as a shot, a pin, or a spicula of bone. In size, they may resemble a pea or a date-stone. They have a smooth, shining, waxy-looking surface of a gravish or brownish colour. Their consistence is hard, and their structure often laminated. Sir William Jenner is of opinion that the retention of these calcult is due in many cases to malposition of the appendix. This process, owing to its length and the attachment of its mesentery, may be bent at an angle (instead of being directed upwards and inwards), so that hardened particles can slip readily into it but are prevented from returning. According to Dr. Sands, the appendix, before destruction of its coats, contracts adhesions to the peritoneum lining the iliac fossa; so that when perforation occurs, the facal matters, instead of entering the serous cavity, gradually pass into the loose connective tissue which lies outside the peritoneum.

In some cases, a typhoid or tubercular ulcer may lead to destruction of the wall of the excum, or the part of the intestine immediately adjoining, and be a cause of extravisation. When the escape of facal matter takes place into the loose tissue behind the excum, it sets up inflammation and abscess. An abscess once formed rapidly enlarges, and tends to point somewhere in the diac region, or in the groin just above Poupart's ligament. The direction in which the pus travels, varies according to the exact seat of the purulent collection. Thus it may pass along the inguinal canal into the scrotum, or along the pseas and ihac muscles to the upper part of the thigh. Sometimes it dips into the pelvis, and opens into the rectum. In other cases, if the ulcerated opening remain patent, the pus may pass through it into the execum; but often after a time the opening closes up so as to shut off all communication with the abscess.

Often, general peritonitis, more or less severe, accompanies the peritophitis, from extension of the inflammation. If, instead of opening into the sub-serous tissue, the rupture takes place from the bowel or appendix

directly into the peritoneal cavity, peritonitis is set up at once.

Sym, toms.—An attack of typhilitis begins suddenly with pain localised in the right three fossa; the child vomits, and the bowels are confined. The pain is constant, and apparently severe. It is increased by pressure over the cream, by cough, or by efforts to vomit. The matters ejected consist of watery and bilions fluids, and the retching may be severe and distressing. At the same time, there is fever which varies according to the nervous impressibility of the child. Usually, the thermometer marks 101° or 102°. The expression of the face is anxious and distressed. On pulpation of the belly, we notice a firm mass in the situation of the execum, and gentle percussion at this spot elicits a dull sound. On account of the tenderness, it is difficult to make a satisfactory examination of the iliae region, for the least touch causes severe suffering. The child lies on his back, inclining to the right side; he flexes his thigh, and cries bitterly if any attempt is made to straighten the limb. Sometimes a distinct swelling may be noticed at the seat of pain.

These attacks are often spoken of as "colic" or "inflammation of the bowe is." and after recovery, a tendency appears to be left to a recurrence of the illness, for it is not uncommon to hear that this is not the first time that the child has suffered from similar symptoms. As a rule, if the lesion remain simple, and be not complicated with ulceration of the wall of the howel, its course is rapid, and in a few days, under suitable treatment, the pain and ten lerness are no longer complained of, and the child is convalescent. In exceptional cases, the disease lists into the second week, and the tender-

uess and swelling only slowly subside.

Pertuphides may be preceded by the symptoms described above as being characteristic of inflammation of the eacum; but more often—probably on account of the more limited area occupied by the morbid process—the stage

of ulcerative destruction passes almost unperceived.

In the first case, the vomiting and constipation cease, and the more acute pain gives place to a dull aching, or even altogether subsides. Still, there is tenderness, and the swelling does not entirely disappear. The child does not seem well. His face retains an expression of distress, and he is dull and

listless and unwilling to play about,

If the perforation occur without having been preceded by the symptoms of typhlitis there is often nothing but a sense of dull aching or discomfort in the right illac region, with occasional passing attacks of more acute pain. On those occasions, there is vomiting of short duration, and the child looks ill, and is feverish. This passes off in the course of a few hours, and the child remains as before—not quite well, but suffering from ill-defined symptoms to which little importance is attached. He is prevish and fretful, capricio is in his appetite; subject to attacks of diarrhora alternating with constipation, and often thirsty at night, with some increase in his temperature

When perforation occurs, if extravasation take place into the perito-

neum, all the signs and symptoms of a localised peritoritis are at once observed. There is pain, swelling, and tenderness in the right side of the belly, with vomiting, constitution, high fever, a furred tongue, and a pinched, haggard face. The child lies on his back with his thighs flexed, and dreads the least touch. The inflammation may become general, and the child quickly die with all the symptoms elsewhere described use Acute Peritoritis). If it remain limited, he may perhaps recover after a

longer or shorter illness.

When the perforation takes place posteriorly, so that the extravasated matters pass backwards into the loose connective tissue behind the cacum, the symptoms are less severe. In such cases, the child at first may continue to be about. He generally looks ill, has a more or less febrile temperature, a capricious appetite, and is listless and languid. He may suffer from pain in the iliac region not very severe, but constant and wearing; or may be attacked by occasional pains of a colicky character, which are often excited by movement. At might, the child is restless, constantly altering his position, and sometimes crying out. At this period, the bowels are usually contined. On examination in the early stage, before any pointing of the abscess has occurred, there will often be noticed a fulness in the right iliac fossa, and this part is tender when pressed upon

In most cases, the child, if he continue able to leave his bed, is noticed to walk with a limp. Soon, however, he ceases to be able to walk at all, and hes in bed on his back with his right thigh partially flexed. If he be assisted to stand, he is seen to rest his whole weight on the left limb, and to keep his right limb partially bent both at the hip and knee, and rotated outwards. With these symptoms, especially if there be any history of a blow or fall, disease of the hip-joint may be suspected. This opinion is often strengthened by the child's complaining of pain in the knee as well as in the groin, and by the suffering caused by any attempt at extension of the hip. If the tenderness is great, any rough manipulation of the limb, as in rotating the head of the thigh-bone, or communicating any concussion to the hip by striking the knee, may be a cause of pain in the groin.

As the disease progresses and suppuration occurs, the pallor and distressed expression of the patient are very noticeable. His pyrexia becomes more marked, and the evening rise is followed by depression, with sweating in the morning. He loses flesh fast, and his tongue becomes dry and brown. The constipation now usually gives place to diarrhea, which may be copious; and the pulse is very rapid and feeble. Great pain is complained of in the belly which may be distended, or even tympanitic; and the swelling in the right line fossa increases in size, but becomes softer. Sometimes severe pains are complained of in the right knee and ankle, and ordems of the limb may occur from interference with the venous

circulation.

If the course of the pus be downwards to the pelvia, so as to show no signs of pointing externally, these symptoms, coupled with the resemblance of the local condition to hip disease, may suggest a secondary tuberculosis. But a careful examination of the belly will usually detect considerable fulness and tension in the situation of the execum. If the pus discharge itself into the rectum or bowel, great relief is experienced, and the local swelling and tenderness undergo considerable diminution. Often, the course of the pus is towards the surface in the neighbourhood of the abscess. The skin then becomes darkish red or purple, and swellen. It gives a doughly sensation to the touch, and, on pressure, we may notice a

alight emphysematous crepitation. An incision into the softened skin

allows the escape of brownish, offensive pus and bad-smelling gas.

These cases generally end fatally. If peritonitis occur, either from direct rupture or extension of the inflammation, death usually ensues in a day or two. If a faceal fistula remain open, life may be preserved for a cons. lerable time—often for years. In most cases, unless the abscess have pointed early, the child is so much reduced by pain and hectic fever that he does not long survive the opening of the abscess.

A little girl, aged thirteen years, had an attack of typhoid fever when eight years old. After that time she was subject to occasional attacks of "colic" and vomiting. Early in December she was ill with what was called "inflammation of the bowels with colic," but recovered for the time. In the middle of February her bowels became very much confined, and after four days' constipution, she had faceal vomiting. An injection was

given, and a large amount of facal matter was brought away.

When admitted into the hospital on February 21st, the child looked iff, and was very pale. The belly was distended and tympanitic, with some uniform tension of the porietes, but no tenderness or fluctuation. She complained of slight colicky pain at times. Her tongue was covered with brownish fur, and was inclined to be dry. There was no sickness. The bowels had been confined since the injection two days before. The temperature at 6 p.m. was 93.4°.

The bowels were unloaded by repeated doses of an aperion saline.

Afterwards, small quantities of hudanum were given to relieve the colicky
pains which still returned at intervals; and the child was kept quiet in
bed, with hot applications to her belly. After this, the bowels continued

to act twice a day, and the stools were normal.

On March 3d it was noted: "Face pale; expression distressed; abdomen not full or tender. The temperature since admission has varied, sometimes reaching 101°." A week afterwards the child complained of more pain in the belly, but this part was not swollen or tender. The bowels were a little relaxed. The child began now to lose flesh fast. She continued pale and very haggard-looking; but although she complained of occasional pains in the belly, there was no tenderness or swelling, and she never vomited. The diarrhosa, however, continued. On March 14th, she began to localise the abdominal pain in the right side just over the situation of the qualitates lumborum. The abdomen was natural in appearance, and not tender. The bowels were still loose, and the stools liquid and homogeneous, without blood or shreddy matter.

After a few days, a fluctuating tender swelling appeared just below the ribs on the right side, and in front of the mass of the quadratus humborum. This grew larger, and there was much subcutaneous codema around the swelling. The child looked ill, and wasted rapidly. Her temperature was between 100° and 101°. The swelling was opened by the aspirator, and an ounce of brownish, fetid pus was removed. The child, however, sank and

died two days afterwards.

On examination of the body, a large abscess was found at the back of the exerum, containing much purulent brown matter. The ilium just above the illuscretal valve was distended, and an ulcerous opening was found in the wall just above its junction with the exerum. A probe could be passed through this opening into the abscess. There was, besides, some slight but general peritonitis. The liver was fatty, and both it and the spleen were adherent to the disphragm. Many of the mesenteric glands were enlarged.

This case of perityphlitis, although really the consequence of ulceration

of the small bowel, and not of the crecum, illustrates very well the orbitary history and symptoms of the disease. The early attacks of cohe, accompanied by vomiting, were no doubt owing to the occasional occurrence of inflammation in this part of the intestinal tube; but the ulcerative process probably dated only from the illness from which the child had suffered at the previous December. This was probably a more severe attack of healised enteritis. The treatment pursued in this case is not to be recommended for imitation. Repeated aperients under such circumstances as must have existed when the child came under observation, could out be injurious. It would have been more judicious to have left the bowels alone.

or to have administered a simple enems.

Cases of ulcerative perforation of the vermiform appendix require que cial mention. This accident is, as has been said, more common in early life thun after adult age has been reached. Often, the initial stage of the he ease has excited no notice, and the first symptoms that arise are due to toextravasation of the contents of the bowel into the peritoneum. In most cases, all the symptoms of acute peritonitis ensue, and the child require dies. The consequences of the extravasation are not, however, always to easy of recognition. In the chapter on Acute Perstontis, mention is have of the occasional latency of the abdominal symptoms in cases where the peritoneum is inflamed. This is sometimes the case when the inflammation is set up by matters extravasated from the bowel; and we may an it as a result of perforation of the appendix, merely pain, vonating, constiput a and some fever-symptoms which are not characteristic of peritoritis, sat tend rather to suggest obstruction of the bowel. In fact, not once, but many times, such cases have been treated for obstruction, even to the catest of actual surgical interference. The obstinacy of the constitution the persistoney of the vomiting, and the colicky character of the pain, make the resemblance curiously close. Often, indeed, very careful examination is is quired to detect the real nature of the attack. It is of extreme important to remember that traumatic peritonitis in the child may be ushered in by such symptoms; and in every case of supposed obstruction of the intesting we should search carefully for some other cause for the illness.

Sometimes, on inquiry we find that on previous occasions the child had complained of slight abdominal pain, lasting for twenty-four hours a perhaps two days, with tenderness in the cascal region and a angle effect of vointing. These passing attacks may be accompanied by flatible a constipation, or diarrhea, and a feeling of distention of the belly. They are due, no doubt, as Dr. With has pointed out, to ulceration of the verte-form appendix, with commencing adhesive peritorities. After perforates has occurred, the local symptoms may remain limited to the discretion or may spread to the whole abdomen. In the first case, if the discretion recognised and properly treated, the child may perhaps recover, in the

second case, he usually dies. Hous may occur before death.

Diagnosis.—Typhhitis is accompanied by such characteristic symptoms that its detection is not a matter of difficulty. A sudden attack of accompanied pain and tenderness referred to the region of the right that food accompanied by vointing, constipation, a pinched, anxious expression, and some fever, at once draws attention to the belly. On examination the presence of an intensely tender swelling in the situation of the commutagether with the drawing up of the thigh on the affected side, sufficiently indicates the nature of the illness. If the occurrence of vointing and obstinate constipation, combined with a localised swelling and some abdominal pain, should suggest intussusception, we may remember that

in the latter disease tenderness and signs of local peritonitis are not early symptoms; that the tumour, if felt, is commonly detected on the left sale of the abdomen; and that violent straining, with the passage of bloody

mucus, is a very constant and prominent symptom.

If, after the signs of general constitutional disturbance have subsided, the local symptoms do not disappear, but more or less tenderness, pain, and swelling persist; or if, after disappearing, the acute symptoms return after only a short interval, and this recurrence happens several times, in either case we have reason to fear that the inflammatory process is going on to alcoration. The occurrence of peritoritis at this time will confirm our apprehensions, and indicate extravalation into the cavity of the peritoneum. If, however, the wall be perforated posteriorly, and an abscess

form behind the cocum, the symptoms are much less striking.

If the patient be not confined to his bed, he often complains of tenderness in the right groin, and halts upon the right leg. The case is then distinguished from hip disease by nothing that although the child keeps the thigh partially flexed, and is greatly distressed when any attempt is made at passive extension, the head of the femur may be rotated readily and without pain, if it be done with care; and that pressure upon the hipjoint on or behind the trochanter, causes no discomfort if the patient's whole body be not joited at the same time. Often, the child, while lying on his back, will readily flex the thigh, and perform the movements of abduction and adduction. It is only extension which appears to be impossible, and any attempt to strughten the lumb causes severe pain. It will be remarked, too, that while the history indicates shortness and acuteness in the illness, the symptoms, if they could be referred to the hip-joint, would suggest disease of considerable duration. Listly, wasting of the muscles of the thigh, which occurs early in acute hip disease, is absent; the gluteal muscles on the affected side are not flattened, nor is the fold of the buttock lowered; the fold in the groin below Poupart's ligament is not obliterated; and distinct swelling and tenderness can be detected in the right that fossa.

Directly signs of pointing are noticed, any remaining obscurity in the

case must disappear.

Ulceration and perforation of the vermiform process are very difficult to recognise with certainty, as the first symptoms noticed are often those due to the extravasition into the peritoneal cavity. Severe peritonitis coming on suddenly, especially if the pain and tenderness can be ascertained to have started from the right that region, is very suspicious of this accident. Essential peritonitis comes on gradually, and the ordinary forms of peritonitis from perforation are preceded by some severe acute illness. It is important to bear in mind that the phenomena resulting from perforation of the caeal appendix may be far from characteristic of influentiation of the peritoneum; and in every case where symptoms arise pointing to sudden obstruction of the bowels (pain, vomiting, and constipution) accompanied by fever, we should carefully exclude this and other possible causes of such symptoms before committing ourselves to the largeous of intestinal occlusion.

Prognoss.—Simple typhlitis almost always ends favourably; but if perforation occur, and extravasation take place into the peritoneum, recovery rarely follows. If a retro-peritoneal abscess result from the perforation, the prognosis is less unfavourable; but here, too, the patient often dies from exhaustion, or from extension of the inflammation to the serous membrane. The most favourable course is that in which the abscess

discharges itself again into the bowel. Of the cases where it opens externally, a large proportion die. Perforation of the caseal appendix is

usually fatal.

Treatment.—In every case of typhilitis our chief care should be to quare peristaltic action, and prevent any movement of the bowels, by the free are of opium. Whether the inflammation has had its origin in a collective of treatmenter in the cocum, or has been induced by other causes, the sum necessity exists for keeping the bowels at rest until the inflammation has subside l. Therefore an aperient in any shape is not to be thought of for a moment. Even enemata would be injurious while the acute symptoms continue.

The child should lie in bed, with a small pillow under his right bee; and hot inseed-meal poultices should be applied to the right sade of the belly, and be frequently changed. Opium should be given by the most. A child of eight years of age will take three drops of hudanum ever four hours. If this be comitted, morphia (one-sixteenth to one-twelfth of a grant can be injected subcutaneously in its stead. The comiting is, hereor, usually checked by the opiate, and the second attempt to administer it in a draught is often successful. A good combination in these cases is that of the tinctures of opium and belladonna. The latter drug is not only of great service in most forms of arrested function of the bowels, but also by its antigonistic action tends to modify the narcotic influence of the last-anum without interfering with its power as a sedative. If this combinate be used, five drops of tincture of opium may be given with twenty of the belladonna tincture three times a day to a child eight years of age

If the child be very strong, and the tenderness severe, tures or for

leeches should be applied to the punful spot.

The dict must consist of milk and broth, given in small quantities it time. The milk should be diluted with an equal quantity of barley was to separate the particles of curd and prevent their congulating in a lamp. It should be also alkalmised by fifteen or twenty drops of the excharged

solution of lime to the teacupful

When the acute symptoms subside the bowels will generally act quaterously. If they do not, an injection can be administered. Purgates of any kind should be avoided for some time after convalescence is callished. We can never be sure that some slight ulcerative process is act going on, and the only hope of the child in such a case would be decitablishment of sufficient a thesions to prevent rupture and extravalues.

Such adhesions, if formed, an aperient would probably destroy.

In cases where we have reason to suspect the presence of a retro-ceed abscess, the same reason for the avoidance of purgatives exists. The chall should be kept in bed, and het applications should be applied to the parful part. He should be fed with nourishing food in small quantities at a time; and a suitable proportion of stimulant should enter into his dist. Minced mutton and chicken, strong beef-essence, yolk of egg, rath and toust should form the staple of his food. If the bowels are obstimately exfined, or faceal vointing occur, an enema may be administrated, but purgatives should be avoided. For medicine, quinine and a mineral acut with small doses of strychnia may be given, and as the child grows weaker are monia and bark. Directly signs of pointing are noticed the pure should be tout at once.

If peritonitis occur, the treatment must be conducted as directed in the chapter treating of that subject.

CHAPTER XII.

ACUTE PERITONITIS.

Act is peritonitis may occur in childhood at any age. It may be present in the feetus, usually as a consequence of syphilis, and is then a frequent cause of miscarriage. It may arise in the new-born infant as a result of pysemic infection, and is invariably fatal. It may occur at a later period of infancy or in childhood, either as a primary disease, or as a secondary malady complicating the course of some other illness. The infective form of peritonitis which occurs in the new-born baby, and is accompanied by jaundice, is described elsewhere (see Jaundice). The present chapter deals only

with the disease as it is seen in later infancy and childhood.

Causation. - As in the adult, inflammation of the peritoneum in children is often induced by traumatic causes. A blow or other injury to the abdomen will occasionally excite it, and it may arise as a consequence of puncture of a hydatid cyst. The commonest of these causes is the extravasation of fluids from the bowel into the peritoneal cavity, owing to perforation of the intestine. In typhoid fever, and in ulceration of the vermiform appendix or of the cucum, this accident may happen, and a rapidly fatal issue to the illness usually follows. Dr. Robert Lee has referred to two cases in children, aged respectively eight and nine years, in whom perforation of the stomach induced the peritonitis. Sometimes a local inflammation of the perstoneum may become diffused, as when a typhlitis or perityphlitis, or an invaginate | portion of the intestine sets up general peritoneal inflammation. Mr. Curling has recorded the case of a little boy, aged two years, in whom the bruising of an undescended testicle produced this result. Again, inflummation may extend from the chest to the abdomen. I can now recall several cases in which a pleurisy has been followed by general inflammation of the peritoneum. I have known this to happen in the first week of the illness, before the fluid had had time to become purulent; but in most cases it occurs later, as a result of the passage of purulent infective matter from the pleural cavity along the lymphatics of the disphragin to the perstoneum. In order that this extension should occur, there must, no doubt, be present some special conditions conferring peculiar infective properties upon the purulent contents of the thorax. Dr. Burney Yeo has described the case of a schoolboy, between eleven and twelve years of age, who was attacked in the course of whooping-cough by pleuro-pneumonia of the left side of the cliest. Nineteen days afterwards this was followed by general peritonitis, and the patient very rapidly succumbed. The same infortunate accident happened to a little boy, eighteen months old, under pay care in the East London Children's Hospital. The child had an attack of pleurisy. As the fluid did not become absorbed his chest was punctured and a quantity of purulent matter was evacuated. The operation had to be repeated several times, and at last, as the purulent fluid still continued to reaccumulate, a permanent opening was established in the chest-wall. The boy seemed to be going on fairly well when extension of the inflammation suddenly took place to the pertoneum and he soon died.

Peritonitis is sometimes a complication of the blood diseases. It is said occasionally to occur in scarlatina, and crystoclas may induce it. Abercrombie has referred to an epidemic of the latter distemper which occurred amongst the children in the Merchants' Hospital in Edinburgh in the year 1824. The disease was of a mild type, but two of the children rapidly died, and on examination pus was discovered in the abdominal cavity. Peritoneal inflammation is also common as a consequence of abdominal tuberculosis, but the subject of tubercular peritonitis will be considered separately.

Besides occurring as a result of the above causes, peritonitis may arise as a primary disease in a child in whom no deviction from health has been noticed. It is sometimes seen in school-children of either sex, and has been attributed by Gauderon to childing of the surface after violent

exercise, and by Legrand to lying prene upon the damp earth.

Marind Anatomy—The pathological characters of peritonitis are the same in the child as in the adult. The vessels are injected, and the normal polish of the serous surfaces is lost, owing to inflammatory exidation. There is infiltration and thickening of the sub-serous tissue, with proliferation of cells in the epithelial covering of the membrane. The exudation poured out from the distended capillaries coagulates on the surface and forms a false membrane, which is at first thin and grayish in colour, afterwards thicker and yellow. It causes adhesion between neighbouring organs, and glues the coils of intestine to one another. There is besides effusion into the abdominal cavity. Its quantity varies. Sometimes it is copious. The fluid is usually opalescent, from proliferated

epithelial cells, or may be distinctly purulent.

The longer the disease continues, the tougher and thicker the exudation becomes, so that it may form bands which pass from one organ to another, and in long-standing cases may constrict portions of the bowel and cause serious consequences. If the patient survive, the fluid becomes absorbed, and the exudation gets tougher and forms firm adhesions between neighbouring parts, as well as opaque fibrous patches upon the surface of organs, more or less thick and hard. When the peritonitis is at first partial, as may happen when the inflammation is due to perforation of the bowel, the exudations and consequent adhesions may confine the extravasated matters within certain limits, and thus localise the inflammation.

Pent up collections of matter may also arise in the following manner: On account of gravitation the purulent fluid is apt to collect in certam spots, especially above and behind the liver. If the child do not die, the fluid, thus accumulated, may become shut off by adhesions so as to produce a local abscess. Abscesses arising in this way are usually seated near the diaphragm, often between that muscle and the liver or sphere. Such a collection of matter may eventually open into the chest and set up pneumothorax.

Symptoms.—In the child peritonitis may give rise to violent and acute symptoms, as it does in the adult. As a rule, it is the primary form—essential peritonitis, as it has been called—which is accompanied by these signs of serious disease. Also, when the inflammation follows upon a blow or other external injury in a child previously in good health, the symptoms are usually striking and severe. In the secondary form, when the child is already reduced by illness, the symptoms, although often sufficiently pro-

nounced, may yet be to a certain extent masked by the state of profound collapse into which the patient is thrown. In other cases the disease may be more or less latent, and indeed is sometimes not discovered until the

boly is subjected to examination in the dead-house.

In the severe primary form the child complains, often quite suddenly, of pain in some part of his belly-in either flank, above the pubes, or about the navel. At first comparatively slight, the pain soon gets more severe and general, and at the same time the belly becomes tender. Vomiting is almost always an early symptom. The child first ejects partially digested foot, and then glairy and bilious matters. If the efforts to vomit are violent, they occasion great distress, on account of the pain and tenderness of the belly; and after each effort the child lies back with haggard, pale face, be als of sweat standing upon his brow. Fever is present from the beginming, and may be preceded by a sense of chilliness, or even distinct rigors. The degree to which the temperature rises varies, as it does in inflammation of the other serous membranes in the child. Sometimes it may reach 104, or even higher, but at other times it remains little over 100°. The sverige degree of pyrexia is perhaps between 101" and 102". At night the child is restless and sleeps little, often waking up and crying with pain in has belly. Sometimes he is disturbed by delirious funcies and talks wildly.

Almost from the first the chill is unwilling to move, and he soon takes to his be L. There he lies upon his back, or inclining to one side, with legs and thighs flexed. His face is pale and distressed, his nose looks sharp, and the nostribare thin and expanded. The slightest touch upon the belly in paneful, and he seems to dread the least movement. If the coat of the bladder is involved, there is retention of urine. If the peritoneal cont of the howel is inflamed, attacks of the most violent colic may come on at intervals, and throw the child into an agony of pain. On examination of the belly, this is seen to be distended with gas; it is motionless in resprration : there is some tension of the parietes, and the tenderness is exces-Gentle percussion elicits a tympanitic sound over the anterior regroups; but in the depending parts, where the fluid collects, the note is dull. Sometimes the fluid is sufficient in quantity, and sufficiently free, to give a distinct sense of fluctuation; but the absence of free fluctuation is no sign of the absence of fluid. There is often effusion between the coils of intestine and in the meshes of the exuded lymph; but this transmits the wave of fluid very imperfectly from one side of the belly to the other. As a general rule, perhaps, fluctuation is imperfect or absent. In these cases Dupareque has suggested that the child should be placed on his side for a few minutes. The whole quantity of fluid will then gravitate to the flank on the depending side. If the child be then quickly turned upon his back, dulness and fluctuation will be found at first at the site of the accumulated fund, but owing to the second change of position will quickly disappear.

If the distention of the abdomen become great, it may cause serious distress by compressing the lungs and displacing the heart. In such cases there is dyspinen, with some lividity of the face, and hurry of breathing. The tongue is furred on the dorsum, red at the tip and edges. The pulse is small, hard and frequent. The urine is high coloured, but not especially acid, and its passage causes no pain. The bowels are confined or relaxed. Constipation is the rule in adults, but in children it is common to find looseness of the bowels with watery and offensive stools. Still, even in the child, if the muscular coat of the bowel be involved, and there be no sub-mucous redema to cause effusion into the intestinal tube, the bowels

may be obstanately confined.

As the illness progresses the vomiting usually ceases, but the other symptoms become more and more severe. The tympanitis increases: the tongue becomes dry and brown; the eyes are sunken, the face is haggard and pale, often eyanotic. The child heavith his eyes half closed in a die my state. His pulse is excessively small and rapid; and death usually occurs

by the end of the week.

In exceptional cases the disease ends in recovery, the fluid being absorbed or discharged through the navel or abdominal wall. I have not with one case in which purulent matter escaped in large quantity through the umbilious, and the child recovered. If the pus be evacuated by this channel, the relief experienced by the patient is usually extreme. The volume of the belly is diminished; vomiting, if it had persisted, ceases; the tongue begins to clean, and some signs of returning appetite are manifested. M. Gauderon has referred to ten such cases, in eight of which recovery took place. The tistula left after the discharge of the purulent matter closes in about a month, sometimes at an earlier date. The discase is said sometimes to pass into a chronic state. Such a termination would excite suspicions of a tubercular origin for the peritonitis. There are few recorded cases of chronic peritonitis in the child, where an opportunity of examining the body was afforded, which do not make mention of tubercle in the abdominal cavity or in the lungs.

When the peritonitis is the result of perforation of the bowel, the occurrence of this serious accident is indicated by sudden severe pain in the belly, which becomes distended with gas and excessively tender. At the same time the child is reduced by the shock to a state of collapse. His face is haggard and ghastly looking; his eyes are deeply sunken; his pulse becomes very quick and small; his breathing is thoracic; his hands and feet are cold, but the temperature of the body, if taken in the rectum is found to be 103°, 104°, or even higher. Sometimes he vomits, and the secretion of urine is suppressed. On examination of the belly it is found that the liver dulness has disappeared. Niemcyer gives this as a certain sign that peritonitis resulting from perforation of the bowel has taken place.

The above is the typical form; but often the symptoms are much less characteristic. Pain and tenderness may be little complained of, and, as Andral has pointed out, sudden increase of the prostration and the ghastly look of the face may be the only symptoms drawing attention to this new complication. Even when the pain has been severe, it often ceases completely for some hours before death. In most cases the child survives perforation but a very few days. Sometimes, if adhesion have previously taken place in the neighbourhood of the ulcer, so as to contine the extravasated matters to the immediate vicinity of the rupture, the peritomismay be localised. An abscess then forms, which after a time makes its way to some point of the surface, and discharges its contents extern dly Under these more favourable conditions the child may recover, but it is needless to say that such cases are exceptional.

Sometimes peritonitis in the child is entirely latent, and is only discovered on post-mortem examination of the body. In such cases the belly may be swellen, and the child may look ill and colourless; but pain may not be complained of; there may be no tenderness of the abdom a, no tension of the parietes, no fluctuation, or other sign to indicate the presence of this serious lesion. I have only observed this latent form in cases of secondary peritonitis. In the little boy, whose case has been before referred to, where peritonitis resulted from extension of the purulent inflammation to the belly from the chest, the abdomen was swellen, and a

watery diarrhora began which resisted all treatment; but there appeared to be no pain or tenderness; the parietes were soft and flaccid; no fluctuation could be detected; and although on account of its fulness the abdomen was repeatedly examined, nothing was discovered to lead to the suspicion of the existence of peritonitis. On examination of the body some purulent fluid was discovered in the peritoneal cavity, and the bowels were more or less adherent from exuded lymph. It is important to be aware of the occasional latency of the inflammation, so that we may not exclude peritonitis, because the symptoms and signs are ill marked and little characteristic of the lesion. If in such a case the debrium, restless-aces, and tendency to stupor are unusually prominent, the most experienced physician may misapprebend the nature of the illness and be disposed to suspect the onset of a maningitis. Dupareque relates a case in which this mistake was actually made, and the error was only discovered on examination of the body.

Disgress.—When the symptoms are well marked the diagnosis of the disease is easy. Swelling of the belly, which takes no part in the respiratory movement and is intensely painful and tender; vomiting; a pale largeard face, and a quick wiry pulse—these, together with the position of the child in his bed, with the thighs flexed, and his dread of movement or even of a

touch, form a very characteristic group of symptoms.

When the inflammation is a consequence of perforation of the bowel, the complication is sufficiently clear. Even if the pain and tenderness are inconsiderable, the sudden occurrence of collapse with tympanitis suffi-

ciently indicates what has occurred.

From tuberculous peritoritis the acute simple form may be readily distinguished by the more violent character of the symptoms and the more rapid course of the disease. In the tuberculous variety vomiting is rare, and the illness runs, as a rule, a very slow and chronic course.

In colic there is often constipation and vomiting, with severe paroxysmal pain in the belly; but between the attacks of pain there is no tenderness; the pulse is less rapid, small, and wiry, and there is none of

the fear of movement which is so characteristic of peritonitis.

Rheumatism of the abdominal wall may be mistaken for inflammation of the peritoneum. The distinctive characters are given elsewhere (see

page 159).

It is important to remember the occasional latency of the symptoms in peritonitis. Tension of the abdominal parieties on palpation, especially if partial, in a child above the age of infancy, must not be disregarded. It may, of course, be voluntary, and the belly be quite healthy; but if the abdomen is full, and the child looks ill, with a haggard, punched face, we should consider the possibility of peritonitis, and make a very careful examination. In cases of chronic empyona we should be always on the watch for the occurrence of peritonitis. If the child, after a period of improvement, cease all at once to gain ground and begin to look pale and distressed, with an elevated temperature, a more or less distended belly, and a rapid, why pulse, we are justified in suspecting peritonitis although there be no tension, tenderness, or other sign connected with the abdomen to give support to this opinion.

It is well in all cases where a feverish child looks ill and has a distended belly, to make trial of Dupareque's plan of placing the patient for a minute or two on his side, so as to allow all the peritoneal fluid to collect in the depending flank. Turning him, then, quickly upon his back, evidences of fluid, if peritonitis be present, will be found at the site of accumulation.

Had this been done in the case of the little boy already twice referred to, the cause of the distention of the abdomen would not have escaped re-

cognitum.

When the inflammation affects exclusively the visceral peritoneum, the muscular coat of the bowel is usually implicated. There is then often obstinate constipation from paralysis of the affected portion of the intestine; there may be vomiting; and excessive tenderness of the belly is combined with paroxysms of colicky pain of agonizing severity. Such eases may simulate very closely obstruction of the bowels, and may be mistaken for intussusception. Some time ago I saw, with Mr. Izod, of Esher, a young lady, aged ten years, who had got up in her usual health on the morning of the previous Sunday. In the afternoon of that day, after running about in the garden (the day was very damp) she complained suddenly of pain in the belty. That night she slept fairly well, but complained of pain again on the next (Monday) morning. A pill was given to her, followed

by a Baline.

This acted on the bowels, but the pain was not relieved. She alept badly that night. On the Tuesday morning she was seen by Mr. Izod, who found a temperature of 102. There was some tenderness of the belly, with frequent paroxysms of colicky pain. She had had no vomiting. Opium was given, but the pains continued, becoming more and more frequent and more and more severe. The bowels were confined all the week except on the Thursday, when they acted spontaneously twice, the stools being copious and lumpy, light coloured and rather offensive. I saw the child, with Mr. Izod, on the following Sunday—the eighth day. She was lying in bed hollow-eyed and livid. Every ten minutes a paroxysm of pain came on, during which she raised herself up in an agony and tried to get on to the floor. The belly was swollen and excessively tender, the slightest touch appearing to induce a fresh access of pain. The child had been kept for some time under the influence of chloroform, but when the anisathetic was remitted the pain instantly returned. Hypodermic injections of morphia and atropine were given repeatedly; but large quantities of these narcotics appeared to dull the pain but slightly. The child died on the following day.

On examination of the body the small intestine was found healthy, except for a reddened and ulcerated patch in the middle of the jejunum. The large bowel was distended with liquid faces. Its parietal cost was very red and inflamed, but there was no injection of its mucous hing. The parietal peritoneum was not inflamed. Its cavity contained much

dirty serum, but no lymph.

If the inflammation, instead of being confined to the visceral peritoneum, spreads through the muscular coat to the nuccus membrane (phlegmonous enteritis) there is, in addition to the above symptoms, a profuse watery diarrheea. The diagnosis is then easy. If the nuccus membrane is not implicated, there is constipation which may be obstinate. In such a case intussusception may be excluded by noticing the early occurrence of tenderness, of abnormal tension of the abdominal wall, and in most cases of fever. Moreover, there is no tenesmus; and the passage of blood and bloody mucus from the bowel, which is such a characteristic feature of intussusception, is absent. If, as in the case just narrated, an action of the bowels, spontaneous or otherwise, occurs some days after the beginning of the illness, there is evidently no complete obstruction of the intestinal channel; but unless the invaginated portion of gut be tightly constructed, secondary peritonitis is very unlikely to arise.

Prognosis.—The disease is fatal in the large majority of cases. In primary peritonitis from cold the chances are perhaps a trifle less unfavourable than in the other varieties. Restlessness and inability to sleep are last signs. In partial peritonitis, if the inflammation remain localised,

the child will sometimes recover,

Treatment.—Directly the existence of peritonitis is ascertained no time should be lost in resorting to energetic measures for its removal. most perfect quiet in bed should be enforced, and the presence of too many attendants should be strictly forbidden. One good nurse can do all that is required. Turpentine stupes should be applied to the belly, and opium should be given by the mouth or by hypodermic injection. For a child ten years of age six or eight drops of laudanum may be given in a teaspoonful of water every four hours, or one-twelfth of a grain of morphia may be injected under the skin, and the operation can be repeated as required. It is best to produce drowsiness, with some contraction of the pupil. Children vary greatly in their susceptibility to this form of narcotic; but inflammation of the peritoneum, if the pain is great, may require larger quantities of the drug than one would be disposed to anticipate to produce a sufficiently sedative effect upon the patient. Thus, I have known a little infant of four months old, who was suffering from agonising colic, owing to inflammation of the peritoneal coat of the bowels, take three minims and a quarter of laudanum in the space of two hours, with but little remission of his suffering. The same infant some hours afterwards had a hypodermic injection of one-twelfth of a grain of morphia; and this powerful dose, although it contracted the pupils to the size of a pin's point, did not completely suppress all signs of pain. Energetic counter-irritation is of great value in these cases, and when the turpentine can no longer be endured upon the abdomen, it may be applied to the front of the chest or to the back. Cold applications are well borne in many cases, and seem sometimes to comfort more than hot flannels. Cold is employed by means of cloths wrung out of ice-cold water and frequently changed.

All purgatives are to be avoided. If it be considered necessary to relieve the bowels, this can be done by enema. If the peritoneal coat of the intestine is involved, constipation is often absolute; but it is best to make no attempt to excite a movement. Our object is to quiet peristaltic action and insure rest. Probably the chief value of opium consists in its influence in this direction. Any attempt, therefore, to oppose its action will be hurtful. If in these cases the paroxysms of pain are frequent and agonising, it is advisable in a robust subject to apply leeches freely to the abdomen. I believe this form of disease to be one in which the abstraction of blood is a distinctly valuable therapeutic means; and should not hesitate to employ ten or twelve leeches, or even more, if the attacks of colicky pain resisted the action of morphia. Even when the inflammation is limited to the parietal peritoneum, leeches may be employed in the case of a sturdy child, when the disease is primary, especially if the pain and tenderness can be referred to any particular spot. In many severe cases of peritoneal enteritis, where the pain is excessive, and morphia, even following the application of leeches, proves impotent to control the paroxysms of suffering, it is advisable to keep the child under the influence of chloro-

form.

If thirst be much complained of, it is best allayed by sucking ice; and the same measure is also useful in checking the tendency to vomit. The food should be concentrated. Strong beef-essence, milk in small quantities at a time, and yolk of egg can be given; and as the patient becomes weaker, a teaspoonful of sound brandy in milk or water should be administered

every few hours.

Tympanitis is a symptom which it is difficult to treat successfully. I have never seen benefit result from enemats of assafe-tida or the passage of a long tube into the bowel. It is best relieved by free stimulation, and the external application of turpentine. If the child survive, and the abdominal distention continue after the inflammation has begun to subside, as a consequence of loss of tone in the bowel, gentle frictions to the belly, compression with a flannel bandage, and quinine and strychnia by the mouth are of service.

When peritonitis is the result of perforation of the bowel, warmth to the abdomen and the feet, the free use of opium, concentrated food, and

energetic stimulation offer the best chances of success.

In every case where collections of matter can be discovered under the skin, either at the umbilicus or elsewhere, no time should be lost in aiding the escape of the pus by the puncture of a lancet.

CHAPTER XIII.

TUBERCULAR PERITONITIS.

The inflammation of the peritoneum which results from abdominal tuberculosis usually runs a subscute or chronic course. The disease is rarely acute; but it is important to be aware that an acute form is occasionally met with, and is very difficult to detect. Tubercular peritonitis may be the only indication of the tubercular disease to be discovered in the body, or may be accompanied by signs of distress from other parts of the system. It is rarely seen in young children, perhaps never in infants, and does not begin to be a common affection before the seventh or eighth year of life. After that age, however, it is frequently met with. The earliest age at which the disease has come under my notice has been three years.

Morbid Anatomy. - On opening the abdomen in a case of tubercular peritonitis we find the bowels covered more or less completely with yellowish, greenish, or gray coloured lymph. The consistence of this varies. It may be loose and soft in texture, or tough. Usually it is mixed up with thick cheesy matter. The lymph often lines the parietal peritoneum, and penetrates between the coils of intestine, which it glues firmly together. Sometimes the whole bowel is so matted together into a confused mass that it is quite impossible to fellow out the course of the canal. More or less greenish or yellow purulent matter is held in the meshes of the exuded lymph, and more is seen to have gravitated to the deeper parts of the ab lominal cavity. On clearing away the lymph from the surface of the perstoneum and contained organs, we find gray and yellow granulations studding the surface more or less thickly. With these are larger masses and even broad plates of cheesy matter, probably also tubercular in their nature. These are yellow or fawn coloured, and may be dotted with black points of pigment. Similar cheesy masses may be discovered lying in the adhesions formed by one organ with another—between the liver or the stomach and the diaphragm, and between the coils of intestine. The more chronic the case the larger and thicker are the caseous masses. When the case is acute, these are usually absent; but the serous surface covered with lymph in the substance of which are scattered gray and yellow granulations varying in size from a pin's head to a pea.

The larger tubercular cheesy masses may cause the intestinal wall to give way, perforated from without. Extravasation of the contents of the intestine rarely takes place into the peritoneal cavity, owing to the existence of the firm adhesions; but in this way a new and unnatural communication may be formed either between two different parts of the intestinal tube, as was noticed by Messrs. Rilliet and Barthez, or between the bowel and the

ambilious, as happened in a case recorded by Henoch.

In the most chronic cases the adhesions may be very tough and fibrous, and even the lymph on the peritoneal surface may resemble connective tissue. The omentum, itself unusually firm in its texture, may be ad-

herent to the abdominal wall; and the mesentery may be tough and contracted.

Tubercular peritonitis is not always general. Sometimes it is partial, and is then usually confined to the upper parts of the abdominal easity—the neighbourhood of the disphragm, the liver, and the spleen. The hver itself is often enlarged from amyloid or fatty change, and has been found by some observers to be cirrhotic. The bowels are often the sent of tubercular ulceration, and the mesenteric glands are enlarged and cheesy.

Besides the peritoneum, tubercle is often found in other organs. In the more chronic cases it may be limited to the abdomen; but in the acute form the abdominal disease is almost invariably a part of a general development of tubercle over the body.

Symptoms.—Tubercular peritoutis always begins insidiously, and its symptoms may be far from being well marked. In some cases attention is diverted from the belly by the more striking phenomena arising from tubercle, and the consequences it involves, in other organs; but even if the tubercular granulations are limited to the abdomen, the early symptoms are often curiously insignificant when we consider the scrious nature of the disease. In these cases of local tuberculous the general nutrition may be good at first, and the appearance of the patient fairly robust; but as the illness progresses the child rapidly loses flesh, colour, and strength, and before death occurs may reach an extreme degree of emacation.

In an ordinary case, the first sign noticed by the mother is that the child's belly looks large, and the next, that it is a little tender. The child is unusually listless and dull. He looks ill. He avoids exercises which cause a jolt or jar to his body, and shows a caution in all his movements which soon attracts attention.

A boy between ten and eleven years old was brought to me at the hospital. The lad had always been healthy and active, although there was a tendency to consumption in his family. For some weeks it had been noticed that he looked pale, often complained of nausea after food, was languid, lay about instead of playing, and cried if he was scolded. Then he began to suffer from pains in his abdomen, and excused himself on this account from running errands as he had been accustomed to do. Pressure on the belly, as in leaning against a chair or table, had not been noticed to be painful; but the boy said that if he leaned forward his "food" rose at once. After some days the abdomen began to be tender and painful. The child complained of feeling cold, and slept badly at night. He was thirsty, but cared little for food. The boyels were relaxed.

The above is a very good illustration of the mildness of the early symptoms, and the stealthy way in which the disease creeps on. The abdominal pains appear to be at first intermittent and of a griping character. The bowels are relaxed or confined. Often the disease is said to have begun with diarrhea, and the attacks of looseness are sometimes separated by periods of more or less marked constipation. Nausea and comiting are not such common symptoms in this form of peritonitis as they are in the simple variety, and the appetite may be preserved for a considerable time.

simple variety, and the appetite may be preserved for a consulerable time.

After some weeks the tenderness of the abdomen and its sensitiveness to the slightest jar or shock, as well as the increasing weakness of the patient, obliges him to keep his bed. But he will sometimes go about as usual, if allowed to do so, for a long time—long after the disease is fully established. He may then be noticed to take very characteristic precontions to avoid joiling his belly when he moves. Thus, he will steady it with his hand as he walks; and go backwards down-stairs, so that he may

the mercury seldom rises above 101" in the evening. In the morning it

may be at the natural level.

If the belly is examined, it will be found to be distended and oval in shape, the projection being more marked about the umbilious and epigastrium than below the navel. The skin has often a shiny look; the veins ramifying over the surface may be noticed to be full; and the natural markings of the belly have disappeared. On palpation there is often increased tention of the recti nuscles, which contract instinctively to protect the tender peratoneum, and the resistance offered by the contents of the abdomen is very unequal. In some parts the parietes are easily depressed; in others certain feeling of solidity is conveyed to the finger, and distinct, firm masses may be often detected here and there. These are usually tender, and frequently pressure upon any part of the helly causes pain. In some cases free fluctuation can be detected. If there be pressure upon the porhal vein by enlarged glands or caseous masses, the amount of ascites may be large. It is then often accompanied by cedema of the lower extremities and abdominal wall, with dilatation of the superficial veins of the belly. It is seldom, however, that these symptoms are noticed. Usually the parount of effored fluid is small, and there is merely an imperfect sense of impulse conveyed from one side of the abdomen to the other; not a disfinet tap of the wave of fluid, such as we feel in the ascites accompanying sirrhous of the liver. If the amount of fluid be small, or its consistence thick, no fluctuation may be discovered; but in these cases it will be noticed that on percussing the belly the tympanitic note which prevails over the greater part of the abdominal wall changes in the flunks to dulness from the presence of fluid; and that if the child be laid on one side, so that the fluid may gravitate downwards, the note on the flank turned uppermost becomes clear.

Of these signs the most characteristic are: The enlargement of the belly, with its smooth, shining surface; the tenderness, the unequal resistance at different parts of the abdominal parietes, and the indistinct flucfuntion. In some cases, however, many of these symptoms may be absent. The tenderness may be insignificant and the parietes perfectly flaccid; Suctuation may be completely absent; and nowhere may any sense of resistance be experienced by the hand pressing the abdomen. Thus, in a little boy of four years old, after three weeks of illness it was noted: *Aletomen large and smooth, with loss of natural markings; superficial verns of chest and epigastrium dilated; abdominal wall perfectly flaccid; no fluctuation to be detected; edge of liver felt one finger's-breadth below the ribs, edge of spleen not felt; several lumps about the size of a walnut ban be perceived in different parts of the abdomen, but not very deeply placed. One of them is immediately below the edge of the liver. They cem tender on pressure, but there is no general tenderness of the belly. Chest healthy. Tongue dry and glazed-looking." The temperature that evening was 98.6 '. The child died about a week after this note, of secondby tubercular meningitis. If, in such a case, the liver be much enlarged from fatty infiltration, a very incorrect opinion is likely to be formed of

the nature of the illness.

As the disease progresses, the akin often gets very harsh and rough. The child looks haggard and distressed; he rapidly wastes, and his temples and cheeks grow hollow. He lies on his back, or turned partly on to his tide, with his knees drawn up, and every movement is painful. The

tongue is dry, and is either thickly furred or is clean and shining, as if denuded of epithelium. The appetite is lost; the finist is great, and the bowels are generally relaxed. Often, the motions consist of dark, watery, offensive matter, with a finky deposit containing black clots of blood. Such a stool is very characteristic of ulceration of the bowels. Instead of diarrhosa, there may be constitution which may prove obstinate. Fatal obstruction, even, may ensue. Sometimes at this period the distention of the abdomen becomes very great, and the child is tormented with spasms of colicky pain. In other cases, the size of the belly diminishes, and hard, tender lumps are felt, apparently in firm contact with the under surface of the abdominal parietes. The temperature, which before was variable and often little raised above the normal level, now becomes higher, and in the evening may reach to between 103° and 104. The emacration of the child is great, and his weakness extreme.

When the disease reaches this stage, improvement rarely takes place; but at an earlier period of the illness it is not uncommon for the initially to take a favourable turn. The tenderness and tension of the belly then diminish and disappear; the appetite returns; the diarrhea ceases; the nutrition of the child improves, and he begins to regain flesh. The favourable change may go on in fortunate cases to complete recovery, and although the belly for a long time remains large, there is no return of the senious symptoms. Often, however, after a longer or shorter interval, the child begins to fail once more; inflammation is lighted up again in his peritoneum, and this time the illness goes on uninterruptedly to the end.

In some cases, the course of the disease is very variable, and is broken by occasional periods of remission in which hopes of amendment are raised only to be disappointed by an early return of the worst symptoms. Often, the end of the disease is preceded by purpuric spots on the body, and by ædema of the legs, with no albumen, or with only a trace of it, in the urine. Death may be hastened by tubercular disease of other organs, especially of the lungs, and sometimes, as in the case referred to, the patient dies with all the symptoms of tubercular meningitis. In rare cases, performing of the bowel takes place, or an abscess forms at the umbilicus

or some other part of the abdominal wall.

This chrome or sub-acute form of the disease is always slow in its course, and usually lasts several months. It is the form the disease assumes in the large majority of cases. Occasionally, however, the peritonitis is acute. In all the cases of acute tubercular peritonitis which have come under my notice, the abdominal disease has formed part of a general tuberculosis. The child complains of pain in the belly, but an examination of the abdomen gives entirely negative signs. There is no tenderness of the parietes, or pseudo-fluctuation; no caseous lumps can be felt; and the belly, although full, may not exhibit any remarkable swelling The child looks ill, and is languid; his appetite is poor, and his evening temperature is higher than natural. Often, his bowels are relaxed. These symptoms, as in all forms of acute tuberculosis, succeed to a period more or less prolonged, of general but indefinite malaise. After an illness lasting a few days or a week or two, the child dies, with or without the symptoms of meningitis. After death, his bowels are found matted together with recent lymph; there is perhaps, a little thin purulent fund in the peritoneal cavity, and the signs of general tuberculosis are discovered over the body. In most cases, the existence of the peritonitis is only revealed by post-worten examination.

A boy, aged four years, was under the care of my colleague, Dr. Donkin

in the East London Children's Hospital. The child was said to have been ill for two weeks. He had first complained of pain in the belly, which was full and distended, and his bowels were relaxed. The pain was attributed by the mother to wind, for it was reheved by hot grog. The looseness of the bowels ceased after a day or two, but the boy remained weak and listless; his feet swelled a little when he sat up, and his face was noticed to be puffy in the mornings. For two or three days before admis-

sion he had had a slight cough.

When the boy came into the hospital his face was a little puffy about the eyelids and bridge of the nose. The heart and lungs appeared to be normal. His belly was distended, but there were no dilated superficial veius; no dulness was noted on percussion in either flank; no enlarged glands or fluctuation could be detected; no pain or tenderness was com-plained of; and the liver and spleen were of normal size. There was a little odems of the scrotum, but none of the lower limbs. His urine was scanty, but there was no albumen. Pulse, 88, regular; temperature, 98°; respirations normal. After a few days, as the temperature was natural, and the boy was up and about and seemed convalescent, there was a question of sending him home. Before this could be done, however, a sudden change took place in his condition. He became very drowsy, and was forced to return to his bed. He then began to vomit; his pulse was 80 and intermittent: his temperature rose again, and he seemed at times to be only half conscious. Three days after his return to his bed, the boy had an attack of convulsions; his temperature went up to 108', and he died. On examination of the body, there was found a basic meningitis with many gray granulations in the cranium. Similar granulations were seen on the pleure. The peritoneum, both parietal and visceral, was profusely studded over with gray and yellow granulations, varying in size from a pin's head to a pea; and there was much recent lymph, which had matted together the coils of intestine, and fixed them with the omentum to the abdominal wall. There was no excess of fluid in the peritoneal cavity.

Such a case is very perplexing. The only symptoms pointing to the ablonum are the abdominal swelling and pain; but these alone, in the absence of tension and tenderness of the parietes, or other equally characteristic symptom, are insufficient to establish the diagnosis of peritonitis. Pain in the belly is a symptom so frequently met with in the child that its occurrence excites little remark; and a large belly in young subjects is not sufficiently uncommon to attract special attention. Still, if we are aware that the illness may run this rapid course, such symptoms, taken in connection with the general weakness, the slight ordems without albuminums, and the terminal mainfestations of cranial disease, may justify us in

at least suspecting the existence of the abdominal complication.

Duquesis. In ordinary cases, the diagnosis of tubercular peritonitis is easy. Inflammation of the peritoneum developing slowly and inadiously, accompanied by rapid wasting and a very variable temperature, and preceded by general impairment of nutrition and abdominal pain, is very suspicious of tubercle. We must remember that tenderness and tension of the abdominal wall may be little pronounced, and that fluctuation is often absent, or, if present, is usually imperfect and indistinct. A definite tap realily transmitted through the fluid from one side of the abdomen to the other, although met with in rare cases of tubercular peritonitis, is yet not at all characteristic of this disease. Indeed, if such free fluctuation be present in a child who is lively and fairly active, it tells rather against than

in favour of the diagnosis. In doubtful cases, it is desirable to test the effect of a sudden jar upon the child. If he be made to jump down to the ground from a low chair, and experience no uneasiness from the little shock, it is improbable that the peritoneum is inflamed. A child with abdominal tubercular disease is invariably dull and hatless from the carliest period of the disease. He looks ill from the first; and although he may be fairly stout, there are usually signs that his nutrition is already impaired. These symptoms are of great importance when combined with abdominal pain, swelling, and tenderness. Chronic digestive derangements are common in early life, and I have known children who have been habitually overfed with farmaceous food, to be subject for months together to attacks of abdominal pain, often of great severity. But such children are lively and active enough; although pale and often flabby, they do not look ill; they have not the careworn, haggard expression which is almost inseparable from serious disease at every period of life; and although the abdomen may be full and sometimes punful, the fulness is variable, often subsiding completely; there is no tenderness or involuntary tension of the parietes, and the temperature is that of health. Such cases are easily cured. Limiting the consumption of farmaceous matters, a gentle aperient, and an alkaline aromatic mixture, will soon put an end to the indisposi-

The acute form of tubercular peritonitis is often puzzling, especially if, as in the case referred to above, the abdominal symptoms are limited to some swelling and pain. In such a case, typhoid fever is often suspected, and the pyrexia, wasting, and increasing weakness may seem to give strength to this opinion. No evidence is to be derived from the state of the bowels; for whether confined or relaxed, either condition is perfectly compatible with enteric fever. Even if more distinct evidences of performing occur, these may be attributed to perforation and consequent influmnation. Still, the absence of rash and of splenic enlargement, the comparatively moderate pyrexia, and the more baggard aspect of the patient are not in favour of typhoid fever; and if fluctuation can be detected in the abdomen, or slight uslema of the legs and face is noticed, this disease may be at once excluded.

Prognosis.—Tubercular peritonitis is not invariably fatal, and therefore we should not at an early period of the illness act as if the case were a hopeless one. Tension and tenderness are important symptoms, and if the child lies in one position, with his knees raised, apprehensive of the least movement, the sign is not of favourable import. A profuse diarrhead or the passage of stools indicating ulceration of the bowels must be viewed with apprehension. If the tenderness is extreme, and solid tubercular masses can be felt underneath the abdominal parietes, recovery, although possible is very unlikely. Also, the presence of signs indicating tubercular disease of other organs is of course to be taken as of serious omen.

On the other hand, increased regularity in the stools, improvement of appetite, reduction of pyrexia, diminution or subsidence of abdominal tenderness, and return of cheerfulness are all encouraging signs. We must remember, however, that alternations of improvement and relapse are common in this disease, and that recovery, although not exactly uncommon, is, at any rate, an exceptional termination to the illness.

Treatment.—Absolute rest, hot applications to the abdomen, and opium internally, form the most useful means at our disposal for promoting the subsidence of the disease. The child should be put to bed, and his belty should be kept covered with hot linseed-meal poultices, frequently re-

acwed. If the weight of these be complained of, and there is much pain and tenderness, great relief is often derived from smearing the surface with a salve composed of extract of belladonna and glycerine in equal proportions, and covering this with a thick layer of cotton-wool. The child should take a draught containing a few drops of laudanum every night, and if his stomach will bear it, cod liver oil may be administered. Diarrhora should be treated with full doses of bismuth and a drop or two of timeture of opium two or three times a day; or three or four grains of extract of harmatoxylum may be combined with three drops of laudanum and three of ipecacuanha wine in a chalk mixture for a draught to be taken several times in the twenty-four hours. Purging will also be relieved by a small injection of starch and laudanum, given at night. If there be constipation, it is better to avoid aperients and trust to injections to relieve the bowels. When necessary, the accumulation can be cleared away by a good enema of soap and warm water.

The diet of the child should be regulated to suit his powers of digestion. Strong beef-ten and other broths, milk, yolk of egg, minced mutton or chicken, fish, bread and butter, and light pudding should be given. But great attention should be paid that excess of farinaceous matter is not allowed, as acidity and flatulence will increase the discomfort of the patient and be decidedly injurious. A stimulant is required as the strength begins to fail. The brandy-and-egg mixture of the British Pharmacoposia

the best form in which this can be administered.

CHAPTER XIV.

ASCITES.

As accumulation of fluid is sometimes met with in the peritoneal cavity in the child as a result of various causes, and it is not always easy to refer the symptom to its true origin.

Consulton.—In childhood, as in after life, ascites may be the consequence of peritoneal inflammation; of obstruction to the flow of blood through the portal vein; and of causes which influence the systemic circulation.

In peritonites the quantity of fluid is rarely great, and sometimes it is so small that it is with difficulty detected. Even in the subacute pentenites which is the result of tuberculous of the serous lining of the abdomen, there is rarely great excess of fluid. In both cases, the symptoms connected with the belly may be so little characteristic that the disease passes com-

pletely unnoticed, and is only discovered after death.

The circulation of blood through the portal vein may be obstructed by causes which act within the liver substance or affect the venous channel before its entrance into the organ. Cirrhosis of the liver may cause great impediment to the portal circulation; and there is every reason to behave that this form of disease is less uncommon in the child than was at one time supposed. So, also, hepatic induration resulting from congestion of the organ may be attended by the same result. A hydatid of the liver, if placed near to the concave surface of the gland, may cause sufficient interference with the flow of blood from the abdominal viscera to lead to scrous effusion. In the rare cases in which the liver is the seat of a malignant disease, ascites may also occur; and I have known it to be produced by syphilitic gummata of the liver in a young baby.

Of causes lying outside the liver, the most common is the presence of a mass of caseous glands in the hepatic notch. This will press upon the pertal vein as it enters the transverse fissure. Pressure may also be exercised upon the vein by malignant or lymphomatous growths of the mesentery.

but these are very rurely met with.

Of the causes which act through the general circulation, heart disease takes the first place. It is common in cardiac lesions to find ascites combined with general ordema, and very often serosity is poured out, not only into the peritoneum and subcutaneous tissue, but also into the pleural cavity. Disease of the lungs seldom gives rise to ascites in young subjects; and in cases of Bright's disease, although general dropsy is common, abdominal effusion is more rarely seen. Extreme assemia is sometimes attended by ascites, but this is not a frequent result of mere impoverishment of blood.

Symptoms.—In a marked case of ascites, the belly is distended and globular. As the child lies on his back the outline of the abdomen is more rounded than in the erect position, for the fluid gravitates and tends to collect in the flanks and swell them out. The skin of the belly is smooth and shining, and may be tense. The umbilious is generally prominent, and often

the superficial veins of the abdominal wall are unnaturally visible. When the observer places his hands one on each side of the belly, a slight tap of the finger sends a distinct impulse through the fluid to strike against the hand in contact with the opposite wall of the abdomen. This sense of fluctuation is not stopped by pressure made in the middle line of the belly.

On percussion, the note is clear over the upper part of the belly, and dull in the flanks. The dulness varies according to the position of the child, as the fluid always sinks to the most depending part of the abdominal cavity. Consequently, the side turned uppermost always gives a resonant note. If the amount of fluid be very large, the dulness may be general, except, perhaps, over the region of the stomach and transverse colon. In such cases there is usually dyspiness from interference with the action of the diaphragm; and this is often so distressing that the child cannot lie down in his bed. It may be accompanied by a certain amount of collapse of the bases of the lungs. The pressure of the accumulated fluid may also set up ordern of the lower extremities and genitals, and this quite irrespective of cardiac disease.

In ascites, although excess of fluid will excite discomfort and distress, there is seldom actual pain unless the peritoneum be inflamed. Still griping pains may be sometimes complained of. These are due probably to the interference with digestion set up by the congested state of the gastric and intestinal mucous membrane. For the same reason, looseness of the bowels is a not uncommon symptom. The appetite is often good; the tongue is usually clean; and, in non-inflammatory cases, the temperature is that of health. Often the skin is dry and the secretion of urine scanty, high-

boloured, and perhaps albuminous.

Other symptoms may be present, according to the disease of which the peritoneal effusion is the consequence. If there be peritoritis, the temperature is generally elevated, and, in ordinary cases, there is tenderness of the belly with abnormal tension of the wall. We must not, however, always expect such definite signs. As described elsewhere, peritonitis, like pleurisy and pericarditis, may be completely latent, accompanied by none of the characteristic phenomena by which its presence is usually revealed. In peritoratis the amount of fluid is small, as a rule; and fluctuation is often for from being distinct. A scanty secretion may gravitate into the pelvis and thus escape detection on superficial examination; or may be retained in the coils of intestine by adhesion of the coats of the bowel to one another. Evidence of fluid may, however, be often obtained by placing the Duparcque. The effusion will then gravitate into the undermost flank. Afterwards, by turning the child quickly on to his back and examining the region lately depending, dulness and signs of fluctuation will be often disgovered before the fluid sinks away again from the surface. Another plan is to place the child upon his elbows and knees; the fluid then gravitates to the umbilical region and gives the usual evidence of its presence.

In cases of hepatic cirrhosis, the peritoneal effusion is usually copious, and fluctuation very distinct. The spleen, in these cases, is often enlarged; signs of digestive disturbance are noted; the skin, in advanced cases, has an earthy tint, or may even be jaundiced; the veins of the abdominal wall, especially in the umbilical region, are unnaturally prominent; and signs of dilated haemorrhoidal veins, even in young subjects, may be

cometimes detected.

When the ascrites is due to cardiac disease, there is general anasarca; the hps are bluish and the complexion livid; the jugular reins are full

and pulsating, and often fill from below; the breathing is oppressed. The urme is scanty and albuminous; effusion into the pleural cavities may be perhaps discovered, and an examination of the heart at once reveals the

cause of the obstructed circulation.

Thurpoons. - A large belly is no sign of ascites. The abdomen in a young child is always relatively large as compared with the rest of Lis body; and if the child be the subject of rickets, or be injudiciously fed, or suffer from looseness of the bowels, the disproportionate size of his belly is still further exaccerated. Flatulence is the commonest cause of abdominal distention in the child, and the increase in size from this reason is sometimes so great as to excite serious alarm in the minds of the parenta It is very common in rickety children who habitually suffer from derangement of the bowels and consequent fermentation of food. In this distress, the flatulent distention is rendered more conspicuous by the relaxed state of the abdominal muscles and the shallowness of the pelvis. Often, in these cases, on palpation of the belly, an indistinct sense of fluctuation may be felt between the hands, placed on either flank. This is conveyed through the distended bowels. It is distinguished from the impulse conveved by a wave of fluid by the effect upon it of pressure made in the middle line of the abdomen. If fluid be absent, the tap of the finger will then at once cease to be felt by the hand placed on the opposite side of the belly.

Enlargement of the abdominal organs may also determine the distention of the belly. Congestion, amyloid and fatty degenerations, hydatid disease, and hypertrophic currhosis of the liver; a spleen enlarged from amyloid disease, rickets, or ague; a kidney the seat of surcoma or hydronephrosis; cancerous or lymphomatous growths from the omentum or abdominal glands—in all these cases the size of the belly may be increased.

The only test of ascites is the presence of fluctuation. Thus, if the amount of fluid is small, can often be obtained by placing the patient in such a position that the fluid may gravitate to the surface and thus be brought within reach of the fingers. It is not enough, however, to detect the presence of ascites. We have to ascertain, if possible, the cause to which this excess of fluid is owing. If the symptoms of the determining disease are well marked, the diagnosis may be easy. If, however, the symptoms are obscure, the case may present great difficulty, and often it is impossible to arrive at a positive conclusion.

A little girl, aged seven years, of healthy parentage, was a patient in the East London Children's Hospital. The child had passed through measles and whooping-cough, and between two and three years previously had had an attack of scarlatina which was followed by dropsy; but this had been completely recovered from. There was no rheumatic tendency in the family, and the girl herself had never suffered from rheumatic pains, but

she was said to be subject to bilious attacks.

Six weeks before her admission she had begun to complain occasionally of feeling cold, and used to come back from school saying she had a headache. She also occasionally complained of pains in the right side of the abdomen, and sometimes vomited. After these symptoms had continued for a fortnight, the pains became more severe and paroxysmal, and the belly begin to swell. From that time she lost flesh. Her appetite had been pretty good, and the bowels usually regular; but she had had two or three attacks of diarrhose, lasting on each occasion twenty-four hours for two or three days before admission she had had attacks of shivering.

When first seen, the girl was in fair condition, and, although pale, bad

no distressed expression of face. Her lips were pink. There was no yellowness of the selerotics. The skin was a little dry, but not harsh or rough. The belly was very full and tense-looking. Its girth was 274 inches. It fluctuated freely, and the veins of the parietes were unusually visible. The lower edge of the liver could not be felt; its upper border was in the fourth interspace. The spleen was estimated by percussion the child lying on her right side) to reach from the seventh to the ninth into There was no tenderness of the belly. The heart's apex was between the fifth and sixth ribs, and the precordial dulness reached upwards to the second rib. On auscultation, a distinct rub was heard with the systole and between the two sounds at the mid-sternal base. The lungs were healthy, except for a little sub-crepitant rhonchus at the bases, which disappeared in a great measure after a cough. The child was thirsty, but had little appetite; her tongue was clean and rather red. Pulse, 128; very intermittent, weak and soft. Her bowels acted regularly every day, and the motions had a natural appearance. The urine was very clear and pale. It was acid; had a density of 1.015, and contained no albumen or bile pigment. The temperature on the morning after admission was 103°.

During the next three weeks the temperature continued to be febrile; the physical signs in the chest became more developed, and the child passed through a well-marked attack of pericarditis with effusion. As the pericardial fluid became absorbed, the ascitic effusion began also to disappear and the abdomen to diminish in size. In four weeks from the time of admission, the child was convalescent and was discharged. About a month afterwards she was readmitted with an attack of well-marked enteric fever. It is curious that during this illness the ascites and pericarditis both returned; but they subsided again, as before, during convalescence from the fever. Eventually, the girl recovered her health convalescence from the fever.

pletely.

The cause of the ascites in this case is not very clear; but the absence of all symptoms pointing to the liver, combined with the natural size of the spicen, seemed to exclude cirrhosis. The history suggested peritonatis, and although the characteristic features of this disease were absent, such absence is occasionally observed. Taking into account the previous symptoms, the high temperature, the occurrence of pericarditis as if from extension of the inflammation, and the completeness of recovery, this view would seem to furnish the most probable explanation of the child's illness.

In some cases fluid may be present in the abdomen from other causes than ascites. Thus, a large hydronephrosis which almost completely fills up the cavity of the belly, may be accompanied by free fluctuation, evidently due to fluid; and it may not be easy to distinguish this condition from a copious peritoneal effusion. On careful examination, however, it will be usually found that in hydronephrosis the swelling of the abdomen is not quite symmetrical, but that the flank on one side shows a greater prominence than on the other. The resistance is also greater over the site of the greatest bulging; and although, as the child lies on his back, the umbilious is absolutely dull, a spot can often be discovered in the less prominent flank where a clear percussion-note is obtained. Lastly, tapping the swelling will withdraw a fluid containing urea.

Progress In cases of ascites, the child's prospects depend less upon the amount of fluid offused into the abdominal cavity than upon the cause of the phenomenon and the general symptoms by which the effusion is accompanied. Causes which affect the system generally, or impede the flow of blood through the portal vein as a consequence of obstruction to

the general circulation, are especially to be feared. Thus, ascites from tubercular peritonitis, or from heart disease, is a symptom of serious import. In all cases, the prognosis depends chiefly upon the pathological condition which has occasioned the escape of serosity. If this cannot be discovered, we must judge of the prognosis by remarking the state of the child's strength, his temperature, and his pulse; and by noting the degree of efficiency with which the skin and the other emunctories of the body are performing their functions. The skin in particular is an important guide. If the temperature is not elevated, the urine non-albuminous and of normal density, and the skin of natural tint, and neither dry nor harsh, we may speak favourably of the child's chances of recovery.

Treatment — The treatment of ascites is dependent upon the illness in the course of which the symptom has arisen. If peritonitis (simple or tubercular) be present, the special measures recommended in the chapters relating to those discuses must be resorted to. If the ascites form a part of general dropsy dependent upon heart disease, it will be relieved by the diureties purgatives, and cardiac tonics and stimulants which are found

efficacious in that serious condition.

In cases of ascites of obscure origin, or dependent upon disease of the liver, iron and other tonics have often a marked influence in reducing the amount of fluid in the peritoneum and improving the general condition of the patient. The exsiccated sulphate of iron is well borne by children, and may be given three times a day, in doses of five grains, to a child of three or four years of age. The uncture of the perchloride of iron with quinne is also useful; but whatever form of chalybeate is used, the dose should be a large one. Violent purgatives are to be avoided, but constipation must be treated by suitable doses of compound laturate powder, compound jalap powder, or, if at the beginning of the treatment, by a grain of calomel followed by a saline. The action of the skin must be maintained by a daily tepid or warm bath; and the child should be dressed in woollen underclothing from head to foot.

If the accumulation of fluid be copious, paracentesis should be performed without hesitation; and it is now generally held that promptness in the performance of this operation is to be preferred to delay. The diet of the child, as in all forms of chronic disease, should be arranged according to the state of his digestion; and a watch should be kept over his capacity for digesting starch, sugar, and all forms of fermentable food. An excess of such matters would encourage flatulence, and coheky pairs.

and must therefore be avoided.

CHAPTER XV.

INTESTINAL WORMS.

Or the many varieties of parasitic worms which infeat the alimentary canal in childhood, three only are of special practical importance from giving rise to disturbance or distress. These are:—The small thread-worm, the long round-worm and the tape-worm. There is one other, the large thread-worm (tricocephalus dispar), which is also occasionally met with; but the creature seems to give rise to no symptoms, and is only discovered

by its presence in the stools,

Description. - The small thread-worm (oxyuris vermicularis), often called seat-worm, belongs to the order nematoda. To the naked eye, these worms have the appearance of fine white threads. Both female and male specimens exist together, the former being the larger. In both sexes the anterior part of the body is of fusiform shape. It is narrowed towards the head, which is abruptly truncated and provided with three tubercles. The male is one-sixth of an inch in length. Its intestinal tube extends the whole length of its body, and terminates in the anus at about the middle of the tail The tail is arranged in a spiral form. The penis is minute and hook-shaped. The female measures nearly half an inch in length. Its body ends in a long tapering tail, which is three-pointed at the end. Under the microscope its uterine ducts can be seen to contain a multitude of ova. The eggs are long and unsymmetrical. They may be readily hatched by exposing them to the sun in a moistened paper envelope, as in the experiments of Vix and Leuckart. When this is done, tadpole-shaped embryos escape at the end of five or six hours, and rapidly develope into slender worms. It appears from the researches of Leuckart and Heiler that the embryos can escape from the ova in the human body. Heller states that their liberation takes place in the stomach under the influence of the gastric juice. From the stomach the creatures pass into the duodenum and upper bowel, growing rapidly as they descend the alimentary canal; and by the time they reach the cocum have arrived at sexual maturity.

According to Dr. Cobbold, the esecum is the customary habitat of these parasites; but they have a tendency to migrate, especially into the sigmoid discurse and lower rectum, and can often be seen moving about in the

folds of the anus.

The long round-worm (ascaris lumbricoides), often called lumbricus, is a large nematode worm of a yellowish red colour. The female is fifteen inches, and the male ten inches in length. The body is cylindrical, tapering to either extremity, but more rapidly towards the head. The mouth is triangular, having three lips. It is armed with numerous (about two hundred) microscopic teeth. The alimentary canal is simple, without division between stomach and intestine. The tail is conical and pointed. In the male it is curved like a hook towards the ventral aspect of the body; in the

female it is straight. The eggs, which are excessively numerous in each female specimen, are oval in shape, and have a thick, firm, clastic, brownish shell, which is usually nodulated on the surface. In these ova, the embryos develope very slowly, for Davaine kept some alive for five years without perceiving any attempt of the immature tenants to escape from the shell. These embryos have a curious tenacity of life, for they cannot be destroyed by frost or complete desiccation. It has been doubted whether the eggs can be hatched, and the embryos escape and pass through their developmental stages to maturity, in the alimentary canal of the subject infested with them. It appears, however, from the researches of Heller that this is possible.

The lumbricus inhabits the smaller bowel, but is migratory in its habits, and has a peculiar tendency to wander. The worms have been consequently found after death in very curious places. They have been seen in the usual passages; in the larynx and bronchi; in the ducts of the liver and pancreas; in the gall-bladder, and even in the cavity of the peritoneum, and in the interior of abscesses communicating with the abdomen. The worm has no power of penetrating the living tissues, but can pass through an ulcerated surface. Thus, it has been known to pass through an ulcerating lesion of the vermiform appendix, and set up peritonitis by entering the cavity of

the abdomen.

The tape-worm is a flat, jointed worm which belongs to the order cestoda. Several varieties of this parasite may be found in the human subject. The most common is the tania medio-cannellata (the beef tape-worm). The tania solium (the pork tape-worm) is also met with. The bothriocephalus latus, another species, is not common in the British Islands, although it is less rare on the continent of Europe. There are other varieties, but these,

as they are very seldem seen, need not be here considered.

All these worms are flat, segmented creatures, destitute of mouth or alimentary canal. They grow from the head, which developes a continuous linear series of new joints by a budding process. The joints are quadrilateral in shape. They are at first immature, but as their distance from the head increases, they become larger and more developed. Strictly speaking, the tape-worm is not a single parasite, but a community of individually distinct creatures, of which only the lower or older members (proglottides) are sexually complete. These contain each their own organs of

generation, both male and female.

Between the T. medio-cannellata and the T. solium, the difference is chiefly in the shape of the head. In each, the neck is tapering and thread-like, and about an inch in length. This passes gradually into the anterior part of the body, which is sexually immature, and is not distinctly jointed. By degrees the transverse lines, which mark the imperfect divisions of the young segments, become more defined and more widely separated, so that, while the more recent segments, or those nearest to the neck, are much wider than they are long, the older joints, as they become more and more mature, grow to be much longer than they are broad. Each mature segment (or proglottis) is about half an inch long by a quarter of an inch broad. It contains an elongated, tubular uterus, branched on either side; and the male and female organs of generation open by a common perforated papilla, which is placed at the border below the middle line, on one side or the other, but not in regular alternation. In a worm eight feet long, the total number of joints has been reckoned at about eight hundred; but it is not until near the four hundred and fiftieth segment from the head that the joints begin to be sexually mature. The head is globular, and

about the size of the head of a small pin. In the T. solium, it forms in front a short cylindrical proboscis (rostillum) having four projecting suckers decorated by a crown of twenty-six hooklets. In the T. medic-cannellata there is no crown of hooklets or proboscis; but the suckers are large and prominent, and there is usually a fifth smaller one in the ordinary position of the rostillum.

These worms often grow to a great length and may measure many yards. They infest the small intestine and may number one or more in the same subject. The eggs, which are very numerous, lie in the uterine ducts of the mature segments; and each contains an embryo which, in the

case of the trenia solium, is furnished with three pairs of hooklets.

The mode of development of the creature is as follows: The tenia, unlike the other worms which have been described, does not pass through all the stages of its growth from the ovum to maturity in the body of the same individual, for the embryo does not develope directly into the perfect worm. There is a transitional stage which requires to be completed in the body of an intermediary. This agent is usually an animal. Thus, when a ripe joint filled with ova is eaten by an animal, it passes into the stomach. There, the eggs are ruptured, and the embryos (pro-scolices) escape. These embryos have a tendency to perforate the tissues of the animal by whom they are harboured. They may thus make their way into the cellular tissue of a muscle, into the liver or the brain. Thus sheltered, they pass through a metamorphosis, and become the cysticercus or bladder-worm. The cysticercus cellulose of pork consists of a cyst-like body, with a head and neck like those of the fully-developed worm. These are usually inverted within the body. As long as the cysticercus is unmolested it undergoes no further change; but when the flesh of the animal is eaten imperfectly cooked, so that the vitality of the cysticercus is uninjured, the creature at once adapts itself to its new situation, and attaching itself to the wall of the small intestine, developes in the course of a few months into the perfect tape-worm.

The bothriocephalus latus, in its general appearance, resembles the two varieties of terms just described, but is rather larger and may grow to a greater length. The mature joints are broader than they are long, and the sexual openings are placed, not at the side of the segment as in the terms, but in the middle of the joint, where they appear as rosette-shaped patches. This tape-worm, like others, has an intermediate or larval stage; and it had long been suspected that its ciliated embryo found shelter in the body of some aquatic animal. Dr. Braun, of Dorpat, has lately found the early asexual form of the bothriocephalus encapsuled in the intestine of the pike, and also in some of the muscles, in the liver, and in the spicen of the same fish. Dr. Braun gave these organisms experimentally to dogs and cats, who were put on a strict diet and allowed only distilled water for drunk. As a consequence, segments of the bothriocephalus began quickly to appear

in the freces of the animals.

Causation. The means by which thread-worms gain access to the human body, is by the direct passage of the ovainto the mouth. The eggs are often introduced clinging to fruit, cresses, and various articles of food. But they may also be directly conveyed to the mouth by the patient humself. It has been said that the embryo is liberated from the egg in the child's stomach by the action of the gastric junce upon the ovum. It has been also stated that each individual female worm contains in itself a multitude of eggs which pass out in large quantities with the stools. The embryos are probably not liberated from the ovain the bowels; but if the

eva are re-introduced into the alimentary canal by the mouth, they become exposed to the action of the gastric juice in the stomach, and their contents may be set free. According to Dr. Cobbold, children frequently carry the eva under their nails; for the irritation to which the presence of the oxyures gives rise, obliges them to seek relief by scratching. In this way the eggs may be transferred directly to the mouth.

The ova of the lumbricus appear to be imported through the medium of impure water. This parasite is said to be especially common in low-

lying, marshy districts.

In the case of the tape-worm, it is through the eating of imperfectly cooked flesh infested with the cysticercus that an individual becomes the unwilling harbourer of the parasite. The terms solium is derived from measly pork; the temia medio-canellata from beef. In children who suffer from a chronic looseness of the bowels, and are consequently fed with

pounded raw meat, tape-worm is occasionally met with.

Symptoms.-The most varied symptoms have been ascribed to the presence of worms in the bowels. Most of these are doubtless due to the intestinal derangement from which the patient is commonly suffering. That they are not a necessary consequence of the visits of these parasites is shown by the fact that it is not rare for the creatures to be found in the stools of children who have not previously exhibited any sign of discomfort or distress. In these cases, the worms are usually few in number, and can be readily got rid of by the administration of an ordinary aperient. It seems necessary for the extensive propagation of the entozoa that a catarrhal condition of the bowel should be present. In the secreted mucus the embryos find a favourable medium for development, and if, as often happens, the flux be profuse, great difficulty may be experienced in freeing the patient from these irritating pests. It is in such cases only that severe general symptoms are found; but these, as has been said, are to be rightly attributed, not to the parasites, which may be looked upon as accidental complications, but to the unhealthy state of the alimentary mucous numbrane, which hinders digestion and impairs the nutrition of the body. These symptoms are described elsewhere (see page 121), and need not be here repeated. There are, however, many special symptoms which are attrabuted directly to the presence of worms; and as they are not necessarily the consequence of the intestinal derangement referred to, and often cease when a number of worms have been expelled, it is possible that they are really due to the irritation set up by the creatures in the bowels.

Most of these special symptoms will be referred to in describing the particular symptoms produced by the several species of worm. It may, however, be stated in this place, that every variety of nervous symptom, from headsche, and other disorders of sensation, to spasm, paralysis, and convulsions, has been found associated with the presence of worms in the alimentary canal. Some of these have been looked upon as pathognomonic. Thus, Dr. Underwood held that an attack of convulsions, accompanied by small pulse and hiccough, was an almost certain sign of worms. Monro was of opinion that unequal dilatation of the pupils pointed positively to the same conclusion. Others have relied upon the rapidity and irregularity of the pulse as furnishing sufficient grounds for the diagnosis. It cannot be denied that these symptoms may be noticed in children suffering from intestinal worms, and may possibly be produced by them; but similar symptoms are found in cases where careful observation fails to dis-

cover any sign of the creatures or their ova in the stools.

There is one symptom which, although not positively distinctive of the

irritation of worms in the bowel, renders the presence of the parasites highly probable. This symptom is a peculiar appearance of the tongue. In all cases where the bowels are the seat of a nucous flux, the tongue gives evidence of this condition. It is flabby, and indented at the edges by the teeth. The nucreased secretion of mucus in the mouth gives to the tongue a slimy, gummy appearance. The lingual surface is covered with a thin coating of gray for, and the fungiform papillie at the sides of the dorsum peer through the fur as round or oval spots, which are more or less red, according to the degree of urntability of the stomach. In cases where worms are present, I have often remarked a peculiar fawn colour of the fur covering the dorsum, and the slimy appearance of the organ has been especially noticeable.

A child may be infested by more than one variety of worm at the same time. It is not uncommon to find round-worms together with threadworms; and sometimes round-worms and tape-worms are present at the same time in the same subject. Thus, a little boy, aged one year and eight months, was under my care for tape-worm, from which he had been suffering for three months. This child, on one occasion, passed a large round-

worm and many joints of the tenia in the same stool

In the case of thread-worms, the patient seldom complains of abdominal pun, but the irritation set up in the rectum by the presence of the entozoa gives rise to a troublesome itching of the fundament, which in sensitive children may cause an extreme degree of suffering. This irritation comes on towards the evening, and at night may be so distressing that sleep is greatly interfered with. In some cases, in addition to the itching, shooting pains may be complained of in the same part. Catarrh of the rectum is not uncommon in such subjects. There may be looseness of the bowels, and the evacuations are often discharged with straining efforts. They may be followed by prolapse of the rectum. The stools often contain glairy mucus, and sometimes blood in streaks, or even clots of considerable size. Difficulty in emptying the bladder may be a consequence of the irritation, and the child sometimes holds his water for many hours together. Itching of the nose, a leaden tint of the lower cyclid, and swelling of the upper lip, are also very common symptoms when thread-worms are present.

The worms are readily detected as white moving threads in the stools, and may be seen in the folds of mucous membrane about the anus. They may pass or be conveyed into the vagina in little girls; and can often be discovered in the bed-clothes. A microscopic examination of the stools

usually discovers a multitude of ova.

The lumbricus, on account of its large size and its habits of nocturnal activity, is a cause of considerable irritation. This worm is said frequently to give rise to nervous disorders in the child; and cases have been recorded in which severe headache, photophobia, choreic movements, convulsions, and even profound come have ceased on the expulsion of a number of these creatures. It is difficult to say what share the worms take in the production of such symptoms. Probably some additional cause is in operation, for in rickety children, whose tendency to convulsions and other forms of nervous disturbance is one of the most characteristic consequences of that phase of general malnutration, I have not noticed that the presence of the long round-worm is especially liable to be accompanied by celamptic seizures. Probably, in most cases where nervous symptoms are associated with intestinal worms, the nervous disturbance is quite independent of any irritation produced by the worms in the bowels. It is common enough for children who are suffering from undoubted disease of the nervous centres

ova are re-introduced into the alimentary canal by the mouth, they become exposed to the action of the gastric juice in the stomach, and their contents may be set free. According to Dr. Cobbold, children frequently carry the ova under their nails; for the irritation to which the presence of the oxyures gives rise, obliges them to seek relief by scratching. In this way the eggs may be transferred directly to the mouth.

The ova of the lumbricus appear to be imported through the medium of impure water. This parasite is said to be especially common in low-

lying, marshy districts.

In the case of the tape-worm, it is through the eating of imperfectly cooked fiesh infested with the cysticercus that an individual becomes the unwilling harbourer of the parasite. The trenia solum is derived from measly pork; the trenia medio-canellata from beef. In children who suffer from a chronic looseness of the bowels, and are consequently fed with

pounded raw meat, tape-worm is occasionally met with.

Symptoms.—The most varied symptoms have been ascribed to the presence of worms in the bowels. Most of these are doubtless due to the intestinal derangement from which the patient is commonly suffering. That they are not a necessary consequence of the visits of these parasites is shown by the fact that it is not rare for the creatures to be found in the stools of children who have not previously exhibited any sign of discomfact or distress. In these cases, the worms are usually few in number, and can be readily got rid of by the administration of an ordinary aperient. It seems necessary for the extensive propagation of the entozoa that a catarrhal condition of the bowel should be present. In the secreted mucus the embryos find a favourable medium for development, and if, as often happens, the flux be profuse, great difficulty may be experienced in free-ing the patient from these irritating pests. It is in such cases only that a vere general symptoms are found; but these, as has been said, are to be rightly attributed, not to the parasites, which may be looked upon as accidental complications, but to the unhealthy state of the alimentary mucous membrane, which hinders digestion and impairs the nutrition of the body. These symptoms are described elsewhere (see page 121), and need not be here repeated. There are, however, many special symptoms which are attubuted directly to the presence of worms; and as they are not necessarily the consequence of the intestinal derangement referred to, and often cease when a number of worms have been expelled, it is possible that they are really due to the irritation set up by the creatures in the bowels.

Most of these special symptoms will be referred to in describing the particular symptoms produced by the several species of worm. It may, however, be stated in this place, that every variety of nervous symptom, from headache, and other disorders of sensation, to spasm, paralysis, and convulsions, has been found associated with the presence of worms in the alimentary canal. Some of these have been looked upon as pathognomonic. Thus, Dr. Underwood held that an attack of convulsions, accompanied by small pulse and hiccough, was an almost certain sign of worms. Monro was of opinion that unequal dilatation of the pupils pointed positively to the same conclusion. Others have relied upon the rapidity and irregularity of the pulse as furnishing sufficient grounds for the diagnosis. It cannot be demed that these symptoms may be noticed in children suffering from intestinal worms, and may possibly be produced by them; but similar symptoms are found in cases where careful observation fails to dis-

cover any sign of the creatures or their ova in the stools.

There is one symptom which, although not positively distinctive of the

irritation of worms in the bowel, renders the presence of the parasites highly probable. This symptom is a peculiar appearance of the tongue. In all cases where the bowels are the seat of a mucous flux, the tongue gives evidence of this condition. It is flabby, and indented at the edges by the teeth. The increased secretion of mucus in the mouth gives to the tongue a slimy, gummy appearance. The lingual surface is covered with a thin coating of gray for, and the fungiform papills at the sides of the dorsum peer through the fur as round or oval spots, which are more or less red, according to the degree of irritability of the stomach. In cases where worms are present, I have often remarked a peculiar fawn colour of the fur covering the dorsum, and the slimy appearance of the organ has been especially noticeable.

A child may be infested by more than one variety of worm at the same time. It is not uncommon to find round-worms together with threadworms; and sometimes round-worms and tape-worms are present at the same time in the same subject. Thus, a little boy, aged one year and eight mouths, was under my care for tape-worm, from which he had been suffering for three mouths. This child, on one occasion, passed a large round-

worm and many joints of the tania in the same stool.

In the case of thread-worms, the patient seldom complains of abdominal pain, but the irritation set up in the rectum by the presence of the entozoa gives rise to a troublesome itching of the fundament, which in sensitive children may cause an extreme degree of suffering. This irritation comes on towards the evening, and at might may be so distressing that sleep is greatly interfered with. In some cases, in addition to the itching, shooting pains may be complained of in the same part. Catarrh of the rectum is not uncommon in such subjects. There may be looseness of the bowels, and the evacuations are often discharged with straining efforts. They may be followed by prolapse of the rectum. The stools often contain glairy mucus, and sometimes blood in streaks, or even clots of considerable size. Difficulty in emptying the bladder may be a consequence of the irritation, and the child sometimes holds his water for many hours together. Itching of the nose, a leaden tint of the lower eyelid, and swelling of the upper lip, are also very common symptoms when thread-worms are present.

The worms are readily detected as white moving threads in the stools, and may be seen in the folds of mucous membrane about the anns. They may pass or be conveyed into the vagina in little girls; and can often be discovered in the bed-clothes. A microscopic examination of the stools

usually discovers a multitude of ova.

The tumbricus, on account of its large size and its habits of nocturnal activity, is a cause of considerable irritation. This worm is said frequently to give rise to nervous disorders in the child; and cases have been recorded in which severe headache, photophobia, choreic movementa, consulsions, and even profound coma have ceased on the expulsion of a number of these creatures. It is difficult to say what share the worms take in the production of such symptoms. Probably some additional cause is in operation, for in rickety children, whose tendency to convulsions and other forms of nervous disturbance is one of the most characteristic consequences of that phase of general malnutrition, I have not noticed that the presence of the long round-worm is especially liable to be accompanied by eclamptic seizures. Probably, in most cases where nervous symptoms are associated with intestinal worms, the nervous disturbance is quite independent of any irritation produced by the worms in the bowels. It is common enough for children who are suffering from undoubted disease of the nervous centres

ova are re-introduced into the alimentary canal by the mouth, they become exposed to the action of the gastric juice in the stomach, and their contents may be set free. According to Dr. Cobbold, children frequently carry the ova under their nails; for the irritation to which the presence of the oxyures gives rise, obliges them to seek relief by scratching. In this way the eggs may be transferred directly to the mouth.

The ova of the lumbricus appear to be imported through the medium of impure water. This parasite is said to be especially common in low-

lying, marshy districts.

In the case of the tape-worm, it is through the eating of imperfectly cooked flesh infested with the cysticerous that an individual becomes the unwilling harbourer of the parasite. The tenia solium is derived from measly pork, the tenia medio-canellata from beef. In children who suffer from a chronic looseness of the bowels, and are consequently fed with

pounded raw meat, tape-worm is occasionally met with.

Symptoms -The most varied symptoms have been ascribed to the presence of worms in the bowels. Most of these are doubtless due to the intestmal derangement from which the patient is commonly suffering. That they are not a necessary consequence of the visits of these parasites is shown by the fact that it is not rare for the creatures to be found in the stools of children who have not previously exhibited any sign of discomfort or distress. In these cases, the worms are usually few in number, and can be readily got rid of by the administration of an ordinary aperient. It seems necessary for the extensive propagation of the entozoa that a catarrhal condition of the bowel should be present. In the secreted mucus the embryos find a favourable medium for development, and if, as often happens, the flux be profuse, great difficulty may be experienced in freeing the patient from these irritating pests. It is in such cases only that severe general symptoms are found; but these, as has been said, are to be rightly attributed, not to the parasites, which may be looked upon as accidental complications, but to the unhealthy state of the alimentary mucous membrane, which hinders digestion and impairs the nutrition of the body. These symptoms are described elsewhere (see page 121), and need not be here repeated. There are, however, many special symptoms which are attributed directly to the presence of worms; and as they are not necessarily the consequence of the intestinal derangement referred to, and often cease when a number of worms have been expelled, it is possible that they are really due to the irritation set up by the creatures in the bowels.

Most of these special symptoms will be referred to in describing the particular symptoms produced by the several species of worm. It may, however, be stated in this place, that every variety of nervous symptom, from headache, and other disorders of sensation, to spasm, paralysis, and convulsions, has been found associated with the presence of worms in the alimentary canal. Some of these have been looked upon as pathognomonic. Thus, Dr. Underwood held that an attack of convulsions, accompanied by small pulse and hiccough, was an almost certain sign of worms. Monro was of opinion that unequal dilatation of the pupils pointed positively to the same conclusion. Others have relied upon the rapidity and irregularity of the pulse as furnishing sufficient grounds for the diagnoses. It cannot be denied that these symptoms may be noticed in children suffering from intestinal worms, and may possibly be produced by them; but similar symptoms are found in cases where careful observation fails to dis-

cover any sign of the creatures or their ova in the stools.

There is one symptom which, although not positively distinctive of the

irritation of worms in the bowel, renders the presence of the parasites highly probable. This symptom is a peculiar appearance of the tongue. In all cases where the bowels are the seat of a mucous flux, the tongue gives evidence of this condition. It is flabby, and indented at the edges by the teeth. The increased secretion of mucus in the mouth gives to the tongue a slimy, gunmy appearance. The lingual surface is covered with a thin corting of gray fur, and the fungiform papillie at the sides of the dorsum peer through the fur as round or oval spots, which are more or less red, according to the degree of irritability of the stomach. In cases where worms are present, I have often remarked a peculiar fawn colour of the fur covering the dorsum, and the slimy appearance of the organ has been especially noticeable.

A child may be infested by more than one variety of worm at the same time. It is not uncommon to find round-worms together with threadworms; and sometimes round-worms and tape-worms are present at the same time in the same subject. Thus, a little boy, aged one year and eight months, was under my care for tape-worm, from which he had been suffering for three months. This child, on one occasion, passed a large round-

worm and many joints of the tania in the same stool.

In the case of thread-corms, the patient seldom complains of abdominal pain, but the irritation set up in the rectum by the presence of the entozoa gives rise to a troublesome itching of the fundament, which in sensitive children may cause an extreme degree of suffering. This irritation comes on towards the evening, and at night may be so distressing that sleep is greatly interfered with. In some cases, in addition to the itching, shooting pains may be complained of in the same part. Catarrh of the rectum is not uncommon in such subjects. There may be looseness of the bowels, and the evacuations are often discharged with straining efforts. They may be followed by prolapse of the rectum. The stools often contain glairy mucus, and sometimes blood in streaks, or even clots of considerable size. Difficulty in emptying the bladder may be a consequence of the irritation, and the child sometimes holds his water for many hours together. Itching of the nose, a leaden tint of the lower evelid, and swelling of the upper lip, are also very common symptoms when thread-worms are present.

The worms are readily detected as white moving threads in the stools, and may be seen in the folds of mucous membrane about the anus. They may pass or be conveyed into the vagina in little girls; and can often be discovered in the bed-clothes. A microscopic examination of the stools

usually discovers a multitude of ova.

The tumbricus, on account of its large size and its habits of nocturnal activity, is a cause of considerable irritation. This worm is said frequently to give rise to nervous disorders in the child; and cases have been recorded in which severe headache, photophobia, choreic movements, convulsions, and even profound come have ceased on the expulsion of a number of these creatures. It is difficult to say what share the worms take in the production of such symptoms. Probably some additional cause is in operation, for in rickety children, whose tendency to convulsions and other forms of nervous disturbance is one of the most characteristic consequences of that phase of general malnutrition, I have not noticed that the presence of the long round-worm is especially liable to be accompanied by colamptic seizures. Probably, in most cases where nervous symptoms are associated with intestinal worms, the nervous disturbance is quite independent of any irritation produced by the worms in the bowels. It is common enough for children who are suffering from undoubted disease of the nervous centres

to be infested with lumbrici. Thus, in cases of tubercular meningitis, one or more long worms are often expelled by the action of aperients, but it is needless to say that in such a case no amelioration in the symptoms follows the expulsion of the parasites. So, also, children under my care suffering from chorea have passed lumbrici, but I cannot call to mind a single case where any unprovement in the disease has directly followed the appearance of the worm in the stools.

If, however, the nervous symptoms supposed to be produced by lumbricismust be looked upon as somewhat problematical, there are other phenomena which can be referred with much greater certainty to the irritation set up by the entozos. Severe abdominal pains of a colicky character are not uncommon in children who suffer from these creatures; and looseness of the bowels, occurring chiefly at night, is occasionally produced by this agency. I have seen several cases of this kind where a character, after persisting for months, ceased immediately that the worm was get rid of.

A little boy, aged four years and a half, was said to have been troubled for three months with persistent looseness of the bowels. The purging was never very severa, but was always worse at night. The motions were said to be very slimy, and after a dose of oil, usually contained threadworms. The child often complained of colicky pain and tenesmus. He had been slowly wasting from the time the purging first began. The occurrence of nocturnal looseness of the bowels, combined with the appearance of the tongue, which was very flabby, shiny, and drab-coloured, with large fungiform papille at the sides of the dorsum, made me suspect the presence of a long-worm. I ordered a powder containing one grain and a half of sustonine and half a grain of caloniel to be given every night for three nights, and to be followed each morning by a dose of custor-oil. After the first powder the child passed a long-worm, and the diarrhou ceased from that time. He then rapidly regained flesh.

As a rule, lumbrici become active at night, and may pass upwards into the stomach, or downwards into the colon and rectum. They have been known to issue spontaneously from the mouth of a child during sleep or to appear from the bowel without being discharged in a stool. Their preence in the stomach may give rise to nausea and retching. Sometimes they pass into the common bile-duct and cause jaundice, by obstructing its channel. If jaunduce rapidly developes in a child who is known to be troubled with this parasite, we should think of the possibility of this rare accident having happened. Sudden dyspuosa has been known to arise. In some instances, at least, this has been discovered to be due to the actual penetration of the worm into the air-passages. Thus, Andral has known death to occur from this cause, and Arronsshon has reported the case of a little girl, aged eight years, who, after suffering for two hours from distressing disputes and cough, suddenly, after a violent paroxyam of cough aported a long-worm and was immediately relieved. In other cases, the difficulty of breathing has been attributed to direct pressure upon the laryna and traches by a number of worms in the gullet, or to reflex action, propagated from the intestine; but these explanations are neither of them very satisfactory. It has been so much the tendency to attribute every kind of discomfort arising in cases where worms are present to the irritation of the parasitic creatures in the bowels, that probably sufficient care has not been always taken to exclude other and less obvious causes of the symptoms.

Lumbrici are sometimes present in very great quantities. The largest number I have known to occur together in one child has been twelve, but they are sometimes much more numerous, and may even amount to several hundreds. When thus multiplied, the worms may form bundles, which impede the passage of the contents of the bowel, and are said in some cases

to give rise to the symptoms of obstruction.

The tape-worm is often found in children and sometimes in infants, the child who came under my own observation began to pass the joints at the age of lifteen months. Other observers have met with the worm in still younger subjects. These, however, are exceptional cases, but in older children, of five or six years and upwards, the affection is as common as it is in the adult. In these patients, little disturbance appears to be excited by the parasites. Pallor and loss of flesh are often complained of, but these symptoms, as in the case of the other species of parasite, appear to be due less to the worm than to the mucous derangement of the bowel with which its presence is usually associated. Headache and discolouration of the lower cyclid also often occur, and may be attributed to the same catarrini condition. Often, however, the digestion remains good, and the child, except for occasionally passing segments with the stools, is to all appearance well.

Dispress.—No symptoms are to be relied upon in the diagnosis of intestinal worms. The only sign from which we can draw any positive inference, is the appearance of the creatures or their eggs in the stools. Therefore, if from any cause we suspect their presence in the bowels, we should at once adopt appropriate treatment, and order the evacuations to be carefully searched for signs of the parasites. A microscopic examination of the matters discharged from the bowels will often discover the

presence of the ora.

Treatment.—With the exception of the teenia, worms are usually expelled readily in young subjects; but it is less easy to prevent their frequent reproduction. In all cases where children continue to be infested for long periods with the oxyures or lumbrici, the bowels will be found to be the seat of a chronic mucous flux. There can be little doubt that in such cases the ova lodge in the abundant secretion and find in it a congenial medium for development. Therefore, in all such cases, the special means adopted for relieving the bowels of their unwelcome tenants must be conjoined with other measures for arresting the chronic derangement of the mucous membrane and restoring the intestinal canal to a healthy state. These measures consist in the adoption of a careful diet, from which sweets and farinaceous matters are in great part excluded; in the frequent use of mild aperients to clear away mucus accumulated in the alimentary canal; and in the administration of alkaline and other remedies to check hyper-secretion from the mucous membrane. This subject is referred to elsewhere (see page 127).

Thread-worms are most effectually and easily removed by the use of enemata. For this purpose, lime-water, or an infusion of quassia, or a solution of common sait (a tenspoonful to four ounces of water), may be employed. In using these agents, the bowel should first be cleared out by a copious injection of warm water. Afterwards, five or six ounces of the special enema should be administered, and be retained for a few minutes by pressing the anus before it is allowed to escape. In obstinate cases, santonin (one grain to a child of four years old) should be added nightly to a dose of the compound liquorice powder or other mild aperient, and five grains of tartarate of iron, with one or two drachms of the compound decoction of aloes, diluted with water and sweetened by a few drops of spirits of chloroform, may be given two or three times a day.

Looseness of the bowels in these cases is readily arrested by a dose of

castor-oil. The nocturnal itching may be grecation to the fundament of an ointment compguentum hydrargyri and lard, as recommend by the use of a salve made by rubbing up one camphor with an ounce of lard. In all these camust be observed, and after each action of the well washed with soap and warm water.

In the case of lumbrun, santonin is especially, best combined with a dose of calomel. Thus, to old, two grains of the former may be given without the drug rarely fails to bring away the round-tures is hidden in the bowels. Santonin is a regiven in too large doses. In some children it it produces giddiness, with impairment of viscem tinted with a green or yellow colour. Usua of urine and gives a yellow tinge to the secretic

For children who, on account of romiting of medicine, cannot take santonin without discombinated by used. Cowhage (the hairs of the musscribed in doses of thirty to sixty grains, given glycerine. Dr. W. Roe speaks highly of the sulphite of soda, and recommends ten or fiftee times a day in water sweetened with spirits of with tincture of orange-peel. Neither of these action. Each should, therefore, be always foll of aloes, senna, castor-oil, or other mild aperied other useful vermifuge. It can be given in a motion a child of six) combined with an equal quant

It is not advisable, in ordinary cases, to contice if the first doses have been given without gotten that all the symptoms of worms (i.e., of it be present although special remedies fail to creatures in the stools. If, therefore, after a discovered, we should attribute the symptoms derangement, and take the necessary steps to end.

The successful treatment of tape-worm in the no little difficulty. Probably the softer innecessable adapts itself more readily to the action case in the adult, for in my experience it is chead to be discovered in the evacuations. The pelled, but the head too often remains behind care should be taken in the examination of the joints should be first removed. The faceal mat with water and emptied slowly from one vasse precaution that the liquid excrets is thoroughly passes over the side of the utensil. The sedication again diluted and strained through a fine bead, if it have passed from the bowel, can sear

Various kinds of vermifuge are relied upon parasites. Kousso, kanuda, filix mas, turpenting fresh bark of the pomegranate root have all t which is the favourite remedy for the adult, is uncertain in the case of children. For young subjects, it is best combined with kamala. A drachm of powdered kamala is made into an emulsion with mucilage, and then triturated in a mortar with a drachm of fern-oil, adding water alowly to make a three-ounce mixture. It is important that the remedy be given fasting. The child should be allowed to take nothing but a little water after his mid-day dinner. The draught should be given on the following morning, divided into two portions, of which the second half must be taken at an interval of three hours after the first. Kanala has an aperient action of its own. This method of treatment, therefore, seldom requires the assistance of a purgative, as is necessary in the case of male fern-oil given alone. After the two draughts have been swallowed, the patient should still continue his fast until the worm comes away in the stool. I have found children bear this method of treatment well, and it is often effectual. If the draught excite vomiting, it should be repeated, preceded by a small dose (M ij.-iij.) of laudanum to quiet the irritability of the stomach.

Kousso is preferred by some. The remedy is given in doses of two or three drachms divided into two portions, and given at an interval of half an hour in milk. The draught should be taken in the early morning, and should be followed in an hour after the second dose by a spoonful of castor-oil. The principal objection to this method of treatment is the large quantity of the drug which it is necessary to swallow in order to produce any satisfactory effect. The same objection applies to the decoction of pomegranate bark. If these remedies fail, turpentine should always be tried. This oil may be given in one large dose, or in smaller quantities frequently repeated. In the large dose it may be administered as recommended for the lumbricus. In smaller quantities, Dr. H. Davies recommends half a druchm to be mixed with honey and given in a draught with mucilage and water every six hours. Every second morning he orders a powder of

calomel and the compound scammony powder.

In all cases where there is much derangement of the bowels, and large quantities of mucus are passed in the stools, a rigid diet, from which starchy matters and sweets are carefully excluded, should be enforced for at least a wee's before the special treatment is undertaken. This precaution greatly

increases our chances of success.

Part 10.

DISEASES OF THE LIVER.

CHAPTER I.

JAUNDICE.

Jaundice is common in early life. This symptom may be found in children as a consequence of the same causes which produce it in the adult. There is in addition a special form of jaundice seen in new-born babies which is called interes neonatorum. It will be therefore convenient first to describe jaundice as it occurs in the new-born baby, and afterwards the symptoms

as it is met with in older children.

Icterus neonatorum, or infantile jaundice, must be distinguished from the yellowish discolouration of the skin which succeeds in many cases to the intense cutaneous congestion of the first few hours or days of life, This staining is not dependent upon the secretion of bile, and is not a jaundice at all. It does not colour the conjunctive or the urine, but resembles the staining of the skin which follows a cutaneous bruise. The face of the child who is born after a difficult or tedious labour, is often at first deep red, with a tinge of violet; and the skin over the body is coloured with an erythematous redness. At the same time, or soon after, pressure upon the surface sufficiently firm to empty the blood-vessels shows a vellowtint of the skin. As the redness fades, the yellowness appears to increase, and soon remains the sole discolouration. Beginning, as a rule, on the second day, it usually persists for about a week, and is commonly over by about the tenth day, or a little carlier, although in exceptic tal cases it may last longer. By some writers, the term reterms neonatorum is confined to this false jaundice, and the same authors apply the name uterus infantum to the true disease. This practice is calculated to give rise to unnecessary confusion. In the following pages the terms ictorus neonatorum and ictorus infantum will be applied indifferently to indicate a stuining of the skin by the pigments of the bile.

Real acterus manifests itself in the child as it does in the adult, by a yellow tint of the skin and conjunctive, light-coloured stools, and often by discolouration of the urine. It may be the result of some comparatively trifling derangement, and is then readily recovered from; or may be the consequence of a serious malformation or grave organic lesion, and is then

almost invariably fatal.

The milder form of jaundice—which may be called the benign variety—appears to be predisposed to by difficulty and delay in the process of parturition. A first-born child, exposed to serious and prolonged pressure before birth, and who, in consequence, is born in a state of semi-asphyxia, is often found to become jaundiced. Again, according to Kehrer, premature birth, or other cause of weakness in the infant, is apt to be followed by the same result. Exposure to cold and damp, and, according to

some writers, a vitiated atmosphere, can also produce it.

Many theories have been advanced to account for the frequency of this symptom in the newly born. Virchow attributed it to a duodenal catarrh, and plugging of the common duct with mucus; and in children who have been exposed to cold thus is no doubt a common cause of the derangement. Frank thought it was the consequence of an accumulation of meconium. Cohuheum believed it to be due to a sudden increase in the bile secretion after birth—an increase too great for the bile-ducts to carry away; but he has advanced no evidence in support of his theory. Many writers have referred the symptom to the disturbance in the hepatic circulation consequent upon the change in the conditions of life incident to birth. The circulation is too full, according to Hewitt and Weber, so that the distended vessels compress the bile-ducts; it is too empty, according to Frerichs, the circulation through the umbilical vein being suddenly cut off, and the tension of the hepatic capillaries diminished, so that the se-

creted bile makes its way into the blood-vessels.

There can be no doubt that the sudden transference of the chief supply of blood from the umbilical to the portal vein must at first produce considerable disturbance in the hepatic circulation. Weber has pointed out that if the functions of the umbilical vein are arrested before the establishment of respiration, as when a child is born partially asphyxiated, great congestion and cedema of the liver are the consequence. Birch-Hirschfeld has shown that the vessels in the notch of the liver are surrounded by a dense layer of connective tissue, and that this arcolar sheath is continued into the organ along the branches of the portal vein. He has noted that in cases of difficult parturition, where the liver is the seat of great venous obstruction, this areolar sheath is cedematous. It becomes pulpy and gray in colour from infiltration of fluid, and a great accumulation of round cells takes place into its meshes. This pulpy condition of the cellular layer is seen also around the umbilical vein, and may even extend into the gall-bladder. It is evident that the swollen tissue must compress the bile-ducts, and Birch-Hirschfeld has shown that this is actually the case. The bile-ducts are distended, and it is difficult to force bile out of the gall-bladder into the duodenum. In these cases he has detected early signs of jaundies where death has occurred during the first day, and reports cases in which life had been further prolonged with a gradual increase in the icteric symptoms. In these mild cases, the presence of the bile-pigment cannot be always demonstrated in the urme; but, according to this authority, the bile acids can be detected in fatal cases in the pericardial fluid.

When the icterus is a consequence of the condition above described, it is seldom very severe. In the mildest cases the conjunctive are only faintly tinted with yellow; the appearance of the urine and the motions is normal; and the staining of the skin is only noticed on the face, the front of the cheet, and the back. The derangement is then only a passing one, and the skin resumes its natural colour in three or four days. In a higher degree, the yellowness may extend to the belly and upper arms. The con-

junctive are yellow; the urine is high-coloured, and stains the linen; but even in this case, the stools may retain their normal tint, which at this age is naturally a golden yellow colour. In this degree, the symptoms gener ally last a week. In other cases, the jaundice is general, and may involve even the hands and feet. The urine is then distinctly icteric; the conjunctive are very yellow; the tears are tinted with bile, and the stools are clay-coloured. In some cases, Seux has noticed an ophthalmia to come of a few days after the onset of the jaundice, with a copious and deeply stained purulent secretion. As a rule, the child seems to suffer little in convenience from his derangement. He takes his food well and has no pain. Often, on palpation of the belly, the liver will be noticed to be in creased in size, and the lower border may be felt at the level of the unbilicus. It is curious that, although the urine is coloured yellow, the most careful examination of the water is unable to detect the presence of ball phagin. MM. Parrot and A. Robin have, however, discovered in the in terie urine yellow amorphous irregular masses, varying in size from a reblood-corpuscle to a vesical epithelium, and differing in chemical test from the colouring matter of the bile. They have also noticed the preence of sediments containing uric send, urate of soda, and ovalate of lime hyaline, epithelial, and fatty cylinders; white globules, and cells from the urinary passages.

When death occurs in infants who suffer from this benign form of jaundice, the fatal termination is owing usually to other causes. There is a variety of the complaint, to which attention has been directed by Seur where the interus is accompanied by all the symptoms of intestinal catarradiarrhosa, a quick pulse, and some heat and tenderness of the belly. There is, however, rarely vomiting. In the favourable cases the diarrhose ceases before the jaundice disappears. If the looseness of the bowels per sists, it is a dangerous derangement at this early age, and the infant often

dres.

Although usually a symptom of comparatively little moment, ictern neonatorum may be the indication of very serious disease. The grace for of jaundice may be the result of three different conditions. There may be a congenital malformation of the gall-ducts; the ducts may be compressed by apphilitic inflammation and growth (the symphilitic perpylephlebits of Schuppel); or the icterus may be the consequence of umbilical philebits.

and nymmie

Infantile jaundice from atresia of the bile-ducts is fortunately not common disease. Several varieties of malformation have been recorded the gall-duct has been found converted into a fibrous cord; the common duct has been known to be obliterated, or absent, or excessively narrowed sometimes all the ducts have been wanting; in other cases, the gall-bladder has been rudimentary and the ducts absent. The liver itself is normal in appearance, or greatly enlarged; usually, it is of a deep olive or nearly black colour. It has also been noticed to be cirrhotic, and its substance has been found to be denser than natural. The microscope shows a overgrowth of the areolar tissue, chiefly in the capsule of Glisson; and broad bands of connective tissue surround the dark green islets of lives cells. This incipient cirrhosis appears to be a constant accompaniment of obliteration of the bile-ducts, and continues to advance as long as the child survivea. In animals, ligature of the ducts has been shown by Da Wickham Legg to lead to marked hepatic cirrhosis and consequent portal congestion.

This rare and distressing form of malformation is sometimes found to

affect several children of the same parents. This tendency to appear in successive children of the same family was noticed by Chevne in 1801, and has been commented upon by other writers. The jaundice to which retention of the secreted bile gives rise may be present at birth, but usually is not risible before a week, a fortught, or even longer. When it first appears, the discolouration has a faint yellow tint, but the colour gets quickly darker. The conjunctive are yellow; the stools soon become colourless and offensive; and the urine is high-coloured and leaves yellow or greenish brown stains on the disper. At first, nothing abnormal is noticed about the belly; but after a day or two the liver begans to enlarge, and may reach a great size in a short time. The spleen may be also felt to be larger than natural. There is some swelling of the belly, and ascress may be present; but the abdominal distention is usually due to the increase in size of the hepatic and splenic viscera, and to flatulent accumulation resulting from the decomposition of food. Dr. Wickham Legg mentions swelling of the hemorrhoidal veins among the occasional symptoms. The child usually takes food well, but wastes quickly. The bowels are often costive. The jaundice is not constant in degree. The tint of the skin varies, and on some days the infant is much more deeply stained than on others. Before death, in some cases, the abnormal colouring almost completely disappears, as very little bile is formed, owing to the destruction of the secreting tissue of the liver. The stools do not always lose colour very rapidly; sometimes for days, or even weeks, meconium or coloured stools may be evacuated; but the colour is usually described as a dark green, and is due possibly to altered blood.

A frequent symptom of this congenital defect which demands especial attention, is hiemorrhage from the navel. This phenomenon is not a constant symptom, but occurs in the majority of cases, and is of very serious augury. The hæmorrhage generally begins a few hours or a day or two after the fall of the navel-string (most commonly between the fifth and the unth day after birth), and usually occurs first in the night. It is not a violent bleeding. Blood oozes gently but continuously from the umbilicus. It appears to be capillary, and the colour may be bright red, or dark and venous. This form of bleeding may be combined with hamorrhage from other parts, such as cutaneous ecchymoses, epistaxia, luematemesis or melena, and bleeding from the mouth. The hæmorrhage, combined with the interference with digestion due to the absence of bile and impaired action of the liver, rapidly exhausts the patient; and he usually dies within the week-often in a few hours. Dr. Legg suggests that the umbilical bemorrhage is a consequence of the cirrhosis and resulting portal congestion ; for the blood is hindered in its passage through the liver, and is forced to seek some other way of escape. It therefore passes from the left portal vein to the ductus venosus, and thence to the umbilicus, where the vessels, newly closed, cannot resist the increased pressure, and give way. The same mechanism (portal congestion) will explain the frequent coincidence of hamorrhage from other parts supplying the portal vein with blood.

Cases of jaundice conjoined with umbilical hemorrhage are rapidly fatal, When this symptom is absent, although the child almost invariably dies, life may be preserved for a much longer period. Recorded cases show that the infant may live five, six, or seven months, and even then, as in Lotze's case, where the child lived into the beginning of the eighth month and died of a bronche-pneumonia, may succumb to an acadental complication. This malformation is said to be twice as common in boys as it is

in girla.

A male infant, deeply jaundiced, aged three months, was brought to the out-patients' room of the East London Children's Hospital and was a once admitted by my colleague, Dr. Radeliffe Crocker, into the wants. The child was born of healthy parents, none of whose other children ind been similarly afflicted. He was said to have been a robust, healthy looking infant at birth, and shortly afterwards to have passed two dark stools. Since that time, however, his motions had been hard and white like lumps of chalk, and the bowels had acted only once a day. The jaundice had first appeared when the child was a week old, and had progressively increased. The infant had been suckled for a month, and was then fest of Swiss milk. He often vomited, not always after taking food, and we capricious about his bottle, sometimes refusing to suck. His water had always been dark, leaving yellow stains on the diaper.

When admitted, the child was fairly nourished. His skin was deeply jaundiced, and his conjunctive were vellow. There was a papular eruption (strophulus) all over his body. The liver could not be felt at this time on account of the child's struggles, but was found a few days afterwards to project two fingers' breadths below the ribs. The boy lived a month after his admission, wasting gradually, and often crying as if in pain. That aphthar appeared in his mouth, and he sank and died. There were no hismorrhages. His jaundice persisted, although it varied curronsly in its tensity; and before his death the tint of the skin was several shades lighter than when he entered the hospital. The liver remained about the same size and felt firm and smooth. The spleen was not enlarged. After death the liver was found of a dark olive colour, and its consistence seemed to be increased. The gall-bladder was rudimentary, and the hepatic and common duets were absent.

When suplishing inflammation of the liver gives rise to jaundice, the organ is enlarged and decply coloured of a brownish yellow tint, and show under the interoscope a great probleration of young cells in the capsule of Glisson, and in the interlobular spaces. In a case recorded by M. D.E.pino of Geneva, the same probleration was noted round the hepatic cells in the interior of the lobules. Moreover, the small bile-ducts were thickened and filled with epithelial cells. There was no obstruction in the larged ducts, and the gall-bladder contained thick and dark-coloured bile. The spleen was greatly enlarged and very firm.

In this case the jaundice was severe and appeared at birth. On the ninth day bleeding occurred from the umbilious, from the bowels, and into the skin; the belly swelled; the liver and spleen were notably enlarged the temperature became subnormal; the child wasted rapidly, and died of the twenty-third day in convulsions.

Jaundice from umbilical phichitis has been called by Schüller "ieteral malignus." This variety appears to be dependent upon an infective process. The poisonous matter is probably the same as that which cause puerperal fever in the mother, and may be conveyed by bacteria, for two forms of micro-organisms have been found in the blood of infants at affected, the one spherical and the other rod-slaped. Whether these two different forms imply two different kinds of infection is not known but Birch-Hirschfeld asserts that the rod-shaped bacteria are especially observed in cases where the general infection is severe and the discassional transfer of the umbilical artery, with a without philobitis of the umbilical vein. In anxive cases collected by the observer, umbilical arterits was found in thirty-two, umbilical philobitis

in eleven, and inflammation of both vessels in three. An examination of the liver reveals profound degeneration. These changes seem to indicate that the infection must reach the liver by the umbilical vein. They may, however, be found in cases where the artery alone is notably diseased; but there are reasons why the morbid appearances should be more conspicuous in the umbilical artery. After birth, the remnant of the umbilical vein is alternately emptied and filled again on account of the varying pressure on the hepatic vessels induced by the action of the heart and lungs. This constant flux and reflux in the vein tends to promote infection of the system, but is unfavourable to the local development of the morbid process. It is found in these cases that the intensity of the jaundice bears no relation to the severity of the vascular inflammation, but that it is in direct proportion to the degree to which the pathological changes have advanced in the liver. It is probably, therefore, the consequence of the swelling of the connective tissue surrounding the portal vein and its branches in the liver, which compresses the bile-ducts.

In these cases, the jaundice comes on a few days after birth, and by the end of the week is well marked. The urine is intensely yellow; but the stools may be of normal tant, although usually costive. The onset of the jaundice is accompanied or quickly followed by fever, which soon becomes high. There is often vemiting of yellow or greenish matter. The child looks excessively ill. His face is livid, with pinched, haggard features, and he refuses the bottle or the breast. His tongue is dry; his hands and feet are purple; his abdomen swells and is tender; fluctuation, more or less distinct, is noticed; and blood or blood-stained pus cozes from the navel. Semetimes the spleen enlarges, and petechine are noticed on the

skin. Death may be preceded by convulsions and coma.

When jaundice occurs after the age of infancy, it is due to the same causes which give rise to the symptom in the adult. Of these, no doubt, duodenal catarrh extending into the bile-ducts is, of all others, the most frequent. On this account, the symptom is usually a trifling one, and is quickly recovered from. It is accompanied by some temporary enlargement of the liver, which can be felt to project several fingers' breadths below the ribs; but except for some delicacy of digestion, little discomfort is experienced. In exceptional cases, the derangement may be the consequence of plugging of the common duct with inspissated bile, and this accident has been notice I in an infant of three months old. Again, a lumbricus has been known to penetrate into the common duct and produce such impediment to the flow of bile as to give rise to jaundice. Ieterus may be also due to acute yellow atrophy of the liver; but this is fortunately a very rare disease in childhood. Of other causes, atrophic cirrhosis of the liver, phosphorus poisoning, and miasmatic influences have been recorded as producing joundice in early life.

Dagnosis. In examining a new-born infant for signs of jaundice, it is often necessary to force the blood out of the skin by firm pressure with the finger before the natural tint of the integrament can be observed. In inspecting the eyes for yellow staining it is advisable to use no force in attempting to open the hids with the finger, but rather to wait until the child opens his eyes spontaneously. A baby, when the eyelids are touched, squeezes them together instinctively. In such a case our utmost efforts will often succeed only in exposing the palpebral mucous membrane, and

this will quite conceal the globe of the eye from view.

The diagnosis between false jaundice and true ictorus neonatorum, if the latter be of the benign variety and little pronounced, is very difficultoften quite impossible. In neither case is the conjunctive stained or the urine yellow. The colour will sometimes help us, for the tint of the jaundiced skin is often more distinctly yellow than the brownish stain left after severe cutaneous congestion. In all cases where the conjunctive and urine are tinted, however slightly, we may conclude that the case is one of true jaundice. The condition of the stools is of less moment, for jaundice

may be present without the motions being clay-coloured.

In cases where the jaundice persusts and becomes deeper and deeper, we have every reason to suspect the existence of some congenital malformation, especially if a previous child of the same purents has died shortly after birth with symptoms of interus neonatorum. If the liver and spleen become enlarged, the temperature remaining low, this suspicion becomes almost a certainty; and the occurrence of bleeding from the navel is, in such a case, practically conclusive. The partial disappearance of the jaundice is no proof that our apprehensions are unfounded, for the yellow tint of the skin may become distinctly lighter, or even quite disappear before the end.

The pyrmic form of jaundice is readily detected. The general appearance of the child, the high temperature, the dry tongue, the swelling and tenderness of the belly, the discharge of blood and pus from the umbilions, and the early death, sufficiently indicate the nature of the disease.

If the jaundice is accompanied by signs of inherited syphilis, or if, without these, we can discover a history of syphilis in the father, or of previous miscarriages on the part of the mother, the probability of s

syphilitic origin to the jaundice must be taken into consideration.

Prognosis.—So long as the jaundice is accompanied by no signs of discomfort, little anxiety need be excited by the symptom; but if diarrhess or vomiting occur, the injurious effect of exhausting discharges upon a newly born infant must not be overlooked. Little information is to be gained by inspection of the stools, for in cases of serious malformation they may remain normal in appearance for a considerable time. It, in any case, the motions become clay-coloured, and the staining of the skin and urine shows no sign of subsiding, there is cause for apprehension. A slight enlargement of the liver (i.e., a projection of one finger's breadth below the ribe) is immaterial; but if the organ continue to increase in size, and if the spleen also begin to swell, the infant's condition is becoming a serious one. It must not be forgotten in these cases to examine the anus; for the appearance of any swelling of the harmorrhoidal veins, as indicating great obstruction to the portal circulation, is an unfavourable symptom of no little importance.

If we are satisfied that the case is one of congenital deficiency or malformation, we can have little hope of a favourable issue, although life may be prolonged for several months. The appearance of umbilical homorrhage is a very fatal sign, and is usually followed by rapid sinking of the patient.

If the jaundice is due to syphilitic disease, it is hardly likely to end otherwise than unfavourably; and in cases of umbilical phiebitis and pyremia, we can hold out no lope of recovery.

In older children, icterus, unless it be due to phosphorus poisoning or some profound hepatic lesion, is in most cases a mild derangement which

soon passes away.

Treatment.—Ordinary benign jaundice in the new-born baby requires little treatment. Emetics, although strongly recommended by some writers, are in most cases useless, if not injurious. A gentle purge, such as casteroil, followed by two or three grains of bicarbonate of soda with a quarter

of a drop of tineture of nux vomica, given three times a day, will soon restore the child's tissues to their natural colour. I now invariably give nux vomica with an alkali in these cases, and believe that in catarrhal jaundice at all ages the former drug has a distinct influence in aiding the child's recovery. If purgatives are prescribed, the aperients used should be those which, like castor-oil or aloes, act low down in the alimentary canal. Senna and other drugs which influence the duodenum and upper part of the bowels may increase the irritation of this part of the intestine, and are unsuitable to cases of jaundier-at any rate to those cases where there is reason to suspect the existence of duodenal catarrh. Mercurals, too, should be given with judgment. It is not advisable to continue acting upon the liver by repeated doses of mercury. One dose of gray powder or of calomel may be allowed, but the remedy need not be afterwards repeated. With regard to diet :- The infant may still continue to take the breast. If he be bottle-fed, no alteration need be made in his food unless vomiting occur with signs of acid fermentation. If these symptoms of gastric catarrh are noted, the diet must be regulated according to the rules had down in the chapter on Infantile Atrophy.

If the jaundice be due to malformation, no treatment can be expected to be of service; but if hæmorrhage occur from the navel, attempts should be made to arrest a symptom which experience has proved to be so speedily fatal. The perchloride of iron may be used locally, followed by a compress; but in most cases, the surgeon has to fall back upon the operation known as the "ligature en masse." The child should be laid upon his back, and two hare hip pins must be passed through the integuments at the root of the mayel, carefully avoiding the peritoneum. A ligature is then twisted

tightly round the needles in the form of a figure of eight.

If syphils be present in the child, treatment for this constitutional condition should be adopted without loss of time. In cases of pyamic jaundice, attempts must be made to relieve the distressing symptoms. Warmth should be applied to the belly; and if there is great tenderness about the umbilious, extract of belladonna diluted with an equal quantity of glycerine, can be applied to the skin round the navel. Stimulants must be given as required.

CHAPTER IL

CONGESTION OF THE LIVER.

Concernor of the liver, although a common derangement in the child, is yet often suspected when not actually present. Many symptoms attributed to a "torned," "maetive," or confested liver, and treated with gray powder, are really due to a disordered state of the stomach dependent upon an improper dictary, and may be readily relieved by the excresse of a little judgment in the child's food and general management. A liver morbally congested gives rise to a very definite group of symptoms, as will be after-

wards described.

Causation.—The amount of blood circulating in the liver may vary considerably within normal limits. During digestion it is increased for the time; and if the child be habitually overfed, or be frequently indulged with highly spiced and stimulating food, the hypersonia lasts longer and is more intense than if he eat more moderately or of a planner diet. exercise and too close confinement to the house will merease the injurious effects of this unwholesome regimen. The other principal causes of mon bid congestion of the liver are: - Any cause which interferes with the return of blood from the liver. The commonest of these is disease of the heart interfering with the return of blood from the lungs. The pulmonary cisculation suffers primarily; and secondarily, the impediment spreads to the vena cava and the portal vein. Congestion of the liver is also a consequence of the ague poison, for malarial fever is as common a cause of hepatic congestion as it is of splenic enlargement, and a swollen hypersenic liver is a familiar symptom in tropical climates. Again, chilling of the surface is one of the most frequent agents in the production of liver congestion, and enlargement of the organ from this cause is a usual accompaniment of catarrhal jaundice.

Morbid Anatomy. - A congested liver is enlarged in all directions, and if very thick; its resistance is increased, and the peritoneal coat is tense and shining. When cut into, the organ bleeds freely, and the section shows a spotted or "nutmeg" surface from dilatation of the intra-lobular venus. Of ton, the colour of the parenchyma surrounding the central vein of the lobule is yellowish from interference with the escape of bile from the ducts; for jaundice is not unfrequently associated with this hepatic congestion.

If the hypercemia of the organ is a chronic condition, further changes take place after a time. The enlargement of the intra-lobular Lepatic veins induces atrophy of the liver-cells in their immediate neighbourhood. Surrounding these cells are others which are stained deeply with bile, and at the circumference of the lobule the cells are often filled with oil. The atrophied cells may completely disappear; and eventually a new formation of fibroid tissue takes place in connection with the inter-lobular ressels. The fibroid growth shrinks, and a condition akin to cirrhosis is set up; the organ becoming granular on the surface and the capsule thickened.

Symptoms — If the liver be much congested, we generally find that there is some pain in the right hypochondriac region; that it is tender when pressed, and that coughing or a deep inspiration is distressing. The child is often unwilling to lie on either side—on the right because of the direct pressure; on the left because of the weight of the congested organ causing an uneasy dragging sensation. On palpation of the belly, the edge of the liver is felt several fingers' breadths below the ribs, and on percussion we generally find that the upper limit of dulness, instead of beginning in the tourth interspace, begins in the third or on the third rib. Sometimes, especially if there is joundice, the distended gall-bladder can be felt as a pear-shaped tumour below the inferior edge of the liver.

Dyspeptic symptoms from hyperemia of the gastric vessels generally accompany a congested liver. The tongue is furred; there may be headache; nausen may be complained of; the bowels may be relaxed, and the stools light-coloured and offensive. The urine is dark, and may throw down a copious deposit of lithates. The skin is often sallow; and if the congestion be accompanied by duodenal catarrh, there will probably be joundice.

If the congestion is due to cardiac disease the child is harassed with dyspaces and cough from interference with the pulmonary circulation; his digestion is deranged, and there is often, in addition, addema of the lower limbs, with albuminuria.

A congested liver is, as has been said, frequent in cases of ague. Often, until this condition is remedied, quinine has but little influence over

the attacks. This subject is discussed elsewhere (see Ague).

Diagnosis.—A congested liver is increased in size, and pressure upon it produces some uneasuress. Mere light-coloured offensive stools are not in themselves a sign of hepatic hyperiemis. It is common for a child who is being fed upon large quantities of farinaceous food, or who, owing to a cutarrhal condition of his stomach and bowels, is for the time incapable of digesting a milk diet, to evacuate more or less semi-solid pasty or putty-like matter from the bowels. But the stools in such a case consist of undigested food, and are not indicative of arrested biliary secretion. If such a condition be treated, as it often is, by repeated doses of gray powder or other form of mercurial, the aperient action of the medicine produces on each occasion a dark biliary stool, but the effect of the drug having passed off, the evacuations continue to be as pasty as they were before. This condition, as is elsewhere explained, must be treated, not by cholagogues, but by measures which rectify the gastric and intestinal derangement (see p. 640).

To justify the diagnosis of hepatic congestion we must require enlargement and tenderness of the liver and a sallow complexion, as well as digestive disturbance and light-coloured stools. We must not, however, conclude too hastily that the size of the liver is abnormal. The organ is apt to vary in size in young subjects from natural causes, and in some children whose chests are exceptionally short may project for a finger's breadth or so below the ribs without being congested or otherwise diseased. Besides, it is important not to mistake a liver merely displaced for a liver morbidly enlarged. The organ may be pushed down by fluid accumulation in the pleura, or by emphysema of the lung; and I have known an extensive pericardial effusion to produce the same effect. In rickety children with deeply grooved cheats, the liver and spleen, although not enlarged, may be felt more distinctly than natural, being forced downwards somewhat from their original position. It is therefore important to ascertain by percussion the upper limits of the liver dulness as well as the exact level of the inferior margin. Again, a liver, although enlarged, may lie

completely under cover of the ribs, and its abnormal condition may thus escape notice. It may be pushed upwards by thurd accumulate and growth in the belly; or may be placed higher than it otherwise would be through the shrinking in the chest of a collapsed or indurated long Therefore, in an examination of the organ, we must remember these sources of error, and ascertain all its limits before coming to a conclusion.

A good example of a congested liver is seen in the following rase: A little boy, aged three years of healthy parentage, was brought to the had London Children's Hospital with the history that for five weeks be had been noticed to be languid and chilly, with little appetite and with sine swelling and tenderness of his belly. The bowels had acted two or three times a day, the motions being light-coloured, thus, and scanty. The said was restless and fretful, sleeping uneasily, and often starting and truth ing in his sleep.

The boy was the subject of moderate rickets. His ribs were besided. the ends of his long bones large, and his chest was flattened laterally. He had cut all his teeth and his fontanelle was closed. The skin was land and dry, and was tinted all over the body of an earthy vellow color The belly was large, and the lower edge of the liver reached to nearly the level of the umbilious. Its substance was natural, without any mercase of firmness. Its edge was not thickened. The spleen could not be felt.

The patient was treated with mercural purges followed by salnes, wit an alkali with bitter infusion was given to him three times a day. In a fortnight after this treatment had been begun, the liver had become unit reduced in size. Its upper border was at the fifth rib, and its lower let der could be felt two fingers' breadths below the ribs. It was emissis pushed downwards by the rickety deformity of the cliest, and was to doubt now of natural size. As the liver became smaller, the clade atpetite improved: his skin lost its earthy yellow tint, and the colour and of sistence of the stools became natural.

In this case, all the symptoms pointed to congestion of the hver, said palpation of the belly detected enlargement of the organ without ary is

teration in its consistence.

In warm climates, it is important to exclude hepatitis. In supportant inflammation of the liver, the pain and tenderness are greater than if the liver be merely congested; the general disturbance, although conscions the serious nature of the disease proportionately slight, is greater, to child looks ill, which is not the case in uncomplicated congestion and there is fever,

Prognosis.—Congestion of the liver is in itself a trifling adment. by danger connected with the case is dependent upon the general conduct

of the child, or the existence of serious disease of a vital organ

Trentment.—If the congestion is dependent upon overfeeding and 2sufficient exercise, we should be careful to regulate the diet, and all weak food which is digestible and unstimulating as well as moderate in quarter The child should be restricted for a day or two to bread and not will mutton-broth or a little boiled fish for his dinner. His belly should be protected by a flannel band, and the action of the skin should be prometal by a warm bath before going to bed. The medicinal treatment shows begin with a few grains of gray powder combined with half a grain ! powdered specacuanha and two to five of palapine. This should be given at bedtime, and in the morning the child may take a dose of hear magnesia or other saline aperient. Remedies which act upon the 42 and kidneys are useful in these cases. We may give two or three times?

day a mixture composed of solution of acetate of ammonia, sweet spirits of nitre, and a few grains of the bicarbonate of sods or potash. Chloride of ammonium (gr. iij. to gr. vj.) is also recommended. It may be made

palatable by extract of liquorice, chloric ether, and glycerine.

The same treatment is useful if the hepatic congestion can be attributed to a chill. In these cases, especially if there is jaundice, we should be careful not to employ senna and other purgative drugs which act principally upon the upper part of the intestinal canal, in order not to increase the irritation of the duodenum; but should keep the bowels regular by aloes or the saline aperients.

If the congestion of the liver occur as a consequence of heart disease, it will be reheved by measures directed to strengthen the cardiac action and lessen the general hypernemia from which the patient is suffering. If it arise in the course of an attack of malarial fever, it must be reduced as

rapidly as possible by saline and mercurial purges (see Ague).

Children who are habitually indulged and injudiciously fed, especially if they are accustomed to warm stuffy rooms, may suffer from frequent attacks of hepatic congestion, and their livers may seem to be permanently enlarged. In such cases, it is useful to send them to a watering-place where they can drink regularly of some natural saline aperient, and take thaily and sufficient exercise in the open air. After a short course of the waters, iron and quinine can be given with benefit.

CHAPTER III.

CIRRHOSIS OF THE LIVER.

Crassess of the liver, although not one of the more common diseases in the child, cannot be said to be very rare. In some children, even at a very early age, there appears to be a peculiar tendency to the formation and proliferation of tibroid tissue. Sometimes the fibroid overgrowth is a general one; sometimes it is more local, and is limited to particular organs—the lungs, the liver, or the kidneys. Fibroid induration of the lungs occurring as a result of catarrhal pneumonis and pleurisy, is a sufficiently familiar experience; but a similar pathological change in other internal

organs is much less frequently met with.

Consution.-The causes of hepatic cirrhosis in early life are obscure. Intemperance in alcohol, to which the disease in the adult is usually attributed, is of course exceptional in the case of a child. It is possible that, as some writers are disposed to believe, this vice may be one of the sus of the fathers which are visited upon their offspring, and that cirrhosis in the child may be due to intemperance in the parent; but this, at present, at any rate, is no more than hypothesis. Congenital deficiency of the bileducts is often-always, according to Dr. Wickham Legg-accompanied by an early stage of hepatic cirrhosis. Syphilis may sometimes produce it; and MM. Cornil and Ranvier have described an interstitial hepatitis as accompanying cases of general tuberculosis. Hepatic cirrhosis has been seen at a very early age. Weber has found the atrophic form in a new-born infant; and in cases of malformation of the bile-ducts, it is always an early change, as death usually takes place in the course of a few months. The hypertropluc form is sometimes, also, met with in very young children. Wettergren has seen it in a boy of five; and Dr. S. West has reported a case in a boy of six. It is curious that in each of these instances the child had been in the habit of drinking largely of coffee.

Morbid Anatomy, - Cirrhosis of the liver may be atrophic or hypertrophic,

and these two conditions have very distinct pathological characters.

In atrophic cirrhosis (the hobnailed liver, cirrhosis of Laennee) there is abnormal development of new fibroid tissue which permeates the organ, following the branches of the portal vein. The new development appears to originate in a chronic inflammatory condition of these vessels. It produces great thickening of the capsule of Ghsson, the prolongation of which envelopes the portal branches, and extending from it into the interlobular spaces, forms meshes which embrace portions of the hepatic substance. These portions vary in size, but all comprise several lobules. The process consists in a rapid proliferation of embryonic cells which undergo conversion into cicatricial fibroid tissue. After a time, contraction takes place in the new material, and the liver becomes small and shrunken, with an irregular granular surface and a dense substance. Its enveloping capsule is

much thickened. On section, the surface is of a dirty yellow colour, and is seen to be divided into irregular meshes by the fibrous network.

The contraction of the dense interstitial tissue compresses the lobules to that the liver-cells become flattened and atrophicd, and causes great obstruction to the portal circulation. Consequently, the whole portal system is congested. Its blood, unable freely to escape, has to find a new channel; and a collateral circulation becomes gradually established by enlargement of the principal veins in the suspensory ligament possing to the umbilicus.

The nutrition of the liver, and the formation of bile, are kept up by the development of new vessels, which permeate the new fibrous tissue and convey blood from the hepatic artery to the intra-lobular vessels. The smaller biliary ducts are but little affected by the changes which take place, so that there is seldom retention of bile or jaundice. In this form of cirrhosis, the organ is somewhat enlarged in the early stage, but afterwards becomes very

funall and contracted.

In hypertrophic cirrhosis, the liver is usually larger than in health, and may be increased to twice its natural size. It is smooth on the surface, with a normal thin edge, and on section, its substance is orange yellow or green in colour. The fibroid overgrowth in this case follows the ramifications of the biliary duets. It begins round the intradebular branches of the duets, and envelopes each lobule so as to insulate it from its neighbour. It forms a less regular meahwork than the preceding variety, and is a more diffused growth, which in some parts is thick and dense so as completely to destroy the hepatic tissue; in others, is comparatively scanty and ill-developed. The affected duets become largely dulated and their epithelium is increased. New duets are also developed, and can be seen by the microscope embedded in the new fibroid tissue. In this form of the disease, the obstruction is chiefly in the duets, so that there is no necessary interference with the portal circulation.

These two forms of the disease, from their anatomical origin, have been

called portal and biliary cirrhosis.

There is a third form which is very rarely met with. It has only been noticed in some cases of inherited syphilis in the infant. The disease is here primarily intralobular, and developes within the lobules round the individual liver-cells. This form, as it is only discovered after the death of the child, and probably gives rise to no symptoms, need not be further referred to.

Symptoms.—On account of the different pathological conditions in the atrophic and hypertrophic varieties of hepatic cirrhosis, the symptoms in the two forms are not precisely similar. In both we find signs of interference with general nutrition, but as the morbid change affects chiefly the portal circulation in the one variety, and the biliary conduits in the other, the later phenomena differ greatly in the two cases, and are usually characteristic.

In atrophic cirrhosis, the early symptoms are merely those of indigention, flatulence, and general discomfort. The child is often peevish and fretful; he is restless, sleeping badly at night; and his complexion is sallow or pasty-looking, with dark discolouration of the lower cyclids. He is noticed early to be flabby, and sometimes is evidently losing flesh. His bowels are often costive. These symptoms may continue for a long time without change. The urine is apt to be thick with lithates, and may contain crystals of uric acid, or even a deposit of uric acid sand. It is often very acid.

Sooner or later, more distinctive symptoms begin to be noticed, and in hospital patients it may be only from this point that the child's illness is

dated by the parent. The occurrence of ascites, with swelling of the belly, is usually the first symptom complained of, and there may be some wandering pains in the side. When the child comes under observation, we usually find dilatation of the superficial abdominal veins, distinct fluctuation in the abdomen, and often a slight enlargement of the liver and spicen. There is httle or no jaundice, but the skin after a time begins to have an earth, tut, and feels dry and rough to the finger. Sometimes there is a little ordena of the feet. The ascites is found to vary greatly in amount, and the general condition of the child is subject to rapid variation. On some days he seems much better than on others, and may be then lively, playful, and although easily tired, even active if allowed to be on his feet. As the disease progresses, the liver shrinks and coases to be felt, but the spleen in most cases continues to increase in size. If the ascites is great, it is often difficult to feel the spleen even when the child is laid on his right side. In such cases, it may be often readily detected by placing the patient on his lands and knees. The weight of the organ then brings it well forward within the reach of the fingers. Hemorrhages occur in the child from the gastraintestinal muccus membrane as they do in the adult; and the motions may be dark and sooty from blood, or pure blood may be passed by stool. Vomiting of blood is also sometimes met with. In many cases, we find a tendence to hæmorrhage from other parts. The nose and gums may bleed, and ecchymotic spots may be noticed on the skin. As the symptoms increase, the digestive derangements become more and more disturbed. The could is much troubled with weight in the epigastrum, and abdominal paus. He often feels sick; sometimes he vomits; his tongue is furred; he is thursty, and his appetite is capricious or is lost. He gets thinner and thinner; the dingy hue of his skin becomes more and more marked; even at this early age, hiemorrhoidal swellings may be noticed, and the distention of the superficial abdominal veins is increased.

When the disease reaches this period, life is very near its close. Often there is general dropsy, but the child may sink and die without the appearance of any fresh symptoms; or diarrhoea may come on and prove rapidly fatal. In other cases he dies from hemorrhage, or from an intercurrent inflammation, such as pleurisy or pneumonia. Unless a complication be present, there is never any fever. The progress of atrophic currisosis is alow, especially in the earlier stages. If he morrhage occurs, it is usually a

sign that the illness is approaching its termination.

In the hypertrophic cariety of circhosis, the initial symptoms of gastro-intestinal derangement, pallor, and wasting, are the same as in the other form; but the after-course of the disease varies from the previous type. While in atrophic circhosis the more characteristic phenomena are dependent upon the obstruction to the portal circulation, in the hypertrophic variety the symptoms are due to interference with the biliary system of ducts. Jaundice, rare and faint if it occur at all in the previous form, is here an early and characteristic symptom. The skin, conjunctive, and urine soon become deeply tinged with orange yellow, and the motions are light-coloured or chalky. The liver is generally enlarged, and the splicin in most cases can be felt of unusual size; but there is hitle dilatation of the superficial veins of the abdomen. Pain may be complained of over the liver. The bowels are relaxed or inclined to be costive. There is no ascides.

As the disease progresses, the jaundice increases in intensity, and the symptoms generally undergo temporary exacerbation. At these times, rapid enlargement of the liver is noticed; there is slight fever; the child is prevish

and fretful crying with pain in his side, and his condition appears to be

changing quickly for the worse.

The illness often closes with all the signs of malignant jaundice, due, probably, to acute degeneration of the hepatic cells. The pulse undergoes currous alterations in frequency, sometimes beating rapidly, at others also kening to 60 or 70. The tonguo gets dry and brown, and sordes appear on the teeth. The child refuses food, and seems to care only to be left alone. He sleeps much, and is drowsy and stupid when awake. Petechæ are often seen on the skin; the gums may bleed, and blood may be vomited from the stomach. The drowsiness soon deepens into stupor; and the child lies with his eyes closed, insensible to all that passes, often granding his teeth continuously. There is no pyrexia. The wasting is now rapid, and the patient sinks and dies without recovering consciousness. Sometimes death is preceded by convulsions.

Although these two types of the disease differ in the distribution of the fibroid overgrowth in the liver, they may be both present together. In such eases the liver is enlarged, and we find jaundice combined with accites and swelling of the abdominal veins. The hepatic disease may be the only lesion of the kind present, or may be accompanied by similar

changes in the lungs, the kidneys, or the spleen.

Inaquosis, -So many cases are now on record of hepatic cirrhosis occurring in children that the diagnosis should be no more difficult in them than it is in the adult. It is probable that many cases of ascites, the origin of which is obscure, may be attributed correctly to this condition of the liver. If in such a case tibroid disease of the lungs can be detected, it renders a similar condition of the liver highly probable. A swollen flucturting ab lomen, an enlarged spleen, dilatation of the superficial verns of the belly, piles, a dry, fuled, earthy skin-these symptoms occurring in a child who is not feverish, but who has a history of previous failure of health and of wasting, should make us strongly suspect the existence of the strophic form of cirrhosis. The absence of fever is an important element in this group of symptoms. If hamorrhages occur from the stomach and bowels, or elsewhere, the temperature still remaining normal, the evenptom is strongly confirmatory of our opinion. The chief difficulty in these cases arises from the occurrence of a febrile complication; but this is a source of perplexity common to most forms of chronic disease in the child. If there be fever when the child first comes under observation, it is advisable to withhold a positive opinion until time has been allowed for the pyrexia to subside.

In the case of hypertrophic cirrhosis, the occurrence of gradually increasing jain lice, with an enlarged liver and pains in the side, but without ascites, piles, or dilated parietal veins of the belly, the child being the subject of chronic digestive derangement and wasting, is a characteristic grouping of symptoms. If the illness end with convulsions, coma, a typhoid condition, and the symptoms of malignant jaundice, the case may be mistaken for one of acute yellow atrophy, especially if, as may happen, the liver is not notably enlarged. The latter is, however, an acute disease, and comes on very abruptly, with few or no premonitory symptoms; while hypertrophic cirrhosis is essentially a chronic illness, with a long history of failing health. Moreover, acute yellow atrophy is so rare in the child

that it may be practically excluded from consideration.

Prognosis — When the disease reaches the stage at which signs of serious impairment of nutrition are noticed, evidenced principally by a dry, earthy-looking skin, the prognosis is very unfavourable; and if

hemorrhages occur, the end may be judged a period, when the spirits are fairly good, even a able ascites, we may take a less gloomy view of rious symptoms are sometimes found to clear at at any rate, even if they subsequently return.

In the case of hypertrophic cirrhosis, rapid of the pulse, or drowsiness and nervous symplectic sym

able import.

Treatment,-It is so seldom possible in the once of hepatic curhosis in the earlier stage, t is confined to attention to the digestion, and t of the various organic functions. toms begin to be noticed, there are two forms adopted. The patient may be treated with all tonics. On account of the gastric derangement bitter is usually prescribed, and this mode of tin most cases. For a child of ten years old grains of bicarbonate of sods with infusion of the addition of a few drops of the tincture of efficacy of the mixture. Most cases, however, iron and quinme. Ten or fifteen drops of the iron with a grain of quinine given three times lengthened period, often seem to have great w and improving the general condition of the chi also be made use of, and laxative doses of the waters are well borne in these cases. A good f sulphate, which agrees well with children. full doses; and two to five grains, according to be taken after each meal in a teaspoonful of be liberal. It is well to allow meat twice a c may be used, having due regard to the stee child's power of digesting them. The action of moted by a daily warm bath, and the patient al to foot in flaunel or some warm woollen materi

The ascites is not benefited by the ordinary chalybeate diuretic, in which the iron is kepl acid, I have sometimes thought to be useful.

If much fluid accumulates in the peritoned by interfering with the action of the diaphrag moved by tapping the abdomen. The operadanger to the child, if the aspirator or a fine to performed early and repeated as often as in unless they are copious, need not modify the bleeding to manifestly weaken the patient and acid, dilute sulphuric acid, and other styptics, are best treated with bismuth and alkahea.

CHAPTER IV.

AMYLOID LIVER.

Astron, albuminoid, or lardaceous degeneration is a common lesion in the child, and the liver is often found to be enlarged from this cause. The liver, however, may not suffer alone. The spleen commonly, and the kidney frequently, are also affected; and often there is a similar condition of the

lymphatic glands.

Causation —The degeneration is always secondary to a general cachectic condition. It occurs sometimes in syphilitic children, and may be a consequence of scrofula and tubercle. The commonest cause is, however, the custence of chronic suppurations and purulent discharges. In fibroid induration of the lung, where there is a copious secretion in the dilated bronchi, amyleid disease is a familiar symptom; and in cases of empyema in early life, if a chronic fistulous opening become established, lardaceous de-

generation of organs very generally follows.

Morbid Anatomy.-The amyloid liver is uniformly enlarged, heavy, and excessively dense. Its edge is thin and resisting; its peritoneal coat very smooth and tense. The section is dry and homogeneous looking, of a gray colour and a glistening bacony appearance. No blood oozes from the cut surface. If, as sometimes happens, there is concurrent fatty degeneration, the knife after the section may look greasy. The sent of the disease in the liver has been disputed. According to Meckel and Virchow it affects the liver-cells, while Wagner and others are of opinion that the amyloid change is confined to the capillaries, and that the cells are merely atrophied. According to Rindfleisch, the morbid process begins in the arterial zone of the hepatic lobules, half way between the centre of the lobule and the circumference, and implicates the arteries, the capillaries, and the hepatic cells. It then spreads to the centre and afterwards to the circumference of the lobules. Kyber, too, declares that he has recognised the change in unmistakable livercells which he had isolated by pencilling. According to this pathologist, the trunk and larger branches of the hepatic artery are never affected, the morbid process being confined to the smaller hepatic arteries; but the change may be detected in the hepatic and portal veins, and even in the vena cava. The affected arteries and capillaries are diseased in various degrees. When the amyloid process is advanced in a vessel, its costs become thickened and pellucid; and the affected hepatic cells lose their normal shape, their granules, bile-pigment, and nuclei, and become irregular and glassy looking. The addition of iodine solution stains the affected parts of a reddish brown colour, and sulphuric acid turns them first violet and afterwards blue.

Symptoms.—Although the enlargement is perfectly painless, the organ may produce inconvenience by its weight. It causes distention of the belly; but as there is no compression of the bile-ducts or of the branches of the portal vein, there is no necessary jaundice, ascites, or prominence of the superficial abdominal veins. All these symptoms may, however, be found.

The mesenteric glands, like other internal organs, frequently participate in the anyloid degeneration; and if the glands occupying the hepatic notch are enlarged, they may compress both the bile-duets and the blood-vessels at this spot. In such a case, the skin, conjunctive, and urine are paindiced; there is some effusion into the peritoneum, and the veins of the abdominal parietes are dilated. Even in the absence of jaundice, the stools may be light-coloured of the disease is advanced, owing to impaired function of the hepatic cells.

On palpation of the belly, the liver is found to project several fingers' breadths below the margin of the ribs. Often its lower edge is on a level with the navel; semetimes it reaches to the crest of the ihum. Its substance feels firm and resisting, and its edge remains thin and sharp. There is no tenderness on pressure. In at least half the cases, the spleen, too, is enlarged, and can be felt several fingers' breadths below the ribs on the left

aide.

Digestive disturbances may be noticed. There may be loss of appetite and vomiting; and sometimes an obstinate watery durrhold comes on, due to amyloud degeneration of the intestine, or to tuberculous or scrofulous ulceration. The child is usually languid and easily tired. After exertion he is apt to look weary and haggard; but if kept quiet, his face, although pailed, shows no signs of distress. Often his fingers and toes are clubbed.

shows no signs of distress. Often his fingers and toes are clubbed.

A constant symptom of amyloid disease is anamia, and the poorness of blood is marked in proportion to the intensity of the degeneration. Consequently, in severe cases, the skin and mucous membranes are pallid, and some ordena of the legs and feet may be noticed. Still, no doubt, the kidneys in many cases participate in the amyloid disease, and the anamia and dropsy may be partially dependent upon the renal mischief. Albuminuria and casts may then be seen in the urine, but, as is elsewhere explained.

these are not necessary symptoms of albuminoid kidney.

Diagnosis. Mere enlargement of the liver is at once detected by palration of the belly. It must be remembered that a hepatic swelling often presses up the diaphragm on the right side, and may cause dulness and weak breathing at the base of the right pulmonary region. Such signs (dulness and weak breathing) may be mistaken for signs of a pleuritic effusion, more particularly as the signs are detected all round that side of the chest-in front as well as behind. A distinction may be made by noticing that in the case of an enlarged liver the dulness reaches up to a higher level in front than it does at the back (in pleurisy it is higher behind); that the dulness does not pass abruptly into resonance, as it would do in the case of fluid, for the thin border of the lung overlies the upper margin of the liver and produces a modified tubular or tympamitic note at that point; and, lastly, that there is no alteration of the percussion-note in the dull area when the patient lies on his left side. A dull note replaced by resonance on change of position is characteristic of fluid, and if the quantity of fluid be small, with little thickening of the pleura, this test of the effect of gravity upon the percussion-note will usually give satisfactory results in the child.

A liver enlarged from amyloid degeneration is smooth and particularly firm and resisting. It often feels hard like wood. Its edge is thin and not rounded, and pressure upon it produces no uneasiness. Such a liver, unaccompanied by jaundice or ascites, and found in a cachectic, pallid child who has a syphilitic history, or has been the subject of bone disease or other form of prolonged suppuration, is in all probability albuminoid. If the spleen is also enlarged, and there is albuminuria with hydrine casts, there can be little doubt of the correctness of this opinion. Absence of splenio

dulness does not exclude albuminoid disease, for an amyloid spleen is not always bigger than natural. In half the cases the size of the spleen is not increased.

Hepatic enlargement from congestion rarely occurs in cachectic, ametaic children; and a fatty liver is soft and yielding instead of hard and resisting; moreover, it is not accompanied by enlargement of the spleen or albuminums.

Proguess -The presence of amyloid degeneration of the liver in any cachectic child must necessarily be considered as an additional element of danger. There is, however, reason to beheve that this form of disease is of less serious augury in the young subject than it is in the adult, provided that the source of irritation and suppuration can be removed. It is undenuable that in cases in which enlargement of the liver and spleen exactly resembling amyloid disease complicates old-standing necross of bone in scrofulous children, removal of the bone disease by a suitable operation is often followed by a return of the liver and spleen to their normal dimensions, and, to all appearance, by complete recovery of health. Mr. Barwell has recorded some remarkable cases of this kind. In one of these the urmo was also albuminous and contained casts of tubes; but after the operation the urine gradually became normal, and the diseased organs eventually returned to their normal size. It may be objected that in such cases the enlargement is not due to amyloid disease. That it is so cannot of course be proved, as the crucial test of dissection is wanting. It can only be said that the organs diseased are those commonly diseased in albuminoid degeneration; that the symptoms and physical signs are such as are found in cases of this form of illness; and that the causes which are acknowledged to be powerful in producing albummoid lesions have been in operation.

Testment.—The treatment of amyloid degeneration consists, in the first place, in attending to the cause of the disease, and removing any long-tending suppurations and exhausting discharges which may be increasing the cuchexia and adding to the weakness of the patient. If necrosis of bone or suppuration of a joint be present, the aid of a surgeon is required. Fibroid induration of the lung, or a chronic fistulous opening in the chestwall, must be treated as directed in the chapters referring to these subjects. We must do our best, in the next place, to remove any secondary complications which may be helping to reduce the strength of the child. The bowels must be attended to; diarrhosa, if present, must be arrested, and if there be any reason to suspect scrofulous or tubercular ulceration of the intestinal mucous membrane, suitable remedies must be employed, as is elsewhere described. Vorniting must be checked by bismuth, dilute trussec acid, and the sucking of ice.

For the liver itself, the preparations of iodine are very generally recommended; and as there is always more or less amenia, iron may be judiciously combined with this treatment. I prefer giving the drugs singly, and have often prescribed (for a child of five years of age) five drops of the tructure of iodine to be given freely diluted before food, and five grains of the exsicuted sulphate of iron in glycerine directly after each meal. If the intestinal mucous membrane be healthy, this preparation of iron does not irritate, and given in sufficiently large doses, is of great value in the treatment of eachectic conditions in the child. If uteration of the

bowels be present, it is less suitable. The syrup of the iodide of iron so often disagrees, promoting acidity and flatulence, that I have long since abundoned its use. Iodide of potassium, combined with the citrate of iron,

may be employed; but the iodide should be administered in appreciable doses. It should be rarely given in smaller quantities than one grant for each year of the child's life. I cannot remember ever seeing any unconfortable symptoms, such as are common in the adult, produced by the remedy. Gardiner's syrup of hydriodic acid (M xx.-xxx.) is also appheable to these cases. Dr. Warburton Begbie speaks highly of the effects of marriate of ammonia in the adult. It may be given to the child in ten-grand doses freely diluted.

The dropsy, being the consequence of the anemia, must be treated with iron; and the chalybeate diuretic of Dr. Basham, recommended drewhere, is here also of service. If the bowels are healthy, an occasional dies of the compound jalap powder will further the removal of the subcutus

eous effusions.

The child must be put on a liberal diet suited to his age and powers of digestion; and if the kidneys are not implicated, he will be beneficially stunulants. The St. Raphael tonic wine is useful in these cases. A suitable climate adds greatly to the patient's chances of recovery. Dr. Beghe recommends a lengthened sea voyage; and there is no doubt that can be tions under which the child, warmly clothed, can pass the chief hour of the day in a fresh, bracing air, are the most favourable to permanent improvement. German writers speak highly of the sulphurous springs of Aix-la-Chapelle, and the waters of Eins and Weilbach, in their influence upon this form of hepatic enlargement.

¹ See page 780.

CHAPTER V.

PATTY LIVER.

Farry liver may be of two kinds. The one consists in a more abnormal deposition of fat-globules in the hepatic cells without any injury or degeneration of the cell-wall. This is called fatty infiltration. The other is fatty degeneration, in which the nutrition of the liver-cells is interfered with. They undergo a retrograde metamorphosis, and fat granules appear in them. Each of these varieties may be found in the child. They are most common

in infancy and the earlier period of childhood.

Causation .- Fatty infiltration of the liver may arise in the child from two causes: From overfeeding with farinaceous foods, and from various forms of exhausting disease. In the first case, the hydrocarbon is supplied from without, and being in excess, is deposited in the liver in the form of fat. Deposition of fat under such circumstances may be looked upon rather as a physiological than a pathological process. It is often a merely temporary phenomenon, and ceases when the diet is changed. In the case of exhausting disease, such as tuberele, scrofula, intestinal catarrh, syphilis, rickets, etc., the fat is reabsorbed from the subcutaneous and other fatty tissues. According to Oppenheimer, in infants dying during the second or third week of entero-colitis, the liver, although of normal appearance to the naked eve, is the seat of a real fatty degeneration. Fatty granules are seen in the hepatic cells along the whole course of the portal vessels, and the degeneration is preceded by the formation of an abnormal plasma in the cells which completely obscures the nuclei. In other structural diseases of the liver, fatty degeneration may occur as a secondary lesion.

Morbid Andony.—The size of the liver is not altered unless the fatty change is carried to a high degree. In that case all its measurements are increase I and its edge is blunted. The surface is lighter coloured than natural, and may have an oily, shining appearance. The hepatic substance feels soft and doughy to the touch, and the section is yellowish red or yellow. In extreme cases the blade of the knife looks greasy after the section. By the microscope granules and globules of fat are seen in the hepatic cells. The oily drops are larger in proportion to the stage to which the infiltration has advanced; and if the process be carried to a high degree, the cells may each be filled by one large drop of oil. The cells at the circumference of the lobules near to the intra-lobular veins are first and principally affected. Those towards the centre are much more healthy. Therefore, on closely inspecting a lobule, the part immediately surrounding the central vein will be found much redder in colour than the periphery. The fat consists of olein and margarine, with traces of cholesterine.

Symptoms.—If the organ is not enlarged, and the degree of fatty infiltration is slight, symptoms may be absent altogether. Even if the liver is enlarged, there is little to draw attention to the belly. Some tenderness may be noticed in the right hypochondrium when this is pressed, and in exceptional cases the child may complain of a feeling of heaviness on that side. Cases where the size of the liver is notably increased from this case are usually those of phthisical children. There may be some digestical rangement from interference with the portal circulation, but there is not jumidice or ascites. The fatty liver is not always easy to feel as it yields readily under the finger, and is easily depressed from the surface. Casequently, like the softened spleen in typhoid fever, its edge may clude the touch. It is of the utmost importance, in consideration of cases and to these, to lose no opportunity of practising the sense of touch and accusating the finger to appreciate slight differences in resistance.

In fatty degeneration of the liver, there is no increase in size of the regan, and the disease, occurring as it does in the course of some exhausting illness, gives ruse to no symptoms which can reveal its presence. It is then

fore seldom discovered during life.

Dagnosis. - A liver enlarged from fatty infiltration differs from other forms of enlarged liver. Instead of being firm and resisting, its substances soft and yielding; and the edge, instead of being sharp and thin, is round and blunt. Such a liver found in a case of tubercular or screfulous pt the or in the course of some other exhausting disease, unnecomparted by dire, ascates, or dilatation of the superficial veins of the abdomen, is a ... probability fatty. Thus, in a little girl, aged three years, the subject of chronic hydrocephalus, who died in the East London Chaldren'- H - In from acute tuberculosis, the hver on the child's admission was four to reach as fir downwards as the level of the umbilious. Its isless win rounded and its substance seemed to be normal. There was no be a jaundice; the superficial veins of the belly were not visible, for could by fluctuation be detected in the abdomen. The spicen was also enlarged After death, the liver was found to be greatly increased in size. Its ave sistence was softer than natural, its colour a fawn brown, and some value indiary nodules were seen on the surface. Its section had a great and The spleen, which was also enlarged, was studded with tuberch a

Proposes. A remarkably fatty liver occurring in the course of a large ing illness implies serious interference with nutration; but the proposed depends more upon the primary disease than upon the state of the last

Treatment.—The indications for treatment must be derived from the primary disease in the course of which the fatty condition of the organism. If a child is known to be taking extraogent quantities of Single cours food, measures must be taken at once to put a step to such a consequence of such a dietary. This subject is treated of elsewhere (see Gastrie Catanian)

CHAPTER VI.

HYDATID OF THE LIVER.

Hyparm of the liver is sometimes found in childhood. The disease seldom occurs earlier than the fourth year of life, although Cruveilhier has quoted a case in an infant twelve days old, and M. Archambault has seen it in a child aged three years and a half. Between the fourth and eighth year it is sometimes met with, but is still rare. After the eighth year it is more common. The earliest age at which the disease has come

under my own notice has been five years and a half.

tausation.—The hydatid growth becomes implanted in the human liver as a result of the introduction into the stomach and intestines of the ova of the tenia echinococcus. This creature is a parasitic worm inhabiting the alimentary canal of the dog and wolf. The tape-worm is a quarter of an inch in length, and has four joints, the last of which (the proglottis or sexually mature segment) contains the ova. The ova are excreted by the animal in whose intestines they have found a lodgment, and contaminating water or articles of food, become introduced into the human body. It is probable, also, that the ova and scolices may be sometimes conveyed to the child directly. In the dog, the presence of the worm in the bowels, and the passage of the eggs and embryos in large numbers through the anua, causes considerable irritation, which the animal endeavours to relieve by licking. If directly afterwards he apply his tongue to the face and mouth of the child, the parasite may pass at once to the child's tongue and be swall oved. How it travels from the alimentary canal to the liver is not clear.

Hydatid disease is endemic in Iceland, where the children are often affected. The enormous number of dogs maintained on the island has been suppose I, with much probability, to be the explanation of the frequency of the disease.

Morbid Anatomy.—Hydatid tumours are more common in the liver than elsewhere in the body; but from the intestine they may pass not only into the liver but also into the spleen, the mesentery, the wall of the abdomen, and even into the substance of the heart and brain. The liver may contain one suc or several. The sac itself consists of a firm fibrous capsule in close adherence to the liver substance, and is very vascular. Inside the capsule there is a clear gelatinous bladder (the envelope of the vesicle; composed of numerous fine concentric strata. This is the mother sac. It contains numerous large and small vesicles floating in a clear fluid, or adherent to the investing envelope. Some of the larger of the daughter vesicles may contain smaller sacs still of a third generation. These are seldom larger than the head of a medium-sized pin. The mother sac itself varies in size from a pea to a marble, an orange, or a child's head. The fluid it contains is non-albuminous and holds in solution salts, principally the chloride of sodium. On careful examination of this fluid, the hooklets

of the embryos (scolices) of the trenia echinococcus may be often recog-

nised by the microscope.

The sculces themselves may be sometimes found. These are from one-twentieth to one-sixth of a line in length. The head, which resembles that of the tenia, has four suckers and a trunk. The latter is encircled by a double crown of hooklets, the number of which varies, according to Kuchenmeister, from twenty-eight to thirty, or from forty-six to fifty-two. The head is separated from the body by a groove, and at its posterior end is a depression into which a cord is inserted. This attaches it to the inner wall of the sac. The shape varies according as to whether the head is stretched out or retracted. On the body, clongated lines are seen passing backwards from the head. These are intersected by transverse striss. Besides these markings, a number of rounded calcareous corpuscles can be detected. The scolices he in groups on the inner wall of the cyst, and can be seen through the vesicular wall as delicate white particles. Sometimes the mother sac contains scolices but no daughter vesicles. Sometimes it contains neither vesicles nor embryos.

The sacs may be seated at any part of the liver, but are more common in the right lobe than in the left. The liver is generally enlarged by them, and may appear uniformly swellen if the sac is deep seated. It superficially placed, the cyst raises a bump or tumour at the corresponding part of the surface. When it lies close under the peritoneal coat of the liver, this membrane becomes thickened and may form adhesions with parts around. The pressure of the sac upon the parenchyma of the organicanses destruction and strophy of the hepatic tissue. The larger blood vessels and bile-ducts are seldom affected; but occasionally the ducts may be obliterated, or a communication may be formed between the sac and large duct or blood-vessel. In such cases the death of the cyst usually fol-

lows.

After a time changes generally take place in the mother sac. rupture from over-distention, and only a few shreds of the original vesicle may be left amongst the daughter cysts. Sometimes the sac suppurates or is converted into semi-solid atheromatous matter composed of phosphate and carbonate of lime, cholesterme, and a substance resembling allouner-In other cases adhesions may be formed with neighbouring parts, and the cyst may burst into the stomach or bowels, or through the disphragm' into the pleura or lung. Accidental injuries have caused rupture of the cyst and extravasation of its contents into the peritoneal cavity. In rare cases the hydatid sac has been known to open externally through the abdominal parietes or a lower intercostal space. After escape of the fluid by any of these means, suppuration of the cyst may still take place, and pyæmia is one of the consequences which may result. Sometimes although rarely, the increase in thickness of the capsule, which may acquire a cartilaginous consistence, so interferes with the development of the echinococcus that death ensues and a spontaneous cure is effected. This however, is not likely to occur except in hydatule of small size which have not been detected during life.

Symptoms.—When the cyst is small and is planted deeply in the substance of the liver, it may give rise to no symptoms at all. In most cases, however, the liver becomes enlarged, but not uniformly. A tumour is felt at one part of the organ which may project upwards into the chest or downwards into the belly. The swelling is painless as a rule, and may give rise to no uneasiness, but a feeling of weight. It is smooth, round, often clastic, and may convey a distinct sense of fluctuation. Sometimes, however,

m in a case to be afterwards narrated, it feels firm and solid like a fibrous growth. In exceptional cases a sense of vibration, first described by Prorry as the "hydatul fremitus," is felt by sharply percussing the finger allowed to rest upon the tumour. This vibration, according to Dr. Sadde, denotes the presence of daughter vesicles. Therefore, if vibration is absent, we should expect to find few or no hooklets. Occasionally, pain has been noticed from mere distention, as in a case mentioned by Prerichs, where the pun ceased after puncture and removal of a quantity of watery fluid from the cyst. As a rule, pain, if present, indicates inflammation and suppuration of the sac.

As the tumour seldom interferes with the channels of the bile-ducts or portal vessels, jaundice and ascites are rare, and dyspeptic symptoms are teldom observed. In ordinary cases, therefore, the nutrition of the child is not interfered with, and there is no fever. The patient is brought for advice merely on account of the unusual size and unilateral hardness of his belly. In young subjects the projection, as a rule, is readily detected by the eye, and if seated near the convex surface of the right lobe, as it usually is, forms a swelling which protrudes downward from beneath the lower vibra.

A little boy, aged five years and a half, was brought to me at the hospital on account of the size of his belly and occasional pains which he complained of in the right hypochondrium. He had, besides, some cough in the morning. On examination of the abdomen, a prominent swelling was discovered in the hepatic region, bounded above by the ribs, and below by a line drawn just below the level of the navel. Its transverse measurement was three and a half inches. The liver dulness began above one finger's breadth below the nipple, and its lower edge could be felt just below the lower border of the tumour. The swelling was smooth, clastic, and gave a semi-fluctuating sensation to the finger. There was no hydatid fremnus. When pressure was made upon it, the child funched and said it was sore. There was no jaundice, ascites, or prominence of the superficial abdominal veins. The swelling was punctured with the pneumatic aspirator through the abdominal parietes, and about an ounce of purulent matter was evacnated. No hooklets could be detected. Ten days afterwards the cyst had refilled. It was again punctured, and a quantity of perfectly clear fluid escaped. The cyst did not again refill, and the size of the liver was greatly reduced when the child left the hospital.

Sometimes the tumour, instead of becoming visible in the belly, may press upwards the right side of the diaphragm and the base of the lung, and project far into the right side of the chest. In such a case the lower ribs on that side are pushed outwards, and the physical signs very much resemble those of a pleuritic effusion. Even if the tumour project but alightly upwards, the respiratory sounds are usually very weak at the right posterior base of the chest, and the percussion-note may be a little higher

pitched, with increased sense of resistance.

If, instead of projecting from the convexity of the organ, the hydatid sac protrudes from the under aspect of the liver, pressure signs may be observed in connection with the biliary and vascular conduits. It is in these cases that joundice, ascites, and ordems of the feet may be noticed.

If spontaneous suppuration take place in the hydatid sac, the symptoms vary in severity. They may be grave or triffing. In some cases a slight rise in the temperature of the child occurs; he looks a little poorly; coughs, and complains of pain when his belly is manipulated, but nothing is noticed to excite the alarm of the parents. In other cases he shavers,

and his temperature undergoes the rapid alternations peculiar to suppuration; the swelling increases in size, and, if left alone, either points at some part of the surface, or sets up adhesive inflammation with a neighbouring organ and bursts into it. The proof that such an abscess is the result of a hydatid eyat is the finding of hydatid membranes or hooklets in the evac-

unted pus.

If the cyst be not interfered with, it will probably in time destroy the life of the patient by bursting into some neighbouring organ. Bohn has related the case of a child eight years of age, in whom the sac burst into the bowel. The patient recovered; but a favourable issue to so severe a complication must be rare. The cyst usually bursts into the cavity of the chest—into the pleura or the lung. Death is a frequent consequence of either accident. In the latter case pneumonia is set up, and the patient dies worn

out by the profuse discharge.

Hydatid of the liver may be complicated by a similar development in the spleen, in the folds of the mesentery, or beneath the peritoneum. It is important to be aware of this possible distribution of the echinococci, as the presence of various tumours in the abdominal cavity may tend to embarrase the diagnosis. Sometimes the lungs as well as the liver are affected. These various cysts often appear to be of different ages, and in that case may arise from absorption of embryos at different periods of time. It has been suggested that germs generated by the elder hydatids may be carried along by the current of blood and deposited in other organs; but in this case they could hardly be conveyed from the liver to the spleen or mesentery against the direction of the blood-current.

Diagnosis — The diagnostic features of a hydatid tumour of the liver are:—A localised swelling of the organ, smooth, elastic, and painless, accompanied by no signs of jaundice, ascites, prominence of the superficial abdominal veins or swelling of the feet, and giving rise to no pyrexia or impairment of the general health of the child. If the characteristic fremitus can be detected on percussion of the swelling, the evidence is com-

plete.

If suppuration have occurred in the sac there may be some fever, and the child looks ill and pale. Pain may be complained of in the right hypo-

chondrum, and the tumour may be tender when pressed upon.

If the tumour feel solid to the touch, as was the case in a child who was under my care in the hospital, the diagnosis would rest upon the slow growth and painless condition of the swelling, and the general absence of symptoms. I have never met with a surcoma or soft cancer of the liver in a child, but it is possible that this disease might be mistaken for a hydatid cyst. The growth, however, would be more rapid in such a case, and we should expect to find some impairment of the general health. In any case of doubt an exploratory puncture with a fine trocar and cannia will remove all hesitation. If a non-albuminous, clear, or slightly turbid fluid escape, especially if hooklets can be discovered in it by the microscope, the diagnosis of hydatids is clear.

If a large cyst project upwards into the chest and compress the base of the lung, it is often mistaken for a pleuritic effusion. The error is one which is easily fallen into, for in both cases there is complete dulness, with increased sense of reasstance and weak breathing, all round the right side of the chest. A distinction may be made by observing that in the case of a hepatic cyst the upper line of dulness is curved with the convexity upwards and that the dulness, therefore, reaches higher in the mid-axillary line than at either the front or the back of the chest. In pleurisy an

exactly opposite condition is found. The upper margin of dulness is concave, being less elevated in the infra-axillary region than at the back. If there is any suspicion that the disease is not pleurisy, an exploring trocar, allowing of examination of the fluid, will soon set the matter at rest. The fluid drawn from the chest in pleurisy coagulates on boiling, while the hydatid fluid, as has been said, is non-albuminous.

In the rare cases where jaundice and assites are produced by a hydatid cyst placed near the concavity of the liver, no localised swelling can be detected, and a diagnosis is hardly possible unless we can satisfy ourselves by puncture or otherwise of the presence of a similar cyst in other organs.

Prognous.—If the child is seen before injury has been inflicted upon neighbouring organs by bursting of a hydatid sac into them, the prognoms is favourable; for the slight operative procedure necessary for the evacuation of the fluid and destruction of the cyst and its contents is usually well borne. If the sac has been evacuated into a neighbouring organ, the situation is a very serious one, and most of these cases prove fatal.

Treatment. Although many internal remedies have been administered in the hope that the drug might pass from the blood to the interior of the cyst, and so destroy the life of the hydatid, it is now admitted that such an object is not to be attained by physic. Our only means of curing the patient is to puncture the cyst and evacuate its contents. If this he done with a fine trocar and canula, there is little risk of escape of the fluid into the peritoneum, and consequent peritorita. It is best to employ the pneum the aspirator, so as to prevent the entrance of air into the sac. After the withdrawal of its fluid contents, the hydatid cyst collapses and its membrane shrinks away from the investing capsule. The resulting space is rapidly filled by exuded serum, and the hydatid quickly dies. Sometimes the operation requires to be repeated. It is usually unnecessary to employ irritating injections after emptying the sac, but if the cyst continually retills, it may be desirable to do so.

A healthy-looking, well-nourished girl, aged twelve years, was under my care in the Victoria Park Hospital, for a swelling in the right side of

the belly which had been first noticed two months previously.

On examination it was seen that the lower ribs on the right side were distinctly prominent, and that the intercostal spaces at that part were widened. The liver dulness began at the lower border of the fourth rib, and the inferior edge of the organ could be felt just below the level of the umbilicus. Immediately below the ribe, a solid-feeling tumour was discovered. This gave no clastic sensation to the finger, and was not at all tender when pressed upon. It descended somewhat on deep inspiration. Below it the substance of the liver could be felt of normal density, conveying to the finger a very different sensation to the solid resistance of the tumour. Posteriorly, the hepatic dulness began at the lower angle of the scapula, and complete dulness one interspace lower down. The respiratory sounds were weak at the right base behind, and some friction was heard in the infra axillary region and at the base in front (the child had had pleursy eighteen months before). There was no jaundice or ascites, and the superficial veins, although more visible than natural over the front of the chest, were not dilated in the epignstrum or on the abdominal wall. The heart's apex was in the fifth interspace in the nipple line. Its sounds were healthy.

An exploratory puncture was made in the tumour with a hypodermic injection syringe, and some colourless fluid containing chlorides but no alba-

men was withdrawn. No hydatids could be discovered in the fluid by the microscope. Some days afterwards the tumour was again punctured with the aspirator through the eighth interspace, and twenty ounces of a clear, straw-coloured fluid were withdrawn, having the characters above mentioned. Its specific gravity was 1.008. No hooklets could be seen under the microscope. A solution of iodine (half a drachm of the tincture to half an ounce of water) was then injected into the cyst, and the child took

a draught containing five drops of landanum.

The operation was followed by no rigors, sickness, or other sign of discomfort; but the temperature rose every night to between 101° and 102°, saking in the morning to nearly the normal level. A fortinght after the first operation, the tumour being rather more prominent than on the child's admission, the cyst was again punctured, and twenty-three ounces of thick greenish pus were drawn off. In another fortnight the operation was repeated for the third time, removing eleven ounces of greenish pus. This was quite sweet, and under the microscope showed hooklets and signs of hydatid dibries. On each of these occasions the cyst had been tapped through the chest-wall; but ten days after the last operation, the cyst inving again refilled, the needle of the aspirator was introduced through the abdominal parieties and twenty-three ounces of pus were evacuated. The operation set up some local peritorities; but this was quickly reduced by poulticing and the administration of six drops of laudanum three times a day.

After the last operation the cyst did not fill again, and when the grillest the hospital a month afterwards, there was slight curving of the spino with the convexity to the lest; the right shoulder and angle of the scapula were a little depressed; the edge of the liver was selt one men above the umbilities, and its upper border was on a level with the nipple. Its substance selt normal to the touch, and there was no distention or tenderness of the belly. Six months afterwards, when the child was seen again, the liver had returned to its normal size; the spine was perfectly straight; the shoulders were on the same level, and no indication was left that the

girl had ever been ill.

Injection of rodine after the evacuation of the contents of the sac is not necessary to the success of the operation. It is usually found that simple emptying of the cyst is sufficient to destroy the life of the hydatid and that irritating injections are usoless. In every case the child should be kept very quiet for a day or two after the puncture, and a firm bandage should be applied to the belly. It is well, also, to give a little opium at night, as was done in the case above narrated.

A sufficient time should be allowed to clapse after evacuating the fluid before repeating the operation. The cyst will often seem to be tilling up again for a time; but, if left alone, it frequently subsides without further

interference and gradually becomes obliterated.

Dr. Fagg has reported several cases of hydratid tumour of the liver in children which he had treated by electrolysis in the manner recommended by Dr Althaus. The operation was performed by passing two electrolytic needles note the cyst, one or two inches apart. The needles were then stached to two metallic wires both connected with the negative pole of a galvanie battery of ten cells. A moistened sponge formed the termination of the positive pole; and this was placed on the patient's skin, at a little distance from the points of entrance of the needles. Its position was changed from time to time during the operation. After the current had passed for about ten minutes, the needles were withdrawn and adhesive plaster was applied to the seats of puncture.

The operation was usually followed by a little febrile disturbance and some pain: but no immediate effect upon the size of the tumour was discoverable. Indeed, the children were sent away from the hospital in much the same state as when they were admitted. But examination, after a period of months, usually detected considerable diminution in the dimensions of the cyst. The operation appears, therefore, to be attended by no danger; but its results are too alow in making themselves manifest to render it smalle for adoption in private practice. With regard to the modus operandi of the procedure, Dr. Fagg suggests that the gradual subsidence of the tumour may be due to slow occing of the hydatid fluid through the punctures made by the needles; for hydatid fluid alone, unaccompanied by over or scolices, appears to be innecuous when extravasated into the peritoneum.

If suppuration have occurred in the sac, and the matter withdrawn be putrid and offensive, the cyst must be washed out frequently with a weak antiseptic solution; opium should be given to allay pain and irritation; and quinine in full doses, with nutritious diet and stimulants, will be required.

Part 11.

DISEASES OF THE GENITO-URINARY ORGANS.

CHAPTER I.

THE URINE

On account of the difficulty of collecting the urine in very young children, it is seldom possible to estimate the average quantity passed in the twenty-four hours. It is not always easy to obtain the quantity necessary for es-

amination of its chemical characters.

In health, the water is clear, light-coloured, and of low specific gravity; but it is subject to frequent variations on account of the readiness with which the child responds to every disturbing agency. The quantity secreted is dependent upon certain conditions, such as :- The degree of blood-pressure in the renal arteries; the facility with which the urmary tubules discharge their contents; and the state of the nervous system generally. Also upon the condition of the other emunctories of the body, the quantity of fluid taken, and lastly, upon the state of health of the individual. Consequently the water passed varies greatly in amount. Sudden copious secretion may be a temporary symptom in many cases of digestive derangement; in particular, attacks of severe abdominal pain are often terminated by a copious flow of almost colourless urine from the bladder. Also, an epileptic seizure, an attack of ague, or a fit of convulsions in the child may be followed by a profuse secretion of limpid urine. Various articles of food seem to have a direct action in promoting secretion from the kidneys. In some children barley-water has this effect; and the nurse complains that while taking it, the child is almost "constantly wet." Again, certain diseases are accompanied by an increased flow of urine. Diabetes incilitus, and diabetes insipidus are in rare cases seen in children. The former, however, uncommon at any age under puberty, is almost unknown under five years of age. The latter is sometimes an accompaniment of gastro intestinal disorders, but ceases usually when the digestive organs have been put into a better condition.

Diminution in the quantity of water passed is the result of many different causes, and usually attracts more attention than the opposite condition. The skin in some children acts very freely; and in warm weather a large proportion of the fluid may leave the body by this channel. In such a case the urine may be very scanty. One morning in July a child aged

ten months was brought to me on account of the small quantity of urine she was passing. During the preceding twenty-four hours she had passed water but once, and then in very small quantity on the evening before the visit. The weather was very warm, and the child perspired profusely, but except for slight costiveness was and seemed perfectly well. I quieted the alarm of the mother, advised that the child should be given pleuty of fluid, and ordered a gentle aperient to relieve the bowels. After this, the mother was soon made happy by seeing a more copious secretion of urine. The amount of water is also diminished by diarrhosa and vomiting, which derangements, as in the preceding case, divert a certain quantity of water from the kidneys. When the reduced secretion is due to a watery flow from the bowels, it may be unnoticed by the attendants; but when the symptom is an accompaniment of vomiting, the small quantity of water passed from the bladder is often a cause of anxiety. In cases of extreme prostration from dencient nourishment in infants, the secretion of urine is scanty and may be completely suppressed. Indeed, Dr. Parrot attributes the cerebral symptomy which sometimes occur in such cases, and are called "spurious hy irrocephalus," to toxic causes, the blood being charged with excrementithous matters which it cannot get rid of. In the februle state, the urinary water is diminished in quantity, and is increased again as the temperature There is, however, no reduction in the solid constituents of the arme, and the specific gravity is consequently raised. Besides the above causes which act through the system generally, other and local causes which interfere with the secreting function of the kidneys may have the same result. Thus, congestion of the kidneys from disease of the heart or liver, and Bright's disease, may reduce the quantity of water to a very umall amount.

Variations occur not only in the quantity of water passed from the kidneys, but also in the amount of solid matters excreted. Thus, in februle discuses the urine is not only more concentrated from deficiency of water, but it is richer in urea and uric acid, although poorer in chlorides. In health the quantity of urea passed by a child is relatively greater than it is in the adult. According to Uhle, children between three and six years of age pass in the twenty-four hours one gramme of urea for each kilogramme of their weight. This fact is important as indicating the active metamorphosas of the protein compounds of the body which occurs in early life.

It has been said that the water of a young child in perfect health is quite clear. In the normal state it is also slightly acid. Very slight causes will give rise to an increase in the amount of said secreted, and the water is then apt to be thick with lithates. As in older persons, the turbidity generally occurs as the urine cools on standing; but sometimes it is turbid while still warm, and may even be passed thick from the bladder. Infants, especially, sometimes alarm their mothers by voiding water thick and milky-looking from a profuse secretion of urate of soda. The appearance of a deposit of lithates may be due to two causes :- To increased secretion of the salts, and to excess of acid in the water. Young children who are habitually overfed continually pass water loaded with hthates; and if they are taking inordinate quantities of fermentable material in their food, the amount of acid is also greater than normal. Thus, both the causes which conduce to turbulity of urine are present. During convalescence from cute disease in a child, when it is our object to further the return of flesh and strength by an ample supply of nourishing food, and at the same time to avoid overburdening the digestive organs by an excess of nutritive material, the state of the water offers a very good index as to whether the necessary quantity has been exceeded. If the child is eating too much his water becomes at once thick with lithates, and warns us to make some reduction in the quantity, or alteration in the quality of his meals.

Besides lithates, young children, and even infants, may pass free uric acid in their water. This subject will be considered afterwards (see Cal-

culus of Kidney).

The urine in infants is sometimes noticed to be very offensive. This is due to a catarrhal condition of the bladder, and denotes rapid decomposition of the urea. Another symptom sometimes complained of by the mother is that the water is very dark in colour and causes stains on the diaper. This may be the consequence of the presence of bile-pigment in the urine.

Albumen is often found in the urine of children, but must not be looked upon as in every case indicating disease of the kidneys. It is seen in many inflammatory complaints and fevers, as in pneumonia, diphtheria, measles, typhoid fever, etc. In such cases it is probably dependent either upon an altered condition of the blood, when it is an expression of the general disturbance of the system induced by the illness, or upon an infectious nephritis, which is found, according to M. Bouchard, in many forms of acute specific fever. Again, a casual admixture of blood or pas with the urine may give rise to the presence of albumen, as in cases of irritation of the urinary passages by calculous concretions. Passive congestion of the kidneys, such as takes place in many cases of heart disease and in some forms of bronchitis, may be a cause of the same symptom, and the albumen may be accompanied by epithelial and blood casts. But in these cases the presence of the albumen, and even of the casts, is no indication of organic disease of the kidneys. We are only justified in inferring the existence of renal disease when we find by the incroscope hyalme or granular casts in conjunction with the albuminuria. A transient albuminuria is sometimes met with, and appears to be a result of some bodily derangement quite independent of renal disease. It may be found in school-boys who are preparing for examination. Dr. Kinnicutt attributes it in many cases to a transient oxaluria or lithuria. It has also been seen in ague districts as a consequence of malaria. Intermittent albummuria—albumen being abundant one day, absent the next—is usually due to an admixture of secretions, and should lead us to suspect a liabit of masturbation.

As in older persons, the wrine of children and even of infants may contain blood. This may be poured out from any part of the urinary passages. When the source of the blood is the urethrn or bladder, the two fluids are passed separately without mingling together. Thus, in a case of vesical calculus, the child passes first water and then a little blood from the bladder. When the two fluids are intimately blended, we are justified in concluding that the blood comes from the kidney. Renal harmorrhage is not very uncommon in young subjects, and may occur in large or in small quantity. When in large quantity-in quantity sufficient to give a dark red colour to the whole volume of urine—the blood may be usually ascribed to one of two causes; either to hamorrhagic purpura or to irritation of the kidney by calculous concretions. In the first case there are signs of humorrhage from other mucous passages and into the skin. In the second, the child may complain of no pain, and appear, except for the harmorrhage, to be perfectly well. In smaller quantities, often enough merely to give a smoky tint to the urine, hæmaturia is seen in acute Bright's disease, in hismorrhagic measles, in scarlatina, diphtheria, and small-pox; sometimes,

also, in ague. Even after suppression of urine in young children suffering from inflammatory diarrheea, the renal secretion when the function of the kidneys is restored, may contain blood. In fact, wherever albumen is present in the urine blood may be present as well. In all such cases the blood-corpuscles may be recognized by the microscope. Occasionally, especially in scarlatina before the appearance of albuminumia, the urine may contain the colouring matter of the blood, but without any of the corpuscles

being discovered by microscopical examination.

There is a form of hæmaturia which is common in some parts of Africa, especially in Egypt and the Cape of Good Hope. The hæmorrhage is due to the presence of the Bilhamia hæmatobia (genus Hematodia). This parasite is found in the portal and mesenteric veins, and in the kidneys and urinary passages. According to Dr. James F. Allen, almost every boy in Natal suffers or has suffered from this parasite, for the embryos develope in water and abound in the running streams. The garls, who stay more at home and drink filtered water, commonly escape. The creatures enter the system by the stomach from drinking the water, or by passing directly into the bladder through the urethra while the boy is bathing. Amongst the natives of South Africa a practice is said to prevail, before entering the water, of tying a piece of tape round the end of the penis to prevent the

entrance of the parmite.

The hemorrhage appears to come from the bladder. After micturition a little blood is passed from the urethra. The quantity is often only a few drops, but may reach several ounces. It occurs on each occasion at the end of the flow of urine. Its passage is nearly always accompanied by a rigor, and sometimes by pain and irritation referred to the bladder. On examination of the urine it is found always to contain blood, more or less albumen, and a quantity of mucus. In severe cases its reaction is alkaline, and it contains triple phosphate crystals. Under the microscope the ova of the biharzia are seen entangled in the blood-clots and free among the blood-corpuscles. They are $\frac{1}{16}$ inch long, ovoid in form, and have a spike at one extremity. If the ovum is broken under the microscope, by pressure of the two glasses against one another, the living embryo may be seen to emerge from its shell. It is ovoid in shape, like the egg, is pointed at one extremity, and projecting from the sides are innumerable cilia, which seem to be always in motion.

The result of the constant loss of blood soon manifests itself. The boy, although tall, is pale and narrow-chested. He has little appetite, is listless, and shows no energy, either mental or physical. Children are said to began to suffer from the parasite at a very early age; but soon after puberty the hamorrhage ceases and the patient recovers. It appears

never to be fatal

Dr. Alien states that internal treatment of every kind, although it may destroy the parasite in the blood, fails to influence the local symptoms or arrest the harmorrhage. To do this local treatment is necessary. He advises the injection into the bladder of a saturated solution of santonine in absolute alcohol. Of this, a quantity varying from half a drachm to two drachms must be used when the bladder is empty, and must be retained as long as possible. The injection sets up a mild cystitis, which should be treated with hyoscyamus and infusion of buchu. If the larger quantity of santonine be used, the patient feels drunk from the remedy affecting the brain, and the cystitis lasts three or four days, instead of merely one or two; but no other ill effects are noticed. The injection may have to be repeated several times, but is invariably successful in the oud.

Afterwards cantonine should be given by the mouth to destroy any cal-

bryos remaining in the blood.

Besides santonine other local applications have been suggested. Iodide of potassium and the liquid extract of male fern are both well tolerated by the bladder. Dr. John Hurley recommends a druchm of the fern extract to be diluted with barley-water and injected into the bladder. Iodide of potassium may be used of the strength of fifteen or twenty grains to the fluid ounce. Dr. J. Wortnbet speaks in favour of the internal administration of oil of turpentine, and records a case in which

a complete cure was effected by drachm doses of this remedy.

Retention of urine is not very common in young children. It may however, be induced by mechanical causes. Thus, some little boys have a very long prepace, with a narrow opening, through which the urine is forced with difficulty. This extra-urethral stricture forms a great obstacle to the complete emptying of the bladder, and may be a cause of serious injury to the health. Cases are occasionally met with in which dilatation of the bladder, ureters, and pelves of the kudneys have been unduced by such long-continued retention and pressure. Another common consequent of the straining efforts which usually accompany the attempt to evacuate the bladder is prolapsus ani. Retention of urine may also result from the presence of a calculus, which, becoming impacted in the urethra, prevents the passage of water from the bladder. I have even known such an accident to lead to rupture of the membranous part of the arethraand extravasation of the urine. Again, irritation of the rectum by worms may be a cause of spasmodic retention of urine. Violent blows upon the lower part of the abdomen may produce a temporary paralysis of the bladder and retention. Lastly, in some cases of febrile disease, such typhoid fever, we occasionally find distention of the bladder from atom of the muscular coat.

Incontowner of urine, or enursis, as it is called, is a much more familiasymptom in young children than retention. Involuntary passage of the water may occur in the night or in the day; and sometimes the child in mable to control his bladder either by day or by night. This distressing infirmity is far from uncommon. It may date from birth, or may be at quired later. When acquired, its first occurrence has been attributed to fright; but it is a popular impression that all nervous derangements are excited by some shock to the nervous system, and too much importance must not be attached to this explanation. In cases where it is not due to manifest weakness of mind or pure laziness of body, and where no disce dered condition is present to which the incontinence can be attributed, we may sometimes, by careful examination, detect some external source of unitation which requires removal. Thus, the urine may be habitually too acid, and deposit crystals of uric acid; there may be phimosis, allowing of accumulation of irritating secretion beneath the prepuce; the urethral oritice may be narrowed externally; the prepuce may be wholly or in part adherent to the glans; or again, great unitation may be excited in the neighbourhood by thread-worms in the rectum. In a sensitive child irritation at some distance from the bladder may act as the exciting cause; Thus, enuresis may be the consequence of chronic disease of the hip-joint and may cease when, by rest and proper mechanical appliances, the critical tion of the joint has been subdued. Sometimes the most careful investigation fails to discover any such exciting cause. The incompetence then attributed to general irritability of the nervous system, or to "spinal irritation.

The mechanism of the phenomenon is well understood. Owing to causes which may or may not be capable of explanation, there is excessive irritability of the muscular fibres of the bladder. Under normal conditions the bladder is closed by the contraction of the sphincter vesices, whose office it is to resist the action of the fibres forming the muscular coat. If necessary, the involuntary contraction of the sphincter can be reinforced by the exercise of the will. In the more common form of incontinence, where the involuntary passage of urine takes place at night only, the urntability of the muscular coat is exaggerated, and the resistance of the sphincter is relatively deficient. There is no atony of the sphincter, but on account of the increased pressure against which it has to contend it requires to be strengthened by voluntary agency. During sleep the agency of the will is removed, and the sphineter can no longer effectually resist the action of the irritable muscular fibres, so that the contents of the bladder are discharged. In cases where, in addition to the abnormal excitability of the muscular coat there is a certain degree of atony of the sphineter, the patient has little control over his bladder even during the daytime. Micturition is frequent, and when the desire to pass water manifests itself, it can hardly be resisted even for a few seconds.

This derangement has been classed amongst the neuroses, with epilepsy, chorea, and other similar affections. According to Trousseau, it is often found in families prone to epilepsy, and may thus be a hereditary failing. It cannot, however, be always attributed to a faulty condition of the nervous system. In many instances it appears rather to be due to the active reflex sensibility which is normal to the healthy child. These are the cases in which the enuresis is manifestly the consequence of some external source of irritation, and ceases when this is removed. We know how promptly, in health, the nervous system of a child responds to reflex stimuli, and we constantly have occasion to observe the perturbation into which the whole system is thrown by the action of some external irritant. No doubt the class of cases in which the power of controlling the bladder returns "of itself," more or less suddenly, are cases of this kind. As the child grows older, the extreme sensitiveness of his nervous system to external impressions becomes dulled. The only variety of enuresis which can be classed justly amongst the true nervous affections is that in which the incontinence is hereditary, or occurs in families subject to epilepsy or other form of neurotic disease, or is apparently a consequence of nervous instability without any external cause being discovered to which the faulty

action can be attributed

Enuresis, when acquired after infancy, is generally observed first between the third and fourth years. It is seen as often amongst the strong and robust cluldren as amongst the thin and delicate; but is, perhaps, more common in boys than in girls. The more obstinate forms of this infirmity are, however, more common in the female sex, probably because in them the complaint is less often the consequence of external irritation. In ordinary cases the accident occurs only at night, and even then not every night. Often for a week or more the bed remains dry. Then it is wetted regularly for several nights in succession, and sometimes the accident occurs on the same night several times. It is usually during the early hours, or later towards daybreak, that the child's bladder seems to be least under control; and it is at these times that the incontinence is

it must not be forgotten that nocturnal incentinence of urine may be the only sign of the occurrence of true epileptic attacks in the night

usually manifested. After continuing for a variable time the infirmity may disappear without treatment. The periods of second dentition and of puberty are popularly supposed to be sometimes marked by this favourable change.

In the treatment of enursis our first care should be to search for any source of external arratation. If this can be found, its removal forms the first step to a cure, and indeed the case may require no further treatment. Thus, the removal of an elongated prepuce; the separation of adhesions between the prepuce and the glans; the expulsions of thread-worms, or suitable medicines by which too great acidity of urine has been remedied all of these measures have been followed by immediate relief from this distressing complaint. Sometimes, however, such measures have to be supplemented by others, directed to lessen the abnormal irritability of the muscular coat of the bladder. In all such cases care should be taken that the child drinks little towards evening, and empties his bladder completely before he goes to bed. Moreover, if the incontinence occur in the early hours of the night, the nurse should be directed to take up the child and see that his bladder is properly relieved before herself retiring

Of medicines which diminish irritability, belladonna takes the first place; but it is important to be aware that this remedy, to be effectual, must be given in full doses. Children have a very remarkable tolerance for belladonna, and will often take it in surprising quantities before any of the physiological effects of the drug can be produced. In obstinate cases of enuresis the medicine should be pushed so as to produce dilatetion of the pupils with alight dryness of the throat. In children of four or five years of age it is best to begin with twenty-five or thirty drops of the tineture of belladonna given three times in the day, and to increase the dose by five drops every second or third day, of course watching the effect. Ergot is another remedy which is often very successful. For a child of the same age twenty drops of the liquid extract may be given several times in the day. Bromide of potassium, benzoic acid (dose, five to ten grains), and benzoate of ammonia, digitalis, horax, canthardes, camphor, and chloral, have all been recommended as specifics in this complaint. Sometimes a combination of several drugs seems to be more effectual than one given alone. I have lately cured a little girl, aged four years, who had resisted all other treatment, with the following draught given three times in the day :-

B.	Tinct. bellad	3 j.
	Potas. bromidi	gr. x.
	Inf. digitalis	3 ij.
	Aquamad.	3 88.
ML	Ft. haustus.	

When the incontinence continues in the day as well as at night, strychnia should be combined with the sedative so as to give lone to the feeble sphincter. In these cases, too, canterization of the neck of the bladder with a strong solution of nitrate of silver ()j.- 5 j. to the ounce of water), has been found successful.

Besides drugs, other measures have been employed in obstinate cases. Thus, abstinence from animal food, including meat-broths, has been found to succeed in cases where drugs and other treatment had failed. In some country places in England a popular remedy consists in wrapping the feet of the patient at night in cloths wrung out of cold water. I have never

used this remedy, but it is said to be an effectual one.

Electricity has been lately employed with advantage in these cases. One electrode in the shape of a spinal disk, connected with the positive pole of the battery, is applied to the lumbar region of the spine. A second electrode is placed above the pubes or in the perinseum. A weak current is then passed for several minutes once a day. It is said that under this treatment immediate improvement is noticed, and that a complete cure follows within a fortnight.

CHAPTER II.

CHRONIC BRIGHT'S DISEASE.

BRIGHT'S disease, both in the acute and chronic stage, is seen in the shid. The acute form is, however, the more generally met with on account of the frequency with which scarlatina occurs in early life, and the ten lency of this specific fever to be complicated by acute renal disease and draps:

Causation.-It is no doubt to scarlet fever that the large proportion of cases of acute Bright's disease in the young child must be referred. See it is not very uncommon to meet with acute renal dropsy in children at are without any history of scarlatina, who show no signs of desquamates of the skin, and in whom no cause for the symptoms but recent expense to cold can be detected. The practice of short-conting infants of a few months old, regardless of the state of the weather, which prevails in the country, is no doubt often answerable for this as for other catarrial isorders in early life. A child of a few months old, who has been recently short-coated, is taken out on a cold damp day almost naked from his said downwards; for his scanty skirts afford little protection to the lover 1-ri of his body. A day or two afterwards he is noticed to be pale and p fr looking about the face; he vomits, and his belly and legs begin to sail At the same time his urine is scanty, high-coloured, perhaps smoky, and throws down a precipitate of albumen on boiling. This is not a rate or stance, but occurs sufficiently often to be a not unfamiliar experient to most medical practitioners. It has been suggested that there is a consetion between eczema and kidney disease in children; and eczema of the genitals has been said to be often followed by fatal renal symptoms: but I cannot corroborate this statement by my own experience.

The form of Bright's disease met with during the first two or throwens of life is generally the neute variety. Infants, however, as well a older children, may suffer from the disease in a chronic form; but no deals this is in many cases a relic of a previous acute attack. Certain disease has lay the foundation of chronic renal muschief, viz., scarlatina, measles of lipox, scrofulous disease of bone and of other tissues causing product suppuration, ague, diphtheria, and (in infants) intestinal catarric

Either the contracted granular kidney (interstitual nephritus), the lace fatty kidney (chronic parenchymatous nephritus), or the amyloid kid may be met with in early life; but the first is rare at this age, although a appears to be sometimes set up by obstruction to the escape of uring of a from impacted calculus or some other cause; and the fibroid interstitution growth may then be profuse.

The large fatty kidney is more commonly met with than the precedure. This lesson is usually the result of acute Bright's disease, and content dates from an attack of scarlatina. It may, however, be chronic from usefirst and arise as a consequence of long-standing suppuration.

The amyloid kidney is far from rare. Children, especially those was

are subjects of the scrofulous cachexia, are very liable to suffer from profuse purulent discharges. If the discharge is continued for a long time together, it will often lead to amyloid degeneration of organs in which the kidneys as well as the liver and spleen are involved.

Morbid Anatomy.—It is unnecessary in a special treatise, such as the present, to enter innutely into the pathological changes to be met with in the kidney in cases of chronic Bright's disease. These changes are the same in the child as they are in the adult, and are described at length in all the text-books. It may be sufficient to recall to the reader's memory

the principal points connected with each of these three varieties.

The contracted granular kidney is, as its name implies, considerably reduced in size. Its capsule is thickened and adherent; its surface is nodular, and its colour a deep red. On section we find the cortex thin; the medulla atrophied, and the substance dense. The essence of the disease consists in a great hyperplasia of the connective tissue of the organ. This abroad overgrowth passes inwards from the surface along the course of the intertubular vessels, and involves more or less regularly the whole depth of the cortex. It thickens the Malpighian capsules, and compresses the capillary tufts and the convoluted tubes. The small arteries are thickened and their calibre reduced. As the increase of fibrous tissue is not evenly distributed, but is much greater in some spots than it is in others, the amount of mjury to the kalney substance varies; and while some tubes are much atrophied and shrunken, others escape almost entirely. The convoluted tubes are often denuded of their epithelial lining, and are sometimes seen under the microscope to be stuffed with fatty débris or with hyaline casts. In some places the denuded tubules dilute here and there into cysts; in other places they atrophy and may be converted into mere threads. The traight tubes in the pyramids are comparatively little altered. The shrinking of the kidney and its granular appearance are late changes, and are due to the contraction of the new fibroid material.

In the large white futly kidney it is the tubular structure which is principally involved—especially the convoluted tubes in the cortex. The kidney is larger than natural, and its capsule can be readily detached. The cortical part of the kidney, to swelling of which the increase in size is due, is perfectly smooth on the surface and pale in colour. No ramifying capillaries are to be seen, but here and there red specks from extravasation of

blood dot the ansemic surface.

On section the cortex has the same pallid tint, and contrasts curiously with the cones of the pyramids which still retain their healthy colour. By the microscope the convoluted tubes are seen distended to twice their natural size; and their epithelial lining is swellen and granular looking. The tubes often contain granular debris and fibrinous exudation, and, sometimes, extravasated blood from a ruptured Malpighian body.

After a time the epithelial cells in the tubes become disintegrated and are removed, and sometimes increase of the interstitud connective tistue takes place as in the preceding variety. The kidney then shrinks and may become granular on the surface, but still continues very pale in

polour.

Amyloid disease in the kidney is usually associated with the same degeneration of the liver and apleen. If the degeneration is marked, the organ is increased in size and has a waxy, pale, and slightly translucent appearance. The amyloid change begins, as a rule, in the vessels of the Malpighian tufts, but soon spreads from these to the vessels (both afferent and efferent), the vascular plexuses (both intertubular and interlobular), and the urinary tubules. This condition is often combined with other forms of renal degeneration.

Symptoms. The symptoms of scute Bright's disease have been already

considered in the chapter on Scarlatina.

The chronic disease in its earlier stages, and until it gives rise to dropey, is accompanied by few symptoms, and, indeed, is probably often exploshed. The child is pale, dull, and listless. He complains of his head, and is capricious in his eating. Sometimes be passes large quantities of water, which—especially if the disease be of the granular variety—may be of normal density, and contain no albumen. Even when dropey occurs,

albummuria may be absent or trifling.

A little boy, aged one year and ten months, with sixteen teeth legan gradually to get poorly. He grew pale, seemed heavy and sleepy, and vomited often after his meals. After this state of things had controld for a month his face became puffy, his eyelids swelled, and general orient appeared over the body and limbs. When taken into the last lone of Children's Hospital, no disease of any organ could be discovered; the hear and spleen were of natural size; the heart was healthy, and the temperature was normal. There was no sign of peeling of the skin. For some days no urine could be collected, for the quantity was scanty, and the child passed it all in his cot. At hist some was obtained, but no albument was discovered, nor could any casts of tubes be seen. Purges and rephoreties soon dispersed the ordena, and the child then took iron and cod-liver oil. The sickness continued for some weeks after the orients had disappeared. The urine was examined several times, but no albument was ever found.

The dropsy in this case was not the result of anamia and weakness for the child was not at all emaciated, and his mucous membranes were fary red. The cedema had all the characters of kidney dropsy. It became a the face, and was distributed very generally over the body. A sense form of dropsy without albuminum or casts is sometimes found as a segui-

of scarlet fever.

In some cases Bright's disease appears to be quite latent until address occurs.

A little boy, aged twenty-one months, with twelve teeth, came into the hospital, under my care, with slight dropsy which had lasted for a use. The child had never had scarlatina or measies, and had been a facts healthy boy, although for some weeks his bowels had been related, and the discharges offensive. He had suffered, shortly before admission in the ulceration of the mouth, which, however, had been soon recovered free He coughed, and his appetite was poor.

When the child was first seen, the ordems, although slight, was general. The urine was scanty and alkaline, and contained one-sixteenth of albumen. There was a deposit of triple phosphate crystals, with may large and small hyaline casts, and some granular casts. The temperaturat first was normal, but after a few days rose to 101.4; the child be at to cough; he was then violently convulsed, and died a few hours after

wards.

On examination of the body the lower part of the right lung was foot to be consolidated. The left kidney was absent. The right measure three inches in length by two and three-quarters in breadth. The capawas adherent, and on removing it small portions of renal sub-tages was adherent, and on removing it small portions of renal sub-tages was torn away with it. The surface of the organ was very granular and religious. On section that that was paler than natural; the pyramids was

red than in the healthy subject, and the cortex was thinned. The whole kulney felt very dense, and its substance seemed unusually tough. Unfortunately, the organ was not examined microscopically, but there can be little doubt that this was a case of granular kidney, and that it was of

some standing, although in so young a child.

Sometimes the only sign of the chronic disease may be the marked pallor of the complexion, with frequent attacks of headache and vomiting. lasting for several days, or a week or more at a time. Sometimes, as in the adult, the sight becomes affected from albummous retinitis. Such cases, without a careful examination of the urine, may be mistaken for cerebral tumour Indeed, a history of frequent attacks of headache and vertigo, accompanied by vomiting, and of gradual failure of the sight, is very suspicious of a tumour of the brain. In all such cases, therefore, it is very important to make a careful examination of the water for albumen, and to search the deposit frequently for casts of tubes. The skin is generally dry and rough, and is often markedly inelastic, so that when pinched up into folds it remains wrinkled, and does not smooth out quickly, as a healthy skin would do. This is especially the case in infants and the younger children. Purpura is sometimes found to be an accompaniment of the renal mischief; but whether it is excited by the nephritis, or, as Dr. Gee suggests, arises with it as a consequence of some bodily condition common to both, is uncertain. Purpuric patches may be seen on the akin, and blood may be passed with the urine and stools.

Usually, acute exacerbations occur from time to time. These mostly follow a chall, and are accompanied by scanty secretion of urine, puffiness of the face, and odema of the limbs. The water is then albuminous, and may be smoky, or even red, from admixture with blood. The headache is often severe, vomiting may be distressing, the dropsy may be marked, and convulsions may occur, with drowsiness or coma. Sometimes the attack is complicated with pericarditis or pleurisy, as it is in the adult. When the acute symptoms subside, the amount of albumen gradually diminishes, and after a time may quite disappear from the urine. There may be then little left to show that the kidneys are not healthy, but repetted examinations of the urine will perhaps disclose a slight deposit,

with fragments of granular or hyaline casta,

In cases of scute renal dropsy, it is common enough to hear that the child had had scarlatina some months or years previously, followed by dropsy; that he had completely recovered to all appearance; but that lately, having been exposed to cold, he had begun to vomit and the cedema had reappeared. In such a case it is reasonable to conclude that the restoration of the kidneys was not so complete as had been supposed. Sometimes the acute exacerbation is preceded by pallor, wasting, vomiting, general wearness, and a look of ill-health. The child passes water much more frequently than natural in the day, and at night may wet his bed.

A boy, aged fourteen, was in the East London Children's Hospital, under the care of my colleague, Dr. Donkin. The patient had had measure and scarlatina. He was said to be very dull at his lessons. His secretion of urine was large, and he seemed to have a difficulty in holding it. A month before his admission the boy had had a rash over the body which had lasted a fortnight. He had then begun to vomit his food, complained of pain all over, looked pallid and weakly, and was manifestly losing flesh.

When admitted, he was pale and thin; seemed very fretful, and looked.

His temperature was normal. His urme was acid, had a specific

gravity of 1.015, and contained no albumen or sugar. The boy coughed a little, but nothing positive was noted about his chest. There was no

sign of peeling of the skin.

After being in the hospital for about three weeks, during which time he had decidedly improved and had gained flesh, the lad was allowed to go out into the garden. The same evening his face looked puffy, and his legs were found to pit on pressure. His temperature that night was normal On the following day the ordema was marked. He vomited several times: complained of severe headache, and seemed very stupid and stubborn. His temperature rose that evening to 100°. His water was smoky, contained a sixth of albumen, and had a flocculent deposit which showed under the microscope many granular easts. On the third day his temperature was 101.8° both morning and evening, and he had a series of convulsive fits, followed by drowsiness which lasted for twenty-four hours. His temperature then became normal again, and the cedema began to de-His water was discoloured with blood for several days, and the albumen and casts only slowly disappeared; but before the boy's discharge, his urine, except for a slight haziness with the cold nitric acid test, had again become normal.

In this case the history and the previous symptoms, as well as the rapidity with which the roual phenomena followed the chill, pointed to some chromic affection of the kidneys, although no albumen was found in the urine on the lad's admission into the hospital. Perhaps in many of these cases careful and repeated examination of the water would be more successful in finding albumen. A great deal depends, too, on the way in which the examination is conducted. Boiling the urine and afterwards adding a few drops of nitric acid is a very coarse test; and if the proportion of albumen is small, it may easily escape detection by this means. far more delicate test is that of floating cold urine from a pipette upon the surface of strong nitric and placed in the bottom of a test-tube. Albumen should never be excluded until the urine has been tested by this process. and allowed to stand for a quarter of an bour in order to give the light, cloudy disk of albumen time to form upon the top of the acid. Still, it cannot be denied that, however carefully the examination may have been conducted, it will often be impossible to discover the presence of even a trace of albumen between the attacks of acute disease. The child, however, is not well. He often remains pale and thin, loses all appetite, and is nervous and excitable. His dislike to eating is a source of great auxiety to his parents, and, indeed, it is often most difficult to persuade him to take even a minimum quantity of food.

The water may be secreted in fair amount, often, indeed, is copious; but its specific gravity is low. It is usually very acid, and sometimes urise acid sand is seen at the bottom of the chamber-pan. Perhaps on this account there is often a difficulty in holding the water, especially at night. There can be little doubt that, although giving rise to no very characteristic symptoms, the kidneys are not healthy, and that their depurative func-

tions are imperfectly performed.

A case which I saw some time ago, in consultation with Mr. E. Stauley Smith, affords a good example of the insidious progress of granular kul-

nev disease in the child.

A little boy, aged nine years, of excitable, nervous temperament, inheriting a tendency to epilepsy on his father's side, and to phthis on his mother's, was said to have been poorly for eighteen months. His indisposition had begun with an attack of "fever" in which the temperature

rose every night to 102° or 103°; he had severe headache, and was at times slightly delirious. He was ill for a week. Since that time he had had similar attacks, but milder in character. He was said often to look pasty and sallow in the face, and to seem languid and inclined to more, although when pretty well in health he was lively and active, and his spirits were high. When poorly, his urine would contain a trace of albumen; it was always very said, and often contained large quantities of uric acid sand. No casts were ever seen at that time. The boy was wasting slowly, although his appetite was good. He slept badly, and was always restless at night. His bowels were usually costive, and after an aperient he passed much mucus. He stammered at times, and the muscles of his face would often twitch. The specimen of his urine shown to me was very acid and of specific gravity 1.024. It contained no trace of albumen; but there was a copious deposit of uric acid sand. After I had seen the boy he did not improve. The albumen became more frequent, and granular casts and blood-corpuscles began to be discovered. On one occasion, a hyaline cast was seen. There was never any trace of cedema, and his heart and pulse were normal.

In this case the feverish attacks were no doubt attacks of acute gastric catarrh. Apart from this symptom, which may have been only an accidental feature in the case, and had probably no other influence than that of aggravating the tendency to flatulence and acidity, there can be little doubt that the boy was suffering from granular kidney. It seems probable that there is a connection between the passage of red sand and the kidney degeneration, for I have noticed the association in other instances. Certainly, in a case where a child habitually passes large quantities of urio acid crystals, I should be disposed to fear the occurrence of Bright's disease; and the occasional presence of a trace of albumen would add strength to my apprehensions.

The after-course of this boy's case is interesting. He was sent to the south of France, and passed a considerable time at Cannes. Dr. G. C. Bright, under whose care the boy was placed, informs me that on arriving at Cannes the urine contained one-eighth of albumen, and that its addiment showed numerous granular casts and much renal epithelium. After a stay of nine months the water had ceased to contain albumen or casts, although there was still an occasional deposit of uric acid sand. Its density was habitually 1.025.

In this boy there was no hypertrophy of the heart; and no abnormal tension of the pulse was ever noticed. Although the albumen ceased for a time to be present in the urine, it is impossible to suppose that all structural leaton of the kidneys had disappeared. This is no doubt another instance of renal disease without albuminuria, or rather, with intermittent albuminuria, for that albumen and easts will eventually reappear can scarcely be doubted. It is curious that a sister of the patient suffered from similar symptoms.

When the kidney is the seat of amyloid degeneration there is no necessary albuminuria, and even increased secretion of urine is not an invariable symptom. Dr M Litten has published the details of four cases which place the truth of this statement beyond a doubt. In a case which was under my own care—a little girl seven years of age—general ædema had been present for two years, succeeding to an attack of scarlatina. The child suffered from angular curvature of the spine of some standing. Her liver and spleen were much enlarged, and felt very dense and resisting. Enlarged mesenteric glands could be detected in the abdomen on deep pressure. The average quantity of water passed in the twenty-four hours was twelve ounces.

It had a copious deposit of lithates. There was never any albumen, nor could any custs be discovered under the microscope. Its density varied from 1.020 to 1.025.

In this case, where the liver and spleen were evidently the seat of anyloid degeneration with probable enlargement of the same kind in the mesenteric glands, it is difficult to suppose that the kidneys had entirely escaped any participation in the disease. Probably only an early stage of the degeneration is characterised by absence of albuminums and a scanty secretion of urme. As the disease becomes more advanced, the quantity of water secreted is more copious; it contains albumen—at first in small quantities, afterwards in considerable amount, and the specific gravity of the fluid is high. Renal epithelium with hyaline, granular, and often fatty casts, may

be seen by the microscope in the deposit.

There is a form of renal disease from which children of various ages are prone to suffer, which appears to be in many cases a temporary adment, but which produces very definite symptoms. The disorder is indicated by pallor, weakness, wasting, constipation, sometimes by sickness, and in every case by a remarkable absence of the natural elasticity of the skin. This loss of elasticity is a very characteristic symptom. When the skin of the abdomen is pinched up, it remains wrinkled, or only slowly recovers its smoothness. On examining the water no albumen is found, but the quantity is small and its specific gravity is low. Evidently sufficient solids are not discharged by the kidneys; and the retention of effete matters in the system, owing to this renal inadequacy, is apparently the cause of the symptoms. A case has been already referred to in the chapter on enteric fever, in which a child convolescent from that disease passed for many days no more than eight or ten onnces of urine in the twenty-four hours, with a specific gravity of 1015. He was excessively feeble, stupid, and lethargic; his skin was markedly inclustic; and it was only after the secretion of water had increased, and its density had risen, that his physical and mental weakness passed off, and the normal elasticity of his skin was restored. It was calculated that this boy secreted by the kidneys, in the twenty-four hours, no more than two and three-quarter grains of solid matters for every pound of his weight-a quantity which is of course considerably below the average amount

The quantity of urea passed daily in childhood is proportionately greater than it is in adult life. In the East London Children's Hospital I caused the urine of thirteen selected cases, in which kidney disease could be excluded, to be collected for the twenty-four hours; and calculating roughly from the specific gravity, it appeared that the average quantity of solid matters passed from the kidneys in this time was five grains for every pound of the child's weight. The ages of the children were between four and ten years. In the adult the daily quantity has been estimated by Dr. Parkes to be three and a half grains per pound weight. My experiment was of course a rough one, making no pretensions to mathematical accuracy; but the conclusion arrived at was, no doubt, sufficiently near the truth to

be useful as a guide in practice.

I believe quite young children sometimes suffer from a temporary deficiency in the secretion of urea, although, as it is impossible to collect the whole quantity of urine passed, I can bring forward no positive evidence in support of this statement. Some time ago I saw a mide infant seven weeks old, who was brought up at the breast of a very healthy mother. He had been perfectly well for the first four weeks after his birth. He had then begun to vomit sour fluid and curd, and at the same time his bowels had become obstinately confined. This state of things had con-

tinued for three weeks, the infant becoming thinner, and his bowels only acting after an aperient or enema. On the morning of the visit he had just been relieved after five days' constipation. The child was thin but did not look iil. No sign of disease could be observed about any part of his body, and the belly was not retracted. The skin was excessively melastic. It lay on the abdomen in loose wrinkles, and when pinched up, the folds remained exactly as they were left without smoothing out. No urine could be obtained for examination. An aperient powder was given, and small doses of the infusion of senna with glycerine were ordered three times a day. After two months the elasticity of the skin had partially returned, and eventually it was perfectly restored. The return of elasticity in the skin was accompanied by progressive improvement in the condition of

the child. The vomiting ceased soon after treatment was begun; but the

costive state of the bowels remained a trouble for a considerable time. The above case represents a form of derangement which is sometimes met with in the infant. It is not an ordinary case of gastric catarrh, such as is common in early infancy, for in this disorder the elasticity of the skin is in no way interfered with. Nausea and vemiting, constination, a dry, inelastic skin, and alight albuminuria, form a combination of symptoms constantly met with in cases of deficient renal secretion in children whose water can be tested, and also in adults, according to Sir Andrew Clark. It seems, therefore, at any rate possible that diminished functional activity of the kidneys may produce similar symptoms in the infant. Kiellberg has observed a frequent connection between intestinal catarrh and parenchymatous inflammation of the kidney in the young child, and mentions as one of the characteristic symptoms of the kidney complication a dry, tough skin without elasticity. In every case, therefore, where we find this condition of the skin in a young subject, we should examine very carefully for signs of renal disease.

Diagnosis.—In examining for albumen a specimen of the urine passed after the first meal in the day should be taken, and the fluid should be afterwards set ande in a conical glass in order that solid particles, if any, may subside. The deposit should be taken up carefully with a pipette, and placed in a shallow cell made by cementing a thin ring of glass on to the or linary microscope slide. This, covered with a thin glass, should be

carefully searched for casts of tubes.

The complete absence of albuminuria and casts is no sufficient indication that the kidneys are perfectly healthy. It seems probable, from the cases which have been narrated, that a certain amount of disease may exist in the kidneys although the urine presents the characters of health; and it is now an established fact that considerable amyloid degeneration may exist in the organ without its presence being betrayed by any abnormal condition of the urinary secretion. In all cases where renal disease is suspected, although no albuminuria can be discovered, it is well to cause the whole amount of water passed in the twenty-four hours to be collected. A calculation can then be made from the specific gravity of the fluid, by means of Professor Haughton's tables,' which will give a rough estimate of the quantity of urea being excreted in the course of the day and mgut. If at the same time we ascertain the weight of the child, the amount of solid matters passed for each pound of his weight can be easily calculated. A healthy child should pass daily between five and six grains of urea per pound of his weight.

¹Given in the Medical Times and Gazette for October 27, 1864.

If albuminuria and casts can be detected, it is not always easy to decide upon the nature of the kidney lesion. The presence of anylon degeneration of the liver and spleen renders the same condition of the kidney very probable. A chronic form of Bright's disease succeeding to an acute attack, such as an attack of scarlatinous nephritis, is usually deto the fatty kidney (chronic parenchymatous nephritis); but this form of Bright's disease may also, like the contracted granular kidney, begin a sidiously. If albuminuria and casts are present without dropsy, the keiney is probably granular.

The constant passage of red sand from the kidneys is to be regarded with anxiety, for in such cases Bright's disease may be developed after a

time, as in the case of the child before referred to

Prognosis.—When Bright's disease is established in the claid, in when albumen and casts are constantly present, the prognosis is very an favourable; for such a condition, if it do not destroy life unassasted and greatly increase the danger of any intercurrent malady. Such children, if attacked by pneumonia or pleurisy, are very likely to die. In the case of amyloid kidney the prognosis is, perhaps, less unfavourable than in the other forms of Bright's disease; for it seems possible that, if the chrosis suppurative process which has excited the structural change can be removed by operation or otherwise, all the symptoms of kidney dering mast may disappear. That such a happy termination to the thiness is proved by a case published by Mr. Burwell, in which, after the removal of a serofulous joint, albuminuria and casts ceased after a time to be found in the urine, and the child grew up into a atrong, healthy woman. From this case we may learn that the existence of amyloid disease of the kidney is no bar to the successful issue of operative procedures; but that or the contrary, surgical interference in such cases is urgently called for.

Mere renal inadequacy, without albuminuria or history of neute Brieft's disease, is probably in most cases a merely temporary condition which under suitable treatment, may be rapidly recovered from. But if a child habitually pass large quantities of uric acid sand, or if he have more than one attack of acute Bright's disease, even although the urine have been normal in the interval, and return to a healthy state after the symptoms have passed away, we should regard the possibility of his ultimately developing manifest disease of the kidneys as one not to be entirely exclused

from consideration.

Treatment.—In cases where we find deficient secretion of urea, without albuminuria or signs of organic renal disease, we should take care to unload the bowels by free purgatives, unless, as in the case before referred to, the child be just convalencent from typhond fever. In ordinary rangery powder and jalapine may be given in doses suitable to the age of the child. He should be made to drink freely of some harmless fluid, and thin barley-water sweetened and flavoured with vanilla is very useful as a mucilaginous diuretic. The aperient should be repeated as often as series desirable to ensure complete rehef to the bowels; and in addition the patient may take a mixture containing citrate of potash with tineture of any vomica, or a few drops of tineture of rhubarb. The child should not be allowed too much animal food. Fish is better for him than butchers ment, and he should take plenty of milk and green vegetables. If both be allowed it must be perfectly fresh, and not be made from "stock." If there he anaroms in these cases, iron can be given after a time.

If a child be the subject of undoubted renal disease, it is of the atmost importance to attend to the working of functions the impaired action of

which will increase the labour of the kidneys. The skin should be cucouraged to act by a daily tepid bath, by warm clothing, and by careful
avoidance of the causes of chill. The patient should be dressed from head
to foot in flaunel or other warm woollen unterial, and should take regular
exercise in the open air. The bowels, if inclined to be costive, should be
kept relieved by aperients; and small doses of senina, or podophylline and
belladonna, or a nightly dose of Hunyadi Janos water, as recommended in
the chapter on constipation, are very useful. The patient should eat
sparingly of flesh meat; but milk and fish are suitable, and a due proportion of farinaceous and vegetable matters should be included in his diet.
If the amount of albumen is great, it may be advisable to put the child
for a time upon a diet consisting merely of milk and bread. Certainly in
such cases animal food should be taken with caution, and should not be
allowed every day.

Climate is a matter of very great importance in cases of chronic renal disease. If possible, the child should be removed for the winter to a neighbourhood where the air is fairly warm and dry. Here he can pass his time out of doors without risk of chill, and the beneficial influence of such a change is often very remarkable. The albumen and casts may quite disappear from the urine, and for the time, at least, the health may

seem to be completely restored.

Of medicines, iron is the best remedy, and the perchloride the best preparation. This salt has a distinctly directic action, especially if well diluted with water. Its influence in promoting the renal secretion is increased by the addition of dilute acetic acid and solution of acetate of ammonia, as suggested by the late Dr. Basham (see page 730). The draught may be sweetened by glycerine or by a few drops of spirits of chloroform.

If an attack of acute Bright's disease come on, with elevation of temperature, ordema, and head symptoms, relief may be speedily obtained in the majority of cases by free purgation and packing in a blanket bath, as recommended in cases of scarlatinous nephritis (see page 46). The influence of energetic purgation, too, is most striking; nothing relieves head symptoms so quickly as a good sweeping aperient. A useful form is the combination of compound jalap powder with compound scammony powder. Enough should be given to produce four or five copious evacuations. Eleterium is too uncertain in its action to be suitable for children.

If the albuminuria persist after an attack of the acute disease, iron should be given directly the temperature becomes normal. The drug may be usefully combined with strychnia and arsenic. A child of eight years old may take three times a day twenty drops of the liq. ferri perchloridi with two of liq. strychniae and four of liq. arsenicalis in a large wineglassful of water sweetened with glycerine. This medicine should be given directly after food, lest it cause nausea. Callic acid has been recommended, but on account of its tendency to constipate often seems to do more harm than good. The first necessity in these cases is to promote free excretion from the bowels. If this function be interfered with, no medicine can be of much value. On this account iron often seems to act better if given in the form of the sulphate with sulphate of magnesia and dilute sulphuncacid; but the other form is equally, if not more, serviceable, if care be taken to keep the bowels free. In obstinate cases fuschine (the chlorohydrate of rosamline) is said to hasten the disappearance of the albumen after an acute attack. This drug may be given to a child in doses of from two to five grams. It tinges the urine of a reddish colour. Recently,

chloral hydrate has been given with the same object. It can be prescribed to a child of five years of age in doses of three or four grains three times a

day.

A fatal ending in uncomplicated cases of chronic Bright's disease from exhaustion and dropsy must be rare in the child. I cannot remember having met with such a case except in connection with anyloid disease, and there the general distribution of the degeneration furnishes other resons for the condition of the patient. Chronic kidney disease is usually fatal in young subjects through the occurrence of some inflammatory can plication. Pleurisy and pneumonia in such cases are excessively diagraous. They must be treated with stimulants and counter-critation. The chest and back should be repeatedly dry-cupped; the bowels should be freely acted upon, and the strength of the patient must be supported by suitable quantities of unsweetened gin.

If the dropsy in any case be copous, it must be treated as recommended under the head of Scarlatmous Nephritis (see page 46). Pilocarpus sometimes useful in these cases. Occasionally it may be necessary to

puncture the legs with Dr. Southey's trocara.

CHAPTER III.

CALCULUS OF THE KIDNEY.

The occasional passage of red sand from the bladder in childhood is not an uncommon occurrence. As a rule, little pathological significance is to be attached to it. Uric acid is very liable to be formed if food is taken largely in excess of the requirements of the system. It is not even necessary that the food be nitrogenous to produce this result; for as Dr. Garrod has observed, it is a mistake to suppose that an animal diet must tend more to the formation of uric acid than a vegetable one. It must be remembered, however, that the presence in the urine of a deposit of lithic acid or its salts is no proof that any excess of the acid is formed and se-The increase is often only apparent. When the urine is seanty from deficiency of water, the uncacid may appear to be in excess. Again, great acidity of urine may cause a deposit of uric acid. The neutral lithates are more soluble than the acid lithates, and these than uric acid. Therefore, if the urme is full of neutral salts, any cause which will remove a part or the whole of the base will throw down a precipitate. The addition of acid will do this. Thus, if very acid urine be secreted into the bla lder when this already contains a neutral or alkaline urine, the acid abstracts the base from the neutral salts and a deposit is formed at once.

The uric acid appears in the urine in the form of crystailine grams, or, if very abundant, as a red sandy deposit. In infants and young children there appears to be a special tendency to uric acid deposits; and these may be thrown down in the kidney itself before the urine has passed into the bladder. The so-called uric acid infarctions of the kidney, forming yellowish red streaks running in the direction of the pyramids, may be found after death in the youngest infants—in them, indeed, more frequently than in older children. These infarctions consist of amorphous mate of ammonia mixed with crystals of uric acid, and occupy the straight tubes of the pyramids. They do not, any more than the saudy deposits in the urine, indicate the existence of kidney disease. They are due to excessive feeding, or, in young babies, to the increased metamorphosis of tissue elements which must take place after birth in consequence of the newly-managurated processes of digestion, respiration, and generation of

A deposit of crystals of uric acid may be formed at any part of the urinary apparatus. The urinary tubules often contain such collections. A particle of crystallised uric acid is deposited in the cortical part of the gland. It may remain in this spot, or may pass further down the urinary apparatus into the straight tubes or the pelvis of the kidney. In either case it is apt to become enlarged by successive additions to the original nucleus. Great irritation is often caused by the passage of these fragments, and even minute crystalline particles, if with sharp angles, may so scratch and wound the deheate membrane liming the fine tubules of the

kidney and calices of the pyramids, as to be a cause of hamorrhage in spite, however, of the frequency of andy deposits, the urine in chibble does not, as often as might be expected, contain an admixture of block At least, an intimate blending of the blood with the urine, such as is known to be characteristic of renal hiemorrhage, is in the child comparative rare.

Besides uric acid, exalate of lime concretions are not uncommon in children. These are dependent upon the same causes as the preceding According to Schenck, uric said is converted by exidation into orders acid, and this is readily decomposed by both acids and alkalies, splitting up into exalic acid and urea. The exalic acid at once combines with the best of any lime salt which may be present, and is precipitated as the insensite exalate of lime. This process may take place in any part of the urnary passages, and if crystals of exalate of lime are found in warm urns before the fluid has had time to cool, it may be inferred that they have been formed inside the body, and we should think of the possibility of calculus.

Besides uric acid and oxalate of lime concretions, small calculated the urates of ammonia and soda may be formed. Often the concretions are compound, and contain a nucleus of uric acid round which oxalate of lass or urate of ammonia has been deposited. If the concretion be encrusted with phosphates, it is a sign that uritation has been set up in the blacker

or pelvis of the kidney.

Causation. - Some children have a greater tendency than others to the deposition of uric acid in the urmary passages. This tendency offer rans in families, and is then commonly associated with the gouty construction The form of scrofuln which is connected with a stout, heavy built and much flabbiness of flesh, is also said to be distinguished by a similar tradency. In both of these cases there is no doubt an inclination to gaster disturbances and the generation of acid in the stomach. The actual depostion of uric acid crystals in the form of and and gravel is apt to be excited by excessive or unwholesome diet-especially of indulgence in the more fermentable articles of food. Thus, large quantities of farmaceous actstances, particularly where the starch is imperfectly cooked, and of fruit or sweets, may give rise to the formation of acid in the digestive ergaze Too close confinement to the house, especially in cold damp weather, to in some subjects load the urine with une acid or its compounds. Indied, any influence which interferes with the assimilative processes, such as feat, grief, and other depressing passions of the mind, over-fatigue of the bady. temporary febrile adments-all these causes may determine a prompitation of uric acid in the urmary passages. According to Dr Ciarred, cocentration of the urine from deficiency in the amount of water exercised by the kidneys is a common cause of gravel in early life. In these cases the habitual passage of red sand is compatible with every evolence of good bealth. Amongst other cases he refers to that of a boy aged five and a half years, whose urine from day to day contained either unic and are tals or deposited a copious red sediment almost immediately after it voided. The whole quantity of urine passed in the twenty four heurs was only sixteen ounces, with a specific gravity of 1.031. Directly the cald was made to take more fluid, so as to increase the quantity of water passed from the kidneys, uric acid ceased to be discoverable in the secretism.

Symptoms. The passage of the ordinary lithates is no more a cause of irritation in the young child than it is in the adult. A baby may passwater thick and milky from the presence of unites without shoung that he is sensible of any unusual sensation while voiding the contents of his

bladder. When, however, free uric acid is discharged with the urine, we usually notice signs of discomfort. Water is passed more frequently and in smaller quantities. The child screams and strains during its passage, and, if old enough, complains of pain in the urethra. In these cases we shall often find red gritty matter on the infant's disper, or red sand at the bottom of the chamber-pan. Sometimes, this urritation is a cause of wetting the bed at night, and therefore the water should always be examined

for uric acid crystals in cases of nocturnal incontinence of urine.

While still in the kidney these concretions may give rise to few or even no symptoms. Sometimes the only sign of their presence is a more or less copious admixture of blood with the urinary water. If the concretions are of some size, the hemorrhage may be accompanied by attacks of pain in the kidney. Hematuria in children, especially in infants, is usually to be attributed to this cause. In the case of infants a stain of bright blood is noticed on the wet disper. In older children the blood is intimately blended with the urine, and the mixture may have a deep red colour if the hemorrhage be copious. The urine is acid, deposits albumen on boiling, and often crystals of uric acid can be discovered with the abun-

dant blood-corpuscles under the microscope.

A little girl, aged four years, the minth child of healthy parents, was admitted into the East London Children's Hospital. No history of gout could be discovered in the family. Of the other children, four had died, one from whooping-cough, the others of brain disease, nature unknown. The patient herself had always been a healthy child, with the exception of an attack of varicella in infancy, until twelve months before admission. At that time the mother had begun to notice that the child's water contained blood. At first this had only occurred about once a week; but the frequency of the hæmorrhage had gradually increased, and during the previous fortught blood had been passed every day. The morning urine, passed after the night's rest, had, however, been always uncoloured until a week before admission; since that time the passage of blood had been continuous.

At first the mother had noticed no other symptoms, but after the hemogrhage had continued for several months, the patient had begun to complain of pain in the left side and back, at first only occasionally, but latterly several times in the day. The child cried bitterly, and attempted to relieve her distress by bending her body backwards across her mother's

knee, with her head and legs hanging down.

On admission, the girl was in good condition and had a florid complexion. Her weight was twenty-two pounds ten ounces. Her liver and spleen were of normal size, and the heart and lungs were healthy. The abdomen was unusually compressible. The aorta and iliac arteries could be felt pulsating on deep pressure, and both kidneys could be felt. They were not tender when touched, and seemed in every way normal. She passed water more frequently than was natural, but there was no pain in micturition. Her skin was not harsh, acted fairly well, and there was no sign of edema. The urine was dark with blood, of specific gravity 1 024, threw down a copious precipitate on boiling, and showed an abundance of blood-corpuscles under the microscope. After a few days stellate crystals of uric acid were also discovered in the sediment.

The child was kept in bed, and was given a mixture containing carbonate of potash. The amount of blood in the water gradually decreased, and in five days had quite disappeared. The urine then became perfectly normal, and ceased to contain albumen or blood-corpuscles. There were

never any signs of casts, of purulent matter, or of mucus. No pair we noticed during her residence in the hospital, and she was seen the hardel. About a month afterwards she was readmitted with the same syngthms but they quickly disappeared as before with rest and alkalies. Her tea-

perature was always normal.

This case is a good illustration of the symptoms produced in children by renal concretions in the kidney. It would be difficult to attribute the humaturia to any other cause. The significant fact that the blooding occurred for the most part after exercise, and that until the amount of blood became excessive, the water was clear in the morning when the child first rose from her bed, were strong arguments in favour of urinary concretions. The patient, besides, was in good condition, and of a boultry spearance, and although her kidneys could be felt on pulpation, no increase in their size could be detected. Lastly, crystals of une acid were found in the sediment.

Examination of the urine in these cases often gives a negative result Calculus may exist in the kidney without giving use to symptoms of any kind. Between the attacks of hematuria the water may contain neither blood nor albumen, and unless sand or crystals of uric acid be actually

passing, it may redden litmus paper but faintly.

Sometimes the irritation produced by the presence of the calculus at the pelvis of the kidney may set up pychtia. The stone then usually be

comes enlarged by deposition of phosphatic salts upon its surface

A child was admitted into the East London Children's Hospital suffering from tubercular meningitis. After death, which took place in two Livines, besides the morbid appearances usual in such cases, the left kaller was found to be extensively diseased. The organ was much enlarge land contained about two ounces of creamy pus. In the interior it was helicard into cavities, and its proper substance was almost replaced by cases matter. A calculus of the size of a cherry-stone was impacted in the upper part of the ureter. Above this, the ureter and pelvis of the Lighty was much dilated. In this case, no doubt, the stone had first, by the irritative it produced, set up pyelitis, and had then become impacted in the ureter, preventing the escape of the purulent matter.

When the concretion passes from the kidney into the ureter, and dearwards into the bladder, there is always pain; but the clubt suffers far less than an adult would do under similar circumstances. Sometimes in attact of abdominal pain in a child, attributed, as all such pain is apt to be abdominal derangement and colic, is followed by symptoms of stors in the bladder. It is therefore desirable in all cases where pain, more than addinarily severe, appears to be suffered, to examine the state of the child water, and inquire of the nurse whether sand or gravel has been seen at

the bottom of the chamber-pan.

If the stone becomes impacted in the ureter, serious consequences respense. The irritation of the foreign body in this situation may set up a flammation, and give use to thickening and contraction immediately about the seat of the impediment. Higher up the ureter becomes greatly distended, and the pelvis of the kidney may suffer dilatation. In some extended, and the pelvis of the kidney may suffer dilatation. In some extended, and the pelvis of the kidney may suffer dilatation. In some extended, and the pelvis of the kidney may suffer dilatation. In some extended, and the pelvis of the kidney into a thin-walled cyst. This is one form of hydronephrosis.

When the stone has entered the bladder, urgent symptoms begin to be noticed. This affliction is more common in boys than in garls, probable for purely mechanical reasons. The urethra in garls is short, straight,

and, when the child stands upright, almost vertical. In boys it is long and sinuous with a double bend. In the bladder the stone produces great irritation. Priapism is common; and there is usually pain, which is ingreased by exercise. During micturition the boy cries with pain, which he refers to the end of the genital organ, and endeavours to relieve by squeezing and rubbing the part with his fingers. The flow of urine often stops suddenly, from the stone being carried by the flow of water into the neck of the bladder, and there forming an impediment to the escape of the arine. Consequently the water is voided with effort, and the straining may give rise to prolapse of the rectum. Actual retention may occur, the stone being tightly grasped by the sphincter vesice, and impacted at the beginning of the prostatic urethra. A little pure bright blood may be passed at the end of micturition, and the uring often gives evidence of severe catarrh of the bladder. Any of these symptoms occurring in a boy should make us inquire very carefully into the cause of his complaints. It must not, however, be forgotten that very similar symptoms may arise from different reasons. Dr. West has pointed out that in cases where the prepuce is abnormally long, with a narrow opening, its edges may become very sore on account of the difficulty and delay with which urine is forced through the ornice; and this may give rise to much pain in micturation.

Inagnosis. -On account of the frequency with which urio acid concretions are found in the urine of children, it is evident that the delicate membrane lining the tubules of the kidney is liable to be exposed to injury from the sharp edges of the crystalline masses. Consequently, harmorrhage in such cases is no matter for surprise. The wonder, indeed, is that it is not a more common symptom of uric acid sand in young persons. That it is not so is probably due to the fact that the uric acid is commonly deposited from the urine in the bladder itself, and not at a higher point in the urmary apparatus. Sir Thomas Watson has recorded his opinion that many of the obscure cases of hiematuria in the adult may be referred to renal calculi. In the case of children it may be laid down as a rule that renal hemorrhage occurring in a child otherwise healthy, and accompanied by no symptoms, nor by hæmorrhage from other parts of the body, is, in the majority of cases, to be attributed to the irritation of crystalline masses in

the tubules, calices, or pelvis of the kidney. Not long ago I saw a little boy, aged ten months, who for six weeks had been passing water mixed largely with blood. Sometimes for a few days together the water would be clear, but the hematuria speedily returned. The specimen brought with the child was bright crimson in colour, and consisted of blood and urne intimately blended together. It had a slightly acid reaction. Many blood-corpuscles were seen under the microscope, but no crystals of uric acid could be detected, although the medical attendant had occasionally found them in the sediment. The child had been brought up by hand and fed upon cow's milk and water. He had no teeth could not stand, and showed signs of being under-nourished. The bowels were confined habitually; otherwise he seemed to suffer no dis-

comfort, and was said never to be prevish or fretful.

As the infant was evidently insufficiently fed, I rearranged his diet, ordering one meal in the morning of oatmeal (one teaspoonful) with cow's milk, two meals of Nestle's milk food, and two or three meals of Mellin's food with cow's milk diluted with a third part of barby-water. I also prescribed a mixture containing the infusions of senna and gentian, so as to act gently upon the ciuld's bowels.

Some months afterwards I heard that the bleeding had continued for a

few weeks longer; that the child had then seemed in great pain for a day and a night; but that after this the water had become clear, and had ever since been perfectly free from blood. The nutrition had begun to improve

immediately upon the change of diet.

There can be little doubt that the hæmaturia in this case was the consequence of irritation of the kidney by a small angular concretion, and the pain spoken of was, in all probability, an attack of renal colic, caused by the passage, or attempted passage, of the little calculus down the creter. In cases such as this, the concretions must be looked for carefully in the urner passed at the end of a fit of colic. They are often no larges

than a mustard-seed, or even a small pin's head.

Prognosis.—The occasional appearance of free uric acid in the urine of infants and children is of no consequence whatever. The frequent passage of sandy particles is of greater moment, for in these cases we are justified in fearing the formation of a stone in the bladder. A mere passing home turis should not have too much importance attached to it, for it is probable that a certain oozing of blood may occur in the kidney, as a consequence of irritation from small crystalline fragments, which may be afterwards washed away. Repeated homorrhage from this source is however, to be regarded with anxiety; and if there are signs of pair in the renal region preceding or accompanying the flow of blood, we have reason to fear the presence of a calculus, and further ill-consequences are

to be anticipated.

Treatment.—The frequent appearance of uric acid crystals, or of sandy deposits, or even the habitual presence of urates in a child's water, shoul make us inquire very carefully as to the food he takes, and the general conditions under which he is living. Such a child should live plant He should take meat once a day with vegetables, and a light custorier batter pudding. For his other meals he should have milk and bread-inbutter, with occasionally the volk of an egg or a little bacon for his breakfast. Care should be taken that he does not overload his stomach, and the quantity of furmaceous food he cats should be duly proportioned to his power of digesting it. Sweet things should be given to the child with caution; and all cakes and biscuits between meals should be strictly forbidden. He should take exercise freely in the open air. His skin should be kept in good order by complete washing every day, and in the celler months he should be dressed from head to foot in some warm woming material. Great attention should be paid to the ventilation of his bedroom, and in the winter he should be dressed and undressed in a willwarmed room. In the case of an infant, vigilance should be exercised that the child does not take too large a quantity of food at one time, and that he is not burdened by too much farmaccous matter to his acale Cleanliness and plenty of fresh air must be always insisted upon.

In addition to the above measures, care should be taken that the patient drinks sufficient flind to freely dilute the renal secretion. Remembering that a concentrated state of the urine is alone sufficient to give risk sandy deposits in the urine, the child should be made to drink half a turbler of water, fasting, one hour before food, twice a day. This sample precaution, in many cases, will at once put an end to any appearance of sand. An infant may be given thin barley-water from his bottle with the

same object.

For medicine, alkalies, such as the citrate of potash, should be green and the treatment must be continued for several weeks. If here on the occur, perfect rest in bed must be enforced. These cases a kilom require

typtics, but if thought advisable, a few grains of gallic acid may be given with dilute sulphuric acid twice a day.

If, from attacks of pain or frequent homorrhages, it becomes evident hat the child has a calculus of the kidney, citrate of potash should be given in sufficient doses to keep the urine slightly alkaline; and this reatment should be persevered with in the hope of dissolving the concreion, or at any rate of reducing its size sufficiently to enable it to escape by the ureter. If great irritation and pain are produced by the continued presence of the calculus, and the health and strength of the child seem to se seriously affected, the question of nephrotomy should be considered.

In an attack of nephritic colic, the child should be kept under the in-

luence of morphia, and hot fomentations must be applied to the abdomen.

CHAPTER IV.

TUMOURS OF THE KIDNEY.

Tunouns of the kidney are occasionally seen in children, and generally occur in the form either of a sarconatous growth or of a hydronephrosa

Sarcoma of the kidney constitutes the ordinary form of renal cases met with in the child. It occurs usually at an early age (the cases word have come under my notice have been all under three years old), and is usually confined to one side of the body. In the kidney, as in other or

gans, the growth often reaches a very large size.

Morbid Anatomy.—The sarcoma is usually of the round-celled variety but the tumour often contains, in addition to sarcoma tissue, striated uncular fibre scattered or arranged in bundles. Under the microscope thee tumours are found to have a fibrillated structure, some fibres being single spindle-shaped, with an indication of a nucleus; others, more clouded with signs of transverse striation; others, again, well-developed, with intinct striation. But even in the best developed fibres no sign of a arrelemma can be seen. In some cases the new muscular and sarcomatic tissue is dispersed through the kidney substance, and the tumour is the really a tumour of the kidney. In other cases the new tissue seems to be separated from the kidney substance proper, although lying within the capsule; or it divides the organ into two parts without, as in the other case, infiltrating its substance. It has been suggested that those growth may be derived from the remains of the Wolffian body.

Symptoms.—No pain seems to attend the development of these is mours, and at first there is little interference with the general head Consequently, the earliest sign to attract the attention of the attendant to the unusual size of the child's helly; and the mother often complains that

the belly feels harder on one side than it does on the other.

On examination, in such cases, we find a globular swelling occupied one side of the abdomen. The swelling is usually little more bloomed does not descend, or moves very slightly, in inspiration. Its borders are rounded, and there is no edge felt, as is the case with the sphere. Its substance is soft and elastic, so as to convey an imperfect sense of the tion. Below, the fingers can be pressed between the lower border and the brim of the polvis; above, the tumour passes beneath the liver, or of the left side is continuous with the splenic dulness beneath the false observed and the special part of the long, and there is seldom any intestinal resonance to be detected between it and the special continuous in the special part of the long and there is seldom any intestinal resonance to be detected between it and the special continuous in the special part of the long and there is seldom any intestinal resonance to be detected between it and the special part of the long and the special part of the special part of the special part of the long and there is no edge felt, as is the case with the special part of the special part of the case with the special part of the long and the

As the tumour grows the only inconvenience felt is the weight of the mass in the abdomen. The appetite is good, often exceptionally had and nutrition is fairly performed. The urine is usually normal, although in some cases it may contain albumen and blood; and towards the call.

may be scanty, with infrequent micturition.

After a time, as the size of the growth increases, secondary deman

ments from pressure begin to be noticed. The earliest sign that the growth is interfering with neighbouring parts is usually an enlargement of the superficial veins of the abdominal wall from pressure upon the vena cava. This is often followed by orderna of the lower limbs and scrotum. Sometimes the liver enlarges from passive congestion; and dyspines may be induced from pressure upwards of the displicagm by the remainiass. When these signs are noticed nutrition becomes affected, and the end is not far off. The child gets thinner, and soon wastes rapidly. His appearance becomes eachectic; aphths: develope in the mouth, and he aims and dies. Before death the emaciation may be extreme.

These symptoms are well illustrated by the case of a patient in the East London Children's Hospital, under the care of my colleague, Dr. Donkin, through whose kindness I had several opportunities of examin-

ing it.

A little girl, aged two and a half years, was brought to the hospital on account of a swelling of the belly. The mother stated that she had noticed three months before that the belly was large and hard on one side, and that a doctor had said there was a tumour of the abdomen. For a month the child had been languid and fretful, picking her nose, and meaning in her sleep. Now and then she had complained of abdominal pains, and once or twice she had vomited. The bowels were disposed to be

costive, and the water was occasionally milky (from lithates).

The child was full-grown for her age and well-nourished. She did not look ill. The abdomen was large and full, especially on the right side, and the superficial veins were distended. On palpation of the belly a large, oval, smooth mass was felt on the right side, reaching from the liver to the level of the brinn of the pelvis. The fingers could be passed under the lower border of the tumour, and above could be pushed a little way between the upper border and the liver, the edge of which could be distinctly felt overlapping the upper part of the mass. Anteriorly, the swelling reached beyond the middle line of the belly, and its limits could be distinctly felt rounded and resisting. Posteriorly, the tumour passed backwards into the rend region, and its boundaries in this direction could not be ascertained, although when the child lay on her left side the resonance of the intestine could be made out posteriorly. In front the colon could be detected lying on the surface of the swelling.

The whole tumour was very slightly movable; its surface was smooth; its substance elastic, and it felt like a tense bag of fluid. There was no ascites; no enlarged glands could be felt in the groins or elsewhere; the edge of the liver reached two fingers' breadth below the ribs; there was no enlargement of the spleen. In order positively to exclude fluid, an exploratory puncture was made into the tumour, but nothing but a little blood was withdrawn. The temperature remained normal after the puncture.

For a fortnight after the child's admission there was little change in her condition. Then, however, her temperature rose; she vomited, and began to look ill and careworn, and a pneumonia developed in the base of the right lung. The urine became intensely acid; it was loaded with urutes, and deposited large amounts of uric acid on standing; there was also a trace of albumen. The liver enlarged; the veins of the abdominal wall became engarged with blood; cadema occurred in the lower limbs; the face got dusky; general convulsions came on, with epistaxis and bleeding from the ears, and the child died in a few minutes.

On examination of the body a round-celled sarcomatous tumour, the size of a feetal head, was seen occupying the lower two-thirds of the right

kidney, infiltrating its tissue. It was covered by the renal capsule. Its substance was of soft pulpy consistence in the centre, harder and firmer towards the circumference. There was one large hemorrhage into its lower part. The turnour pressed upon the inferior vena cava, which was distended by a large decolourised thrombus, perforated in the middle by a channel of the diameter of a goose-quill. The thrombus reached from the level of the turnour upwards to the right ventricle of the heart. The liver and spleen were both much congested.

This case may be considered a typical example of a renal tumour. The only doubt possible was as to the nature of the swelling, and this the exploratory puncture removed at once. Fluid being thus excluded, the rarity of any other form of solid growth made the diagnosis of sarcoma

comparatively an easy one.

Sarcomatous tumours of the kidney generally grow rapidly, and the course of the disease is seldom protracted. Death often occurs within a year of the swelling being first discovered, and in the longest case life is

rarely prolonged beyond eighteen months.

Hydromephrosus is almost invariably in children a congenital affection. It is often associated with some form of arrest of development, such as club-foot, harelip, imperforate anus, or absence of the prostate gland. Both kidneys are more often affected than one alone, and the most common cause is impervious ureters or an imperforate urethra. According to Dr. Englisch, the obstruction may take its rise in the valvular folds, situated at the upper part of the ureter, or at its lower part; and in five cases he referred the cause of the obstruction to a curving of the mucous membrane at the orifice of the urethra into a diverticulum.

In rare cases the disease is acquired during childhood from impaction of a calculus in the ureter. The other causes of acquired hydronic phroma, viz., retroflexion and prolapse of the womb, etc., do not come into play

until a more advanced period of life.

Whatever be the cause of the retention, the essence of the disease consists in accumulation of urine in the pelvis of the kidney. The pressure of this fluid produces very serious consequences. Every degree of dilatation of the parts is seen according as to whether the fluid can partially escape or is wholly retained. In every case the renal pelvis is greatly dilated, but there are many degrees of alteration of the kidney substance, from mere flattening and toughening of the papillæ to actual conversion of the organ into a membranous sac filled with fluid. If the obstruction is low down in the ureter, this tube is also dilated and its wall thickened. The fluid has a low specific gravity, and contains the elements of urine although in feeble proportion: i.e., urea, uric scil, urates, and often crystals of oxalate of lime. Its reaction is faintly alkaline. Its colour is clear amber or turbid, and may be yellow from pus or reddish from blood. Sometimes it contains epithelium, and in rare cases the consistence is increased to a thick fatty fluid.

Symptoms.— Although almost invariably congenital, the hydronephrosis is often not noticed until several months or even years have clapsed from birth. The mother then observes that the abdomen is enlarged, and that the chief swelling is limited to one side of the belly. Her attention being thus directed to the child's abdomen she finds that this progressively in-

creases in size, and a medical practitioner is consulted.

The tumour is a punless one and forms a soft elastic swelling in the situation of the kalney. The cyst sometimes reaches a large size, and may cause great inconvenience by its weight, or interfere with respiration

by pressing upwards against the diaphragm. The lumbar region on the affected side is then seen to be prominent as the child lies on his face, and fluctuation is transmitted freely from the front to the back. In a case recorded by Dr. Hilber—a child three years and a half old—the swelling filled the whole abdomen, and five pints of clear non-albuminous fluid were withdrawn by tapping. Sometimes an escape of some of the retained fluid occurs from time to time, and the size of the tumour may thus undergo marked variations. If the accumulation be due to an impacted calculus, attacks of nephritic colic may occur, with bloody urine. If both kidneys are affected, and the escape of fluid is entirely prevented, the child may die with symptoms of urienia. Such a condition is of course incompatible with life, and if it be a congenital one, the child is generally stillborn.

Diagnosis of Renal Tamours.—We have first to satisfy ourselves that the tumour is due to enlargement of the kidney, and then to ascertain the nature of the swelling. In order to arrive at an accurate diagnosis, a careful examination of the abdomen is of course indispensable; so that if the child is fretful and uninanageable, crying and contracting his abdom-

inal walls, he should be put under the influence of an anæsthetic.

A rounded mass in which no edge can be detected, situated in the region of the kidney, and little affected by respiration; one which does not dip into the pelvis, but passes upwards to the liver or spleen and backwards into the lumbar region—such a tumour is in all probability an enlarged kidney. Renal tumours may be confounded with tumours of any other abdominal organ, or indeed with a swelling anywhere within the abdominal cavity.

On the right side the renal enlargement must be distinguished from a tumour of the liver. The latter rises and falls with respiration, and will be noticed to be close up under the ribs so that the fingers cannot be passed between its upper border and the disphragm. Moreover, a hepatic tumour is rarely covered by a coil of intestine; and on careful manipulation the edge can usually be detected. Thus, of course, at once excludes the kidney, for a kidney, whether enlarged or not, is rounded in all directions.

On the left side a splenic tumour must be excluded. Enlargements of the spleen are very common in children, but they can never be mistaken for a ki liney by a careful observer. An enlarged spleen lies very superficially; its position is markedly influenced by respiration; it is freely movable; it has a distinct edge towards the middle line, in which the notch can usually be felt, and its upper border passes upwards beneath the ribs

On either sale the renal tumour may be mistaken for a mass of enlarged glands, a page abscess, frecal accumulations, and, in girls, ovarian enlarge-

ments.

Enlarged glands lie very deeply against the spine, and have to be felt for with care. They are only slightly movable. Still, palpation alone may be insufficient to distinguish a swelling of this kind from an enlarged kidney. By attention, however, to the general symptoms, we may usually arrive at a conclusion. A kidney only slightly enlarged from succoma produces no impurment of the general health; while caseous glands, sufficiently large to be detectable by the touch, are associated with a history of ill-health or of more or less interference with nutrition. The patient has usually suffered from attacks of diarrhoza, and may perhaps have signs of chronic diceration of the bowels. In such a case he would look ill even although the bowels were not actually loose.

A proper of the loins and extends forwards into the belly. It is, however, placed more deeply

than a tumour of the kidney, and cannot be so easily felt. Little information is to be derived from the presence of fluctuation in the swelling, for this is difficult to ascertain in a pages abscess, and a sarcomatous kidney conveys a sense of pseudo-fluctuation which is often very deceptive. A far more important distinction is that furnished by the actual position of the mass, for a renal tumour reaches far higher in the abdomen than an abscess. Moreover, the latter is distinctly tender on pressure, while the kidney tumour is quite painless. Lastly, in pages abscess, although there may be no curvature of the spine, careful examination will often discover the existence of disease of the vertebric (see page 185).

Other abscesses in the neighbourhood of the kidney can usually be detected by their causing enlargement behind in the renal region. According to Sir William Jenner, this is rarely the case with a simple swelling of

the kidner.

Fiscal accumulation may be, perhaps, mistaken for a renal tumour; but a mass sufficiently large to give rise to hesitation must be very rare in the child. Fiscal lumps lie very superficially, and can be indented with the finger. Besides, they can be cleared away by a copious injection.

Ovarian tumours are sometimes found in little girls. These dip down into the pelvis, and the fingers cannot be passed beneath their lower border. Moreover, they are rarely covered by cods of intestine. These are

all pressed away towards the lateral regions of the groin

Having ascertained the existence of a renal tumour, it is sometimes very difficult to decide upon its nature. If the tumour be double, or be accompanied by signs of severe nephritic colic, it is probably due to a hydronephrosis. So, also, if the awelling is noticed to be diminished in size after a copious flow of urine, it may be attributed to the same condition. Usually the doubt can be only removed by an exploratory puncture of the swelling. If fluid be withdrawn containing ures, there can be no further hesitation as to the nature of the tumour.

The distinction between hydronephrosis and ascites is described in the

chapter treating of the latter disease (see page 703),

Treatment. In cases of sarcoms of the kidney we can do nothing but attend to the general nutrition of the patient. In the case of hydrone-phrons -If occasional reductions in the size of the tumour have been noticed to follow a copious discharge of urine, friction and shampooing of the abdomen, such as proved successful in a case reported by Dr. W. Roberts, may be made use of. In other cases occasional tapping may greatly relieve the patient. Dr. Day reports a case in which nephrectons was successfully performed by Mr. Knowsley Thornton, and the child recovered. A cure may, however, he effected by a less serious operation. It appears from a case recorded by Dr. Tuckwell, and Mr. H. P. Symonds, of Oxford, that persistent drainings of the sac may sometimes lead to its shrinking and contraction. In the case referred to- a boy eleven years of age—an incision was made into the sac in the lumbar region, and a large dramage-tube was introduced through the opening. Antiseptic dressings were employed, and at the end of thirteen weeks from the operation the tube was finally removed. The child recovered perfectly, and six months afterwards no sign of the tumour could be discovered on examination of the belly. Operative interference in these cases should not be undertaken unless a healthy state of the urine indicates that the opposite kidney is free from disease.

CHAPTER V.

VULVITIS.

Vulviris, or vulvo-vaginitis (for the catarrhal inflammation of the mucous membrane often penetrates for some distance into the vaginal canal), is very common in little girls. The complaint may be seen at a very early age, even during the first few months of life; but is more common in children of five years of age and upwards. M. Parrot has described a variety of the derangement which he calls "aphthous vulvitis," and states that it is met with most frequently in children between the second and fourth year.

Causation.—Catarrhal vulvitis is especially common in children of scrofulous constitution, and appears to be excited by want of cleanliness and insanitary conditions generally; also by local irritation in the neighbourhood, as by ascandes in the rectum. In very rare cases it may be the consequence of sexual violence. Certain forms of the complaint appear to be contagious and capable of being communicated from one child to another by sponges or towels; and Dr. Atkinson, of Baltimore, has stated his belief that the discharges from a purulent ophthalmin may be conveyed to the vulva, and set up a similar inflammation in that situation.

Vulvitis is sometimes a secondary disease. Thus, it may come on after some of the acute specific diseases. Parrot has seen aphthous vulvitis succeed most commonly to measles, next to whooping-cough. He has also met with it after varicella, ervsipelas, pneumonia, and diphtheria. In

only a few cases was it apparently a primary derangement.

Symptoms. - In catarrial vulvitis a purulent discharge may be noticed to issue from the vulva. At first it is scanty, and is seen on the child's body linen. On inspection of the parts the mucous membrane is found to be red, and the larger labia to be a little swollen. The discharge is yellowish or greenish in colour. It is usually fetid, and in many cases as very profuse. In hospital out-patients, who are often neglected in the matter of cleanliness, the opening of the vagina is often found bathed with a thickish, yellow, offensive matter. If the catarrh is not quickly cured, it may lead to considerable swelling of the labia, and the mucous membrane may become exceriated. In these cases there may be some pain in walking; and if the catarrh extends to the orifice of the urethra, there may be smarting in micturition. There is not usually any enlargement of the inguinal glands; but in bad cases, occurring in unhealthy, neglected cluldreu, irritable sores may form on the inner surface of the labas, and the glands may then become slightly swollen, and a little tender. I have never aren suppuration of these glands. If left untreated, spontaneous recovery may take place, or the discharge may become chrone, and persist for months or even years. The swelling in these cases subsides, but thin purulent matter, small in quantity, continues to be secreted. I have

thought, in some of these chronic cases, that irritation has been kept up

by a habit of masturbation.

Aphthous culvitis, according to Parrot, attacks the labia majora, and sometimes the smaller lips and the chitoris. From these parts the aphthous inflammation may spread to the genito-crural folds, the groins, the perineum, and the borders of the anus. It begins by an eruption of small, rounded, or semi-spheroidal elevations of the epidermis, of a grayish white colour, and often depressed in the centre. The little patches closely resemble the aphthous spots on the buccal mucous membrane, and are surrounded by a red, slightly-swollen ring. In number they are five or six to fifteen, and may be placed singly or in groups; sometimes they are confluent. After a period varying from thirty-six hours to three days, the patches give place to ulcers which have a gray or yellowish base, and a red They cause considerable irritation, which it is difficult to prevent the patient from reheving by the use of the fingers. At the height of the disease the edges of the sores are raised, and the parts around, especially the minor labra and the clitoris, are swollen and bright red. Under suitsble treatment the swelling soon subsides, and the ulcers heal; but in unhealthy subjects the lesion may take on a gangrenous process. When this occurs the constitutional symptoms are severe, and the gangrene may spread extensively, and present all the features described elsewhere (see Gangrene of the Vulva, page 170).

Prognosis.— Vulvitis is a very common derangement amongst the children of the poor, but may be found in any condition of life. Knowing its frequency, we must be on our guard against accepting any suggestion (such as some mothers are very ready to make) that their child has been tampered with by a person of the opposite sex. If this have really taken place, we should expect to find ecchymosis and recent abrasions of the external genitals. The hymen is rarely ruptured, on account of the small-

ness of the passage.

The aphthons spots are distinguished from nucous patches by the absence of all signs of constitutional symptoms in the child. The ulcers are distinguished from venereal sores by the absence of any hardening at the base. Moreover, the latter are never grouped or confluent, as as almost

invariably the case with the aphthous ulcers.

Treatment. The utmost cleanliness must be observed. The parts should be bathed frequently or syringed with warm water, and afterwards a little pledget of cotton-wool, seaked in a mild lead lotion, should be passed between the labia. If the catarrhal inflammation seem to have extended into the vagina, the lotion may be injected with a syringe. If there be great irritation of the parts, a weak solution of perchloride of mercury (one grain to eight ounces of water) may be used instead of the lead. If the case be obstinate, the parts should be well dabbed with a weak solution of nitrate of silver (gr. vj.-x. to the ounce of distilled water).

Dr. Gaillard Thomas recommends for all obstinate cases the careful syringing of the vagina with warm water, and the use afterwards of a letton composed of one ounce of black wash to the pint of water. The lotton must be injected with a syringe twice a day, and on each occasion the passage must be previously cleaned by careful injection of warm water. Dr. Thomas attributes the chronic course of many of these cases to the imperfect application of remedies. He urges the importance of instructing the mother in the use of the syringe, directing her to introduce the nozzle of the instrument well into the vagina, so that the upper part of the passage is reached

by the fluid. In all instances where the child is anomic or of scrofulous aspect, iron wine and cod-liver oil should be given internally. Care must also be taken that the bowels are regularly relieved, and that objectionable

habits are no longer continued.

In the aphthous form of vulvitis, Parrot recommends the use of the powder of iodoform once a day thoroughly after careful washing. He then applies a covering of lint. Parrot states that this application quickly cures the sores, and prevents the occurrence of gangrene.

Part 12.

DISEASES OF THE SKIN.

CHAPTER L

DISEASES OF THE SKIN.

In childhood the skin shares the general susceptibility of the whole system, and is very liable to disease. At this period of life the surface of the body is delicate and readily irritated by the presence of accumulated dirt and dried secretion. Amongst the poor, neglect and want of clearly ness are common causes of cutaneous affections in the young. Moreover in the young subject, gastro-intestinal derangements are expecially liable to be accompanied by the various forms of crythema; and childhood appears in itself to increase the susceptibility to the parasitic disease of the skin. In a work treating of disease in early life, a consideration of the various cruptions to which childhood is hable must not be entirely texplected; but attention will be confined to the more common forms of suc disease met with at this period of life, and the subject must necessarily be discussed somewhat cursorily, and chiefly with a view to diagnosis and treatment.

The papular eruptions do not require very extended notice. Laborated very rare in the young subject. The form called laborated in the most common; but this eruption appears to be more a modification of not the rash than a true lichen, and will be afterwards referred to under the head of urticaria.

Prurage is occasionally met with in dirty, neglected children in the form of slightly projecting papules, which give rise to considerable irration; but in early life the rash seems to induce a less intense form of itching than that which is a cause of so much suffering to older persons. At Hutchinson has described a prurige of infants which appears often to be a sequel to or modification of chicken-pox; and he is disposed to believe that an abortive varicella is often the original cause of the outbreak. The papules are hard and rough, and may be mixed up with wheals of urticasts. In some cases they are large, and resemble half-developed which of notice rash, "with perhaps even some tendency to vesication." The itching aring from the cruption is often greatly relieved by the use of warm takes medicated with the liquearbonis detergens, in the proportion of two the spoonfuls to the gallon of water. This bath should be used twice a detailed the skin may be afterwards anointed with a salve composed of one outside.

of storax, two drachms of white wax, and half an onnce of olive-oil. If the child is feeble or delicate, cod-liver oil and from wine should be prescribed, and the diet should be regulated on the principles elsewhere recommended

(see Infantile Atrophy).

Strophulus is a common eruption in infants, and usually arises as a consequence of laboured digestion. It is met with in two principal forms—a red and a white variety. Red strophulus consists of small red papules of the size of a large pure head. These papules often occur in groups, and occupy the face, the trunk, and sometimes the himbs. They cause some itching. In white strophulus the colour of the papules is pearly white. Each papule lasts a few days, and the rash usually comes out in successive crops. It is not accompanied by any general symptoms, and the only treatment required is attention to the digestive organs, and some necessary modification in the diet.

Of the vesicular and bullous group, herpes and pemphique are both far from rare. Herpes of the hp is as common a symptom of croupous pneumonia in the child as it is in the adult. Herpes of the pharynx is described elsewhere (see page 580). Herpes zona is comparatively rare in the child, but is sometimes seen, and then differs little from the same eruption in the adult except that it is much less frequently followed by

intercostal neuralgia. It requires no treatment.

Pemphygus is occasionally met with in the child. In new-born infants a syphilitic form of the disease is not uncommon, and usually indicates profound contamination of the system. Syphilitic pemphygus is referred

o elsewhere

Pemphigus attacks ill-nourished children, and may be found to occur during convalescence from acute febrile diseases such as scarlatina. It is also apt to be met with as a frequently recurring complaint in children of fairly robust appearance, and in such cases it is difficult to know what is the cause of the repeated returns of the bullous eruption. In the more common variety of the disease the cruption begans in the form of small red spots. On these spots the cuticle rises rapidly into a bleb, which increases in size until it is as large as a marble or a walnut. The bladders thus formed are tense, and filled with fluid, and their base is surrounded with a red zone of inflammation. The fluid is at first clear, but soon becomes opaque. The blebs may last unbroken for some days, but usually they burst very early, and give place to thin yellowish brown scabs on a purplish ground. The eruption comes out in successive crops. Many blebs do not appear at one time, but the repeated succession of crops covers the body with bladders, crusts, and stains from the various stages of the affection being simultaneously present on the skin. All parts of the body may be affected, even the lips and the cars, but the palms and soles usually escape. The appearance of the eruption is accompanied by some constitutional disturbance, which is often found to vary in severity according to the extent of surface involved in the disease. There may be some fever. In a hoy aged eight years, who was admitted into the East London Children's Hospital with extensive pemplingus, the temperature during the first three days was over 101' both morning and evening, and for a fortnight afterwards it rose sometimes in the evening to 99.8" or 100°. Thirst, restlessness, and loss of appetite are also noticed, and there is sometimes diarrhoa. The emption at first may be accompanied by some stehing, but after the bursting of the blebs the resulting sores cause pain and smarting

An occasional form of the disease is that called pemphigus solitarius,

where a single bleb rises on the hand or foot, often on one finger, and quickly attains a great size. Sometimes the bleb involves the whole of the hand. Mr Naylor described a variety of pemphagus which he called "pompholyr destinus in children." This form begins like ordinary pemphagus as a small red spot, which becomes a bleb and rapidly charges. After the bladder has ruptured the sore still continues to spread, and becomes covered with a thin wrinkled crust with a narrow raised rim, the remains of the bleb. The disease appears to be a purely local one, and the general health is quite unaffected. Dr. R. Liveing has doubts if this affection be a true pemphigus.

The sore of pemphigus, like other sores, may assume a gangrenous form in unhealthy, cachectic children. The resulting condition is very much that already described as a consequence of gangrenous varicella (see

page 49).

The duration of the disease is apt to be prolonged, and sometimes the cruption returns very rapidly after apparent cure. The nature of the affection can hardly be mistaken, for the large blobs or blasters surrounded by healthy skin are pathognomomic. Blobs are often seen in the course of other forms of skin disease, such as scables, eczema, erysipelas, etc. In the latter mahaly the extensive reddened, brawny surface on which the bladds is seated will be a sufficient distinction. In the case of the two forms complaints the characteristic appearances peculiar to these disorders will be observed. The bullous syphiloderm is distinguished from periphiguish the presence of other signs of the constitutional disease. In infant bullous eruptions are commonly of syphilitic origin.

The lest treatment for pemphigus is arsenic. The remedy should be given in full doses, for a child of any years and upwards will take doses a large as those usually prescribed for an adult. If the irritation and discomfort of the skin and general nervous disturbance prevent sleep, oping is useful, more especially as in the opinion of experienced observers the drug has a direct curative influence upon the disease. It is especially serviceable in the early acute stage. The screep on the skin must be kept very clean and treated with some mild application, such as a lead letion of

zine ointment.

Esthymatous pustules are very common in early life. In children of all ages, irritation of the skin is very apt to be followed by the development of large flattened pustules seated on a broad base and surrounded by red zone of inflammation. Their favourite seats are the face, hands, and feet. The subjects of the complaint are often under-nourished, and it is therefore very often seen amongst the children of the poor, but in all ranks of life any derangement or other cause which determines a temporary reduction of strength appears to have a predisposing influence in inducing the cruption. Such children are usually pule and flabby, and in them any slight scratch may be followed by a festering sore which continued unhealed as long as the debility from which the patient is suffering remains unrelieved. Quinine has a specific influence in removing this troublesome affection After the alkaloid has been taken for a few days of a week the pustules disappear, the sores heal, and the child is well. In all these cases the diet should be attended to and any error of feeding corrected. A little wine is often of service, and the child should have plenty of fresh air and exercise.

A mild form of psorasse is met with in children. The eruption usually occurs in the form of psorasse guttata, the little patches being scattered about, not very thickly, on the trunk and limbs. The patches are usually

small, of a pale red tint, and are more or less scaly on the surface. They may be attended with slight itching. Psoriams is seldom obstinate at this period of life, and usually yields without difficulty to arsenical treatment. Sometimes, however, the perchloride of mercury seems to be more useful than arsenic. As a local application the unguentum picis, or a mild chrysophanic acid ointment (gr. x. to the ounce of lard), may be made use of.

The parasitic diseases of the skin will be described afterwards. In the present chapter reference may be made to the form of disease called al opena areata, which is not unfrequently seen on the heads of children of five years of age and upwards. The disease is characterised by the loss of hur in spots on the scalp. At these spots the hair-bulbs atrophy, and the hairs, growing losse, are shed without undergoing any other alteration in structure. In this way bald patches are formed, in which the scalp is completely smooth, white, and hairless. At the circumference of the patch the hair grows thickly as on the unaffected parts of the head. The number of patches may be one or more, and they may spread so as to unite and almost denude the head of its hair. At one time the disease was thought to be parasitic, but it is now allowed by most pathologists to be a simple atrophy of the hair-bulb; and the hairs examined microscopically are found to resemble in every respect those which are cast off in the natural process of decay.

The disease usually tends to spontaneous cure. The bald patches become eventually covered with a fine down which grows thicker and darker until at last the spot ceases to be recognised. In some cases the new bars remain colourless and give a curiously variegated appearance to the head. In others the hair is only partially reproduced, so that in places

the scalp may remain permanently bald.

The only treatment for this condition is energetic stimulation with irritating applications, such as tincture of iodine, cantharides, etc. Dr.

Tun recommends sulphur ointment.

The above varieties of cutaneous eruption may be dismissed without further notice. There are, however, other forms of skin disease which from their frequency or importance require a more detailed description. The following chapters will therefore be devoted to the consideration of the erythemata, eczema, molluscum contagiosum, the parasitic diseases, and sclerema.

CHAPTER II.

THE ERYTHEMATA.

In the crythematous group of skin affections the rash presents itself in the form of slightly raised patches of redness. These patches are of variable size and shape, give rise to little or no constitutional disturbance, and rue a very rapid course. In all cases the redness shows a smooth surface without scales, and disappears on pressure, returning when the pressure is removed.

The varieties which will be described are: Erythema simplex and it varieties; erythema nodosum; urticaria, and roscola.

ERYTHEMA SIMPLEX.

The simple variety of crythems appears to be in many cases the consequence of digestive disturbance. The rash is seen in the form of patelos often of some considerable size. The colour is red, bright or inclining to be dusky; and the affected part is in most cases sensibly elevated from exudation of serum and leucocytes into the cutis and subcutaneous tisent The duration of the rash is variable. In the commonest form, which if called erythema fugax, absorption of the exuded matter takes place very rapidly, and in the course of a few hours the redness has completely disappeared. This form is common in the face of a child who is fed in judiciously, and suffers in consequence from fermentation and acidity, The patches are of very irregular shape and are imperfectly circumscribed They are often accompanied by some irritation or a sense of tingling There is little swelling of the skin; indeed, the affection appears to be httle more than a cutaneous hyperemia. When the crythenia occurs is small rused blotches it is called erythema populatum. The rush then consists of flattened red spots of the size of a large pin's head or a pea. Their margin is well defined and they are accompanied by some little irritation A common seat of the eruption is the extremities, and it is rare on the trunk and face. The rash lasts a few days, then begins to fade, and se sumes a blush tint before it finally disappears. If there has been much swelling a slight desquamation is left on the skin.

A common form of crythema in infants is that known as crythema intertrigo. In this variety the redness appears between the folds of skin in fat babies, and seems to be due to the friction of adjacent surfaces upon one another. It is seen in the neck, ampits, groms, and inner parts of the thighs. If the redness does not quickly disappear the surface become moist and slightly exceriated. It is then often called common intertrigo. In severe cases linear ulcerations may be seen to occupy the bottom of the folds. In this stage the disorder can no longer be considered as a meregythema. The ulcers have sharp, inflamed edges, and pour out a sero

purulent fluid in considerable quantities. A variety of crythema intertrigo is the superficial dermatitis which is common in children who suffer from diarrhea. The irritation of the discharges from the bowel produces a more or less extensive erythems of the buttocks and perinsum, which,

however, quickly disappears under treatment.

There is one other form of crythema which requires mention, viz., that which is produced by the action of belladonna upon the system. This form of crythema resembles very closely the rash of scarlatina. In some children it is induced very readily, and is not to be taken as an index of the susceptibility of the system to the action of the drug. The readiness with which it is produced seems to depend more upon the sensitiveness of the skin than upon any intolerance of the drug special to the individual child. As a rule, young subjects can take large quantities of belladonna without inconvenience; and in some cases we find the characteristic rash developed in a child in whom much larger doses are required to produce any dilatation of the pupil.

Prognosis. - These varieties of erythema simplex can scarcely be mistaken for any more serious disease. If the patches are of some size, they are distinguished from erysipelas by the want of sharp outline, the lighter colour of the redness, the absence of any brawny sensation to the finger, the normal temperature, and the entire absence of constitutional disturbance. Erythema papulatum may perhaps be sometimes confounded with measles, but it is distinguished by the larger size of the blotches, the want of crescentic arrangement, the limitation of the rash to the extremities,

and the absence of catarrial symptoms and fever.

Treatment -In ordinary crythemn little treatment is required. Any digestive disturbance must be remedied, and it is well to act upon the bowels with a moderate dose of rhubarb and sods. If the rash persists after twenty four hours, a mild disphoretic may be administered, such as hq. ammoniae acetatis with spirits of chloroform, diluted with water.

In errthems intertrigo the part should be bathed with warm water and carefully dried. Afterwards, a piece of lint wetted with unboiled white of egg, or a weak lead lotion, should be inserted between the folds of skin and the affection is quickly at an end. If there is constipation, a mild aperient -castor-oil, or rhubarb and soda-should be administered. If ulceration have occurred the part should be washed frequently so as to prevent accumulation of secretion, and the same application should be made use of. The crythema, which is excited by the irritation of fixed disclarges, quickly vields to frequent bathing with warm water, caroful drying, and dusting with lycopodium, or with a powder composed of oxide of zine diluted with three times its weight of starch.

ERYTHEMA NODOSUM.

Although erythema nodosum is usually included amongst the varieties of erythems, it is right to say that the affection is looked upon by some observers as a specific illness which ought properly to be classed with enteric fever and the other varieties of acute specific disease. By others the complaint is supposed to have a distinct connection with the rheumatic countitution, and there is no doubt that it often attacks the subjects of

The appearance of the rash is often preceded by pains in the limbs and lassitude. The spots themselves are large oval patches or swellings. of a rosy red tint, and measure from one to three or four inches in their long diameter. They usually occupy the front of the legs and are accompanied by some tenderness. At first they are hard, but after a day or two become softer, and may even give a sensation of semi-fluctuation to the tinger. At the same time the colour grows more and more purple until it finally disappears, leaving a yellow discolouration of the skin. The patches are almost always present on both legs, and sometimes attack the forearms as well, or even other parts of the body. Their number is usually eight or ten.

Each swelling goes through the changes characteristic of a brunse, always turning first purple, then yellow, and lasts for two or three weeks. The duration of the complaint is, however, often much longer; and convalescence may be considerably delayed by the appearance of successive

crops of the nodose patches.

A little girl, aged twelve years, was a patient in the East London Children's Hospital. The girl had been suffering for nine weeks from successive crops of large red blotches which occupied the forearms and legistere were also a few on the belly. They began as small red spots, which grow larger and became clevated and swollen. Their colour afterward became purple and they then faded away like a bruise. The child was said to have had a similar attack two years before. She had complained for a fortnight of panus in the joints, and her knee had been swollen for week or ten days.

While the patient remained in the hospital various joints were in turn swollen and painful. After the knee had recovered the right wrist because affected, and later the articulation of the jaw on the right side was painful Afterwards, the pain and swelling returned to the wrist. There were assigns of cardiac mischief; and the temperature was always normal in the morning, rising at night to between 99° and 100. She was said never the

have had rheumatic fever Her urine was normal.

The child took iodide of potassium, quinine and iron without benefit but improved directly the treatment was changed to drachm doses of of turpentine. Under this remedy she quickly recovered her health. The medicine produced little aperient action on the bowels.

According to M. Germain Sée, erythema nodosum is apt to be complicated by disorders of the respiratory apparatus, especially pleurisy and

broncho-pneumonia.

Diagnosis. – Frythema nodosum cannot be mistaken for any other form of eruption. The large oval soft swellings seated upon the front of the legs, their tenderness on pressure, and the successive changes of colour such as is characteristic of a bruise, which the swellings undergo in their progress to recovery, can leave little doubt as to the nature of the complant. In purpura bruise-like patches are often seen, but the spots are much smaller, are not elevated, are accompanied by no tenderness, and are not altered in colour by pressure of the finger. Moreover, that disease is often accompanied by hæmorrhages, which are never seen in uncomplicated crythema nodosum; and the large bruise like patches on the skin are mixed up with small deep-red petechiae. It must be remembered, however, that the two diseases may occur together, for crythem nodosum is an occasional complication of purpura.

Treatment.—The patient should be kept in bed and be treated with quinine; and the bowels should be kept regular with mild aperients. No local treatment is required unless the tenderness of the patches and the pains in the limbs form a subject of complaint. In that case the limbs

may be wrapped in cotton-wool. In the more chronic cases where successive crops of swellings appear, oil of turpentine may be given, as in the case mirrated above, in doses of one or two drachms three times a day. The child may have meat once a day, but no potatoes or sweets should be allowed while the pains continue troublesome.

URTICARIA.

In urticaria, or nettle-rash, the crythematous cruption appears in the form of wheals which produce the most distressing irritation. The complaint may be acute or chronic, and sometimes continues with varying intensity for months or even years. In the acute form, nettle-rash is a common consequence of indigestion and acidity, and is often excited by special articles of food, such as shell-fish, mushrooms, etc. Insanitary conditions have been said to have an influence in promoting the disorder Whether this be so or not, the affection is no doubt common in neglected children amongst the poor. In such cases it may, however, be the consequence of uncleanliness, for in subjects with delicate skins external irritation alone will set up the complaint. Thus, the eruption may be produced by pediculi, and is a not uncommon complication of scabies and eczema. In the chronic variety nettle-rash appears to be in many cases a disorder of purely nervous origin; for the eruption is often quite uninfluenced by modifications of diet, while it yields readily to large doses of quinne, as will be afterwards described,

Symptoms.—In its common form the rash consists of a number of small elevations which rapidly increase in size and become white in the centre with a red border. These wheals are of various sizes and shapes. The smaller may be of the diameter of a pea; but the larger may measure one or two inches in breadth and reach a considerable elevation above the surface. Sometimes the spots assume an elongated form like thick streaks; or, again, may appear as a bright red more or less diffused erythematous blush. In any case they give rise to a stinging irritation which necessitates repeated frictions for its relief. The itching, however, is increased by the means used to relieve it, and the act of rubbing and scratching the skin produces a fresh crop of spots. The course of each individual wheal is very short, for the spots come and go with great rapidity. Any part of the body may be affected. The wheals may appear on the face, the hands and feet, the limbs, and the trunk; and the rash is usually roughly symmetrical. Sometimes the eruption is not limited to the skin but affects the mucous membrane as well. Thus, the tongue or throat may suddenly swell up and produce alarming symptoms; but the swelling subudes again as rapidly as it arose.

In acute urticaria there may be well-marked constitutional symptoms. The rash may be preceded by fever, a furred tongue, vomiting, a quick, feeble pulse, and in some cases a distressing feeling of prostration. These symptoms are greatly relieved when the wheals appear. An acute attack of nettle-rash lasts from a few hours to several days. Even in this short time, it varies much in intensity, and is usually greatly aggravated at night.

In the chronic form, the disorder continues for months. Its course is always very variable, and is subject to occasional remissions, so that it more rescubles a series of acute or sub-acute attacks. In this form the cruption may be confined to certain localities (urticaria conferta), or may

50

be general and affect all parts of the body indiscriminately. The wheals are sometimes mixed up with small papular projections, and the complaint is then called lunen articulus. Another variety of the chronic complaint is that called by Dr. Sangster articura pigmentosa. The wheals are here

very persistent, and leave yellowish pigmented spots on the skin.

Disgrams.-Urticaria is readily recognised. The characteristic wheals resembling exactly the sting of a nettle, the irritation to which they give rise, and the rapidity with which they come and go, leave no room for heaitation. The severe constitutional symptoms which sometimes precede the acute attack might conceivably arise from so many causes that no opinion should be hazarded until the eruption appears and explains what was obscure. The beginning of the exanthemata may be marked by similar phenomena, and the metastasis of mumps to the testicle or breast is occa-

sionally preceded by like symptoms.

Treatment. - In acute nettle-rash it is important to attend to the condition of the digestive organs. If there be any nauses, a mild emetic, such as a dose of ipecacuanha wine, should be administered; and the child should live plainly for a day or two, without sweets or excess of starches in his diet. For medicine, an aperient dose of rhubarb and soda will usually put a speedy end to the attack. The stehing, while the eruption continues, will be greatly rehered by dabbing the surface with a solution of cyanide of potassium (one drachm to the pint), or with the lotion referred to by Sir Thomas Watson, composed of a drachm of carbonate of ammonia and the same quantity of acetate of lead dissolved in eight ounces of water.

A warm bath at bedtime in some cases is found very soothing.

In chronic urticaria excess of fermentable food is to be avoided; but the most careful dieting will often produce no beneficial effect upon the eruption. In the majority of cases, whatever be the cause of the persistence of the disorder, it will be found to yield readily to full doses of quinine. I have used this remedy for many years, and have not yet met with an instance of its failure to put an immediate end to the complaint. The dose should be large, and may be roughly calculated at one grain and a half for each year of the child's age. The remedy is administered once in the day, at bedtime. As an illustration of the prompt action of the aikaloid so administered, I may quote the case of a little garl, two years and ten months old, who had suffered from chronic urticaria for two years. The rash had varied in intensity from time to time, but had never disappeared entirely; and the child was said to be in a state of constant suffering from the distressing itching to which it gave rise. A few powders, each containing three grains of quinine, were ordered; one to be taken every night on going to bed. After two or three powders the rash completely disappeared, and two years afterwards I heard that it had never returned.

ROSEOLA

Roscola, or the rose rash, is a form of crythema which is often seen in early life, and although a very trifling complaint, is yet on account of the resemblance it bears to measles of some clinical importance.

The rash is especially common in the spring and the autumn, and this partiality to certain seasons of the year has given rise to the names of roscola seativa and roscola autumnalis. Like the other forms of crythesia the complaint is not contagious. It is common for one child of a family to be the only one attacked, although mixing freely with the others, and

exposed to exactly the same conditions. The rash may occur several times in the same individual, for it is in no way self-protective; indeed, the contrary seems to be the case, and its tendency rather is to recur.

The causes of the complaint appear to be digestive derangement and slight chills. The eruption occasionally complicates other diseases. Thus, it may come on in the pre-cruptive stage of small-pox, and is apt to occur

tu vaccinated children, and in rheumatic subjects.

Symptoms.—The appearance of the rash is usually preceded by slight aigns of disturbance. The child's eyes look heavy, his appetite is poor, his tongue is furred, and sometimes he vomits. In rarer cases the bowels are slightly loose. It is said that at this time there may be slight elevation of temperature. The pre-cruptive stage lasts usually for a few hours. The rash then appears as bright rose spots, which come out very rapidly, and soon cover large surfaces of the body. The size of these spots is very much that of the cruption of measles; and sometimes, as in that disease, they assume a crescentic arrangement, so that except for the much brighter colour of the rash the general appearance of the child is that of one suffering from measles. There are, however, no catarrhal symptoms of any moment; the throat is seldom reddened, and there is no cough.

The rash lasts a few hours or a day or two, and then subsides. Usually, if it has appeared quickly, it fales with some suddenness; but if it has come out slowly, spreading gradually over the body, it disappears in an equally leasurely manner. Sometimes the cruption appears in the form of small circular spots which remain isolated or joined irregularly; and in some cases the rash bears a close resemblance to that form of scarlatina in which the spots remain discrete, so as to be separated by skin of healthy colouring. During the cruptive stage the temperature rarely rises above the

pormal level.

A little girl of eight years old, the only daughter of very careful parents, was said to have been perfectly well without any sign of catarrh or other disturbance until noon on Murch 18th. It was then noticed that her eyes were heavy, but she ate her dinner as usual. In putting the child to bed in the evening it was found that she had some red spots on the shoulder. During the night she sneezed once or twice. On the morning of the following day the face and body were covered with a crescentic rash which tore a close resemblance to the cruption of measles. It differed only in colour, for the tint was peculiarly bright and rosy. On the cheeks the rash was confluent, and it was rather papular on the jaws. There was very slight injection of the conjunctive, but the fauces were not reddened. The child did not cough or snuffle, and there was no rhonchus or other abnormal sign about the lungs. A painless, movable gland, the size of a filbert, was felt just below the occiput. The bowels were not relaxed. There was no special thirst or loss of appetite. The temperature at 2 r.m. was 99°. Pulse, 100.

The next day (March 20th) the rash was fading fast. The temperature

was normal. No catarrhal symptoms.

Sometimes the roscolous eruption comes and goes with great rapidity, lasting only a few hours. In such cases it usually readily recurs. The spots sometimes group themselves in rings. This arrangement is held to constitute a special variety—roscola annulata.

Despuses -Roscola, when it assumes the crescentic form, is distinguished from measles by the absence of lengthened prodromata; by the colour of the rash which, instead of being yellowish-red or dull red, is of a bright rose tint; by the normal or only moderately elevated temperature,

and by the absence of cough and coryza. These points are well illustrated by the case above narrated. It is more difficult to distinguish the complaint from rötheln; for in both disorders the eruption appears early with only slight prodromata, and the temperature soon becomes normal. In rötheln, however, there is a sensible elevation of the temperature during the first day or two; the soreness of throat, which is almost absent in roseola, is a marked feature, and the eruption is dull red with none of the bright rosy tint of the roseolous rash. Still, in spite of these differences the resemblance between the two complaints is sufficiently close to make it probable that roseola is often called rötheln, and that the patient is supposed to have had an attack of "German messles."

The diagnosis between roseola and scarlatina is given elsewhere (see

nage 42).

Treatment.—The treatment required for roseola consists in keeping the child quiet, and attending to any digestive derangement which may be present. Usually no medicine is necessary.

CHAPTER III.

ECZEMA.

Ezzata, one of the commonest of skin diseases in early life, and often one of the most obstinate, is characterised by an cruption of papules, vesicles, and sometimes of pustules. The rash forms more or less extensive patches of redness. These secrete a thin gummy fluid which dries into scales and crusts. The disease is accompanied by much irritation, and in severe cases the constant itching interferes with sleep and keeps the unfortunate patient in a state of constant restlessness and distress. It may attack children of all ages, and in infants especially (eczenia infantile) is apt to assume a sub-acute form which persists for months or even years with varying in-

tensity, and is very difficult of cure.

('quantion,-Infants attacked by the disease are usually of sturdy build without other sign of ill-health. In such cases it is by no means easy to discover any cause to which the complaint can be attributed. Often one child of the family is alone affected, although the conditions of life appear to be the same in the case of the patient as in that of his more fortunate brothers and sisters. Sometimes, if the child is at the breast, we can detect by careful inquiry the existence of dyspepsia in the mother, or of some error in diet which affects the quality of her milk. In hand-fed babies excess of starchy food may seem to be inducing an acid state of the alimentary canal which may promote and maintain the cutaneous eruption. In some cases a gouty or rheumatic family tendency may exist, and it appears extremely probable that this constitutional disposition is often to blame for the occurrence of eczema in young children. It has certainly seemed to me that infantile eczema is more common in such families than in others where no such proclivity exists. Again, we not unfrequently find, especially in scrofulous subjects, that the eczematous rash appears as a sequel of one of the scute specific fevers. Thus, it may come on after measles, scarlet fever, or small-pox. The disease is, however, often met with in cases where no error in management can be discovered, where the animal functions appear to be satisfactorily performed, where the child has not lately suffered from fever, and where no family tendency to gout or rheumatism can be found to prevail.

Destition is often supposed to be an exciting cause of the cutaneous affection, and no doubt a limited amount of eczema is often present in teething infants. But it is common for the rash to appear at the fifth or sixth month, before teething troubles have begun; and the cruption not unfrequently lasts long after the whole crop of milk-teeth has appeared

through the gum.

In older children irritants to the skin, such as profuse swesting, etc., may produce the disease; and at this age excess of fruit and other errors of diet may lead to the disorder. Scrofulous children are very liable to it.

Symptoms.—Eczema usually begins as a bright red patch, on which a crop of papules very quickly appears, or the surface becomes covered with a number of minute, clear vesicles. There is great itching of the inflaned portion of skin; and the friction to which the part is subjected very rapilly destroys the normal appearance of the rash. The papules are torn by the nails, and the vesicles also become ruptured and exude a thin third which dries into scales. The parts affected are usually those where the skin is delicate and soft, such as the folds of the joints, the generals, the partneum, the lips and cheeks, the inner sides of the thighs, and the backs of the legs, especially just above the aukles. It is, however, also common on the scalp; but here the disease usually assumes the pustular form, and thick scabs are seen, under which there is a purulent fluid. In some children this variety is often accompanied by pediculi.

The constitutional disturbance is seldom great; there is rarely any noticeable rise of temperature, and the appetite is little impaired. Is very acute cases, however, the burning sensation to which the inflammation gives rise may produce great distress. The child's sleep is disturbed, and all his functions may be deranged by worry and want of rest.

Several varieties of the disease are common in children. Those which will be described are:—Eczena simplex, eczena rubrum, eczena cajate.

eczema tarsi, and eczema infantile.

Ecrema simplex is the commonest form of the disease. It attacks clasdren behind the ears, at the orifices of the nostrals, on the cheeks, and todeed on any part of the body. The rash occurs in patches of redness or which papules or vesicles very quickly appear, and later pustules are generally seen. In the latter case the disease is often called comma improvenodes. The red rash exudes a gummy fluid, which dries into then reddish or brownish crusts. When these are removed, the surface is seen to be red and moist, or covered with fine scales. On bairy parts, a few pustules are almost always seen as well. The pustules are larger than the vesseles. and are situated at the oritices of the hair-follicles; for the hair can be seen to pass through their centre. They soon burst, and discharge their contents. The fluid dries and forms thick crusts, which are sometimes turned up at the edges. There is some infiltration of the skin at the affected part, and a good deal of itching and heat is complained of by the patient. The pustular form is most common in scretchous subjects, but may occur in others who suffer from no such constitutional predistrantes

In coverna rubrum the inflammation and redness are very great, and the surface of the patch is seen to be studded with deeper red points, which correspond to the orifices of the cutaneous follicles. The secretion forms thick scabs under which small excorations are seen—the correquence of rupture of the vesicles. This variety is especially frequent at the folds of the joints, such as the groins, the arm-pits, and at the backs

of the knees. It causes much itching.

Eczema capitis occurs in the pustular (eczema impetiginodes) or the scaly form. The exudation to which the eruption gives rise becomes extangled in the hairs and mats them together, so that it can with difficulty be removed. In neglected cases it is not uncommon to find the leavenered with a kind of cap or large scab, composed of the hair matisfiation a mass by dried exudation. This feels soft and boggy to the touch from the quantity of contained purulent fluid which wells up through an opening in the scab. The odour is most offensive, and usually in such cases pediculi abound. Superficial ulcerations and small sub-interest abscesses may sometimes be seen on the scalp when the crusts are re-

mored; and the glands of the neck and those at the back of the head often become inflamed and swollen. In very chronic cases the hairs may fall out, but they grow again when the disease is at an end.

In infants the scaly form is the more common. The scalp may be seen to be covered with scales, but exudes only a limited amount of secretion.

A variety of eczems capitis has been described as impetigo contagiosa, being supposed by some authorities to be conveyed from one child to another by actual contact. There is no doubt that we often find several children of the same family suffering from impetigo of the scalp at the same time, but the contagious nature of the cruption is not universally recognised. It is, indeed, denied by many good observers. Dr. Tilbury Fox, who believed in the communicability of this form of the disease, states that contagious impetigo always begins as little watery heads.

In eccema tars the disease affects the edges of the eyelids. This form is common in scrofulous children and may be combined with strumous ophticalmia and conjunctivitis. A number of pustules appear at the orifices of the hair-follicles. These burst quickly and form scabs. The eruption is attended with considerable itching and some swelling of the edges of the lids. The margins of the eyelids are scaly from small crusts which ching round the shafts of the hairs as these issue from the follicles. The hairs are often glued together by the secretion, and at night-time the edges of the eyelids are also very apt to stick together. When the scabs are removed, small ulcers are often to be detected on the skin beneath. Eczema tarsi is a very chronic complaint. It is often accompanied by much weakness of the eyes and lachrymation. If allowed to go on it eventually causes obliteration of the Meibomian glands and hair-follicles, and the eyelashes are apt to fall out, or if they remain, to grow irregularly and in very inconvenient directions.

Exema infuntule is a very obstinate form of the disease. It usually appears before the end of the sixth month, and attacks infants who in other respects seem to be in perfect health. It begins generally on the cheeks and spreads thence to the neck, chest, arms, and body generally. At first it is not uncommonly complicated by wheals of urticaria. In any case the clisens is accompanied by intense itching which evidently causes the ntmost distress to the child, and often it is necessary to secure his hands, so as to prevent his increasing the irritation by constant friction. Even when this is done he will rub his cheeks against the pullow of his cot until the skin is completely excoriated, and often wears the bair from the back of his head by constant movement of the occiput upon the pillow to relieve the irritation. The parts affected are intensely red, and are rough and scaly from drying of the secretion poured out by the ruptured vesicles, and pustules. In severe cases the child hardly sleeps at all on account of the constant itching. The course of the disease is seldom uniform; usually it undergoes curious alternations of improvement and relapse. An attack of acute gastric catarrh will often cure the skin affection completely for a time, but the eruption returns as badly as ever when the gastric derangement is at an end.

A sturdy little boy, aged five months, had suffered for a month from an attack of acute eczema infantile, which occupied the whole of the head, face, sides of the neck, and the greater part of the chest. The irritation was extreme. The child had worn the whole of the hair from the back of his head by friction of the occiput against the pillow. This infant had an attack of acute gastric catarrh with violent and repeated vomiting. The occema at once began to fade, and in the course of three days had almost.

completely disappeared. Directly, however, the vomiting had ceased and the appetite had begun to return, the cutaneous cruption reappeared, and in a day or two was as bad as before.

This form of eczema often continues for years, and may persist throughout the whole of childhood. In such cases, however, the eruption generally clears away completely from the head and face, but remains as a patchy rash, more or less extensively diffused over the body and limbs.

The diagnostic characters of the eruption are:—A red, inflamed, and rather infiltrated surface which gives rise to extreme itching, and presents many scales or crusts, and a more or less punctated appearance, i.e., the reddened skin has a dotted look from small points of a deeper red covering the surface of the patch. It is very important with regard to treatment to exclude scables, for this parasitic eruption has often the general appearance of eczenia; indeed, a true eczenia is often present on the body excited by the irritation of the acarus. In all doubtful cases the characteristic furrow produced by the itch insect should be diligently searched for for this, if discovered, is pathognomomic. It must be remembered that in young children scables mirely affects the hands and wrists, but is more commonly found about the buttocks, the belly, the feet, and the ankless Ecthymatous pustules seated upon the soles of the feet are very strong evidence in favour of scables.

Sometimes patches of procuses, especially if the silvery scales have been removed, bear a great resemblance to eczema in the dry or chronic form. In such cases we should carefully examine all the patches discoverable about the body. In eczema the patches are brighter in colour and lead well defined at the edges, the scales are thin and loosely attached, itching is a marked feature, and the parts affected are usually the fiexures of the joints and other regions where the skin is delicate and disposed to be moist. In provinciant the patches are well defined and pater in colour, the stabs are thicker and more adherent, and itching is of moderate intensity. Moreover, psoriasis attacks by preference the outer parts of the limbs where the skin is comparatively thick and coarse.

Suphditic eruptions in the infant are readily distinguished from ecrenal by their more coppery tint, the absence of itching to any notable degree, and the presence of hoarseness, snuffling, and other well-marked signs of

the syphilitic cachevia.

Ezzema capitis can scarcely be confounded with tines tonsurans or finess by any careful observer. There are no broken or brittle hairs, such as are so characteristic of the former disease; and the bright yellow cup-shaped crusts of favus have no resemblance to the scabs of impetigo of the scalp. It must be remembered, however, that a real ezzema capitis may occur as a complication in a late stage of tines tonsurans, but in such a case, when the ezzema is cured, the broken hairs of the parasitic disease can be discovered on careful examination.

I have known acute eczema in the early stage to assume a crescentic, slightly papular form, which has been mistaken for measles; but the absence of pyrexia and of cough or lachrymation will serve in such a case to

exclude the exanthem.

Treatment.—In cases of eczema we must not confine ourselves to local applications to the inflamed surface. Often the general health of the child will also require attention. Eczematous eruptions are common in children of scrofulous constitution or debilitated frame. In such patients the local remedies must be aided by general tonic treatment, if any permanent

benefit is to be obtained. In scrofulous children the general treatment recommended for that eachectic state should be adopted, and if the child is thin and spare, coll-liver oil will be found of service. Iron-wine is also a valuable remedy.

In obstinate cases arsenic may be usefully combined with the iron, and as children bear arsenic well the drug can usually be given in the same doses as are found beneficial in the adult. There is, however, no advantage in cases of arsenic in pushing the dose to the utmost limits of toleration. It is seldom necessary to exceed tive drops of Fowler's solution

three times a day.

If any tendency to acidity and flatulence is noticed, the alkalies are sometimes of service, and the quantity of fermentable matter allowed in the diet should be restricted. Too much importance, however, need not be attached to the subject of diet in the treatment of eczema. If a case is obstinate and resists ordinary remedies, I have not found the prohibition of sweets and fruit of much value in promoting a cure. Other observers, however, seem to have met with more success. In cases of flabby (not plethoric) children, Mr. B. Squire advocates an almost total deprivation of the fat-forming elements of food. He allows milk diluted with twice its bulk of water; dry toust, or dry biscuits; lean beef or mutton with all the fat carefully removed; white fish broibel; green vegetables (but not potatoes, turnips, carrots, or other vegetable roots), and cooked fruit unsweetened. Mr. Squire states that great improvement is seen in these cases within ten days of beginning this diet.

In all cases the digestive organs should be attended to, and any derangement remedied as quickly as possible. Constipation must be reheved, looseness of the howels arrested, and it should be our care to see

that the animal functions generally are in good order.

In cases of acute eczema tonic treatment is not always the best suited to cause the dosuppearance of the eruption. The disease sometimes attacks sturdy, florid children, with a good colour and plethoric habit. These cases should be treated with a mercurial purge, followed by saline laxatives to keep up a gentle action upon the bowels for several days. The child should take no meat, but should be put upon milk, broth, light puddings, and bread-and-butter. Again, in cases where there is an evident tendency to rheumatism, or a strong gouty element in the family history, guaracum often has a very marked influence in curing the disease. The simple timeture is the best preparation; it should be given in doses of twenty minims three times a day (to a child of ten years old).

The local treatment is of great importance in the treatment of eczema. When the eruption is very acute, stimulating outments should not be used, but the part should be kept moist with a simple water-dressing, or be bathed frequently with bran-water made by pouring boiling water upon bran and allowing it to cool. Dr. R. Liveing recommends the application to the affected surface of a powder composed of three drachms each of oxide of zinc and starch, and thirty grains of camphor. Over this is to

be placed a warm linseed-meal poultice

In a later stage alkaline wurm baths are useful. Dr Buckley recommends that for this purpose the carbonates of soda and potash and the biborate of soda be used; two to four teaspoonfuls of each to the gallon of water. To these two to four teaspoonfuls of dry starch are added. This bath should be used without soap, the child being merely soaked and bathed in the medicated water. After ten minutes or so he is removed, dried without friction, and then well dusted over the body with lycopo-

dium powder. Much washing is to be forbidden in cases of acute eczenia, as it is said to injure the process of repair. Dr. Buckley only allows it when the accumulation of exuded matter prevents the ointments from

reaching the diseased surface.

A useful form of bath is made by medicating the water with Wright's liquearbonis deturgens in the proportion of two drachus to the gallon. This can be given at first every night for half an hour; afterwards on alternate nights. Local patches of eczema are often benefited and in many cases quickly cured by keeping the part constantly moist with a lotion composed of two drachms of the liquearbonis deturgens to tenounces of water. To be effectual, however, the moistened rags in contact with the affected surface should never be allowed to get dry.

Zinc and lead are two of the most valued applications for eczematous patches. In the most variety a salve composed of oxide of zinc and the solution of the subscetate of lead—a drachm of each to the ounce of vaschut is very useful. In the dry, scaly form of the rash this ointment is made more efficacious by the addition of twenty to thirty grains of the ammonichloride of mercury and a drachm of the liq. carbonis deturgers. It itching be very distressing, the following application, taken from the pharmacopæia of University College Hospital, is of great service:—

B.	Calatoine (zinci carb.)	gr. xl.
	Zinci oxidi	gr. xxx.
	Glycerini	m xx.
	Aquam rose	5 j
M.	Sig.—To be painted with a brush on the affected	part.

In eczena capits the crusts must be first carefully removed. This is best done by covering them at night with a thick layer of lard and placing over this a large lineed-meal poultice. In the morning the softened crusts can be picked off with forceps or bathed away with warm water. When completely cleaned the scalp must be anointed with animonic-chloride of mercury omtinent diluted with an equal proportion of lard or we may use the salve composed of oxide of zinc and subsectate of lead already referred to. Children who have this form of impetiginous eczens in a severe degree are usually of strumous constitution and require tonic treatment. In obstinate cases of eczema of the scalp the disease can often be cured by tarry applications. Half an ounce of common tar, oil of cade or oil of birch (olei rusci) may be added to two ounces of glycerine of starch. This can be painted over the head twice a day. In very chronic cases one thorough application of undiluted liquid tar will sometimes produce a complete cure of the disease.

Eczema of the nostruls is usually cured very quickly. The crusts must be first removed from the nostrils by softening them with an orded plug and afterwards bathing with warm water. Unguentum hydrargym ammonio-chloridi can then be applied freely to the interior of the nostril with

a folded morsel of linen rag or lint.

In eczema tara it is often necessary to pull out the cyclashes, and in obstinate cases the operation is almost always necessary. The scabs must be carefully removed with tine forceps or the head of a large pin, and the edges of the hids be afterwards smeared with any of the outments which have been recommended. A mild mercural salve, perhaps, answers the best.

Eczema infantile is often a very obstinate complaint, and from the dis-

tress it occasions to the infant and through him to his mother or nurse, whose sleep is necessarily broken by the wakefulness of her charge, is one upon which it is important to make some immediate impression. When the disease is very acute and the skin red and intensely irritable, a rapid improvement is produced by large doses of quinine. I was led to employ the remedy in these cases from noticing its striking influence upon chronic urticaria in young children. In eczema a dose of two grains given at bedtime to a child of six or eight months old, and repeated every second night, reduces, in a remarkable manner, the general reduces, soothes the irritation, and consequently greatly relieves the child's distress. He begins to sleep better at night, and in the davtime is less irritable and fractious, Perchloride of mercury, given internally in small doses, is also a valuable remedy. A child of eight months old may take ten or fifteen drops of the solution (P. B.) three times a day, and the eruption often seems to improve greatly under its use. Thirty or forty drops of the infusion of rhubarb with a few grains of bicarbonate of soda, given regularly two or three times a day, will often also be followed by considerable benefit.

As in older children, the simple tincture of guanacum is a remedy which sometimes produces very rapid and decided improvement. I have seen the fiery reduces of the general surface fade, and the itching almost entirely cease under a week's use of this remedy given in doses of ten minims three times a day. When it succeeds, guaiacum seems to take all the acuteness out of the complaint, and reduces the cruption to a common vesiculo pustular rash which yields readily to ordinary applications.

The alkaline bath recommended by Dr. Buckley, and the bath medicated with the liq. cirbonis deturgers (see page 794), are both very useful. They, the latter especially, have great influence in relieving the itching, and the calamine and zure application already referred to may be used with the same object. Too frequent washing of the infant is bad in these cases, and the mother should be cautioned against disturbing the treatment by the too energetic use of soap and water.

Vaccination of the child is said in some obstinate cases to produce a complete cure of the disease, and many observers have borne testimony to the occasional value of this method of treatment. In successful cases the eczematous rash clears away completely in from one to four weeks after

the operation.

A method of treatment by covering the affected surface with some impermeable material, such as caoutchouc cloth, so as completely to exclude the air, has been found useful in many cases. According to E. Bessener this plan is especially applicable to cases of eczema of the scalp where there is much secretion. The india-rubber sheeting must be adapted accurately to the head, so as to fit like a skull-cap, and must be kept scrupulously clean, being regularly removed for washing and drying. By this means speedy improvement is said to be effected even in obstinate cases, so that the eruption will quickly yield to the ordinary ointments.

CHAPTER IV.

MOLLUSCUM CONTAGIOSUM.

Molleysonm contagiosum is a disease more common in childhood than a after-life. It is often seen in London children, especially amongst the poor, but appears to be less prevalent in country districts, or even in other large towns in England. The contagious nature of the disease is now will established. It may be communicated by one child to another, or live sucking infant to its mother's breast, and Dr. R. Liveing states that he lass seen nine children of the same school all affected with molliscum at the same time. In addition to being contagious the disease may also are

spontaneously.

Morbid Anatomy.—The exact seat of molluscum contagiosum is still matter of debate. Many observers hold the view that the little tunious have their seat in the schaceous glands of the skin. This was long and denied by Virchow, and after this authority others have supported the opinion that the bodies consist of a morbid growth of the cells of the cuts Sections of the tumours show that some are simple evat-like bodies, etlers are lobulated and surrounded by a fibrous capsule from which fine age pass between the lobules. The subject has been lately investigated area by Dr. Sangster, who concludes, as a result of his observations, that notluscum contagiosum is a disease of the epidermis in which three lavers take part. The external portion is formed by the cells of the rete, for an earful vertical section of the earliest specimens procurable the rete is seen a direct continuity with the lobular expansions of the new growth. The cells probably undergo simple hyperplasis, and those placed at the books are elongated and vertical. Next to these is a granular layer compact of polygonal cells more or less infiltrated with fat-globules. In the centre are roundish bodies, translucent and watery-looking, which are called "molluscum corpuscies." All these are arranged in masses which he m the meshes of a granular reticulum. The tumour is covered by the more superficial layer of the corium, and at its base is a network of fine ter-Hela.

Symptoms.—Molluscum contagiosum appears in the form of small white, hard, translucent swellings which gradually increase in size until they reach the dimensions of a pea, or even a nut. Their form is circular, with a flattened top, and at this part is seen a minute depression, which is supposed by those who recognise the sebaceous origin of the tumous to be the mouth of the sebaceous cyst. The smaller growths are usually sessile; the larger are pedunculated. A milky-looking thackish juncture has been squeezed out of the central depression, especially if a puncture has been previously made with the point of a lancet.

There is no itching or uncasiness connected with the growths in their ordinary state, but sometimes one will inflame and be converted into pustule. When left alone the tumours gradually dry up, leaving some

thickening at their site. The older ones are usually succeeded by a fresh crop.

Their seat is usually the skin of the face, the eyelids, or the neck, but they may be also seen on the chest, abdomen, genitals, and inner part of

the thighs.

Diagnosis.—These tumours must not be confounded with the molluscum fibrosum, which is altogether a different disease. These are small bodies of solid, somewhat gelatinous structure, and consist, according to Rokitansky, of a protrusion of the corium, "which is pushed forwards by accumulation of young, gelatinous connective tissue in one of its deepest meshes." They have no umbilication like the contagious molluscum, and no milky juice can be obtained from them by pressure.

Treatment.—The smaller tumours must be touched with nitric acid or other strong caustic. The larger must be divided with a lancet and the

contents squeezed out. A little caustic can be afterwards applied.

CHAPTER V.

THE PARASITIC DISEASES.

The varieties of parasitic disease of the skin which will be described are:—Scabies, due to the irritation of the scarus scabiei or the itch-insect; and certain vegetable parasitic fungi, viz., tinea tonsurans and tinea favora.

SCARIES.

The symptoms to which the acarus scabici gives rise are due to the irritation produced by the insect as it burrows in the skin. The female acaru works its way into the epidermis and forms a narrow tunnel called "cuniculus." The intense itching thus occasioned forces the child to relieve him self by scratching; and the consequences are seen in the wheals, papular vesicles, and even pustules which in a typical case are mixed up together in

a manner which is very characteristic of the complaint.

The cumculus or furrow appears as a whitish curved line, which whenewly formed may be easily overlooked; and in children, especially in infants, who are well tended and frequently washed, may escape notice altogether unless narrowly searched for. In hospital patients they are result discovered as they become darker and more distinct from small specified durt. The furrow is about the eighth of an inch in length, but may be longer, and to the naked eye closely resembles the scratch of a pin. Viewed with a lens it has a dotted look, and sometimes at one extremity a small white object can be detected, which is the female insect. With care this may be extracted with the point of a pin,

In infants the furrows are rarely seen on the wrist and between the fingers as they are in older children and in the adult. In these young subjects they must be searched for on the abdomen, the waist, the buttocks round the ankles, and on the soles of the feet, but in babies in well-to-defamilies, where cleanliness is properly attended to, the sign may clude the closest inspection. In young children after the age of infancy they are also usually scated on the buttocks, feet, and ankles. It is only in children of five or six years and upwards that they are often to be detected between

the fingers The scalp and face are rarely attacked.

The itching to which the presence of this parasite gives rise is of the most distressing character, and at night may be extreme. The child will be seen to dig his nails into the skin in his efforts to obtain relief. As consequence we find reddened linear scars from small furrows made by the nails; and as another result of the violent scratching, can usually discover small papules, often exceriated and tipped with a minute crust of dried blood, little vesicles, and even large deep-scated pustules. These latter are often seen on the soles of the feet. In very delicate subjects a real eczema may be set up either by the irritation of the nails or of the applica-

tions used for the destruction of the parasite; and large wheals of urticaria are far from uncommon.

Pragness. The simultaneous appearance of a variety of cruptions on the body of an infant is a very suspicious feature; and if with a lens we can succeed in discovering the characteristic furrow, no doubt can remain as to the nature of the complaint. In the case of an infant, the hands of the mother or nurse will be always found to be affected. Therefore in every case of doubt a careful inspection should be made of the hands of the attendant. In searching for the furrow in young children attention should be always especially directed to the buttocks, abdomen, and the soles of the feet. In older children the furrows may be seen between the fingers and on the wrist as in the adult; and as at this age, especially in boys, cleanliness of these parts is often neglected, the cuniculus seldom fails to be discovered.

Treatment. - Scabies can only be cured by local treatment which kills the paramitic insect, and the favourite and most efficacious remedy is the application of sulphur outment to the skin. It must be remembered that in children, in infants especially, the skin is delicate and scusitive to irritants. Therefore, while care is taken to make effectual use of the salve so that the acarus may be destroyed, we should avoid maintaining the cutaneous irritation by too prolonged or too zealous application of the outment. At mighttune the child should be first thoroughly washed over the whole body with a strong soap, and be then well bathed with warm water, so as completely to soften the skin and lay open such furrows as may be present by destroying their roofs. He should then be well dried, and an omtment made of half a drachm of precipitated sulphur to the ounce of lard must be rubbed into the skin of the whole body except, of course, the head. It is important that the salve be rubbed into the skin and not merely smeared over the In the morning the skin should be again thoroughly washed. This one application will cure the disease in most children. It is advisable, however, to rub a little of the cintment into the parts which seem to have been especially affected for two or three nights longer. We should then prose to watch the effect of the treatment. Itching often continues for some time after the parasites have been destroyed, as a consequence of the various forms of eruption set up by the acarus. In cases where it is doubtful whether the disease be cured or not, Dr. R. Liveing recommends an ointment made with the balsam of Peru (3 ij. to the ounce of lard).

If it be thought desirable to disguise the sulphur in the ordinary ointment, this can be done by a drop of creasote or oil of bergamot. Dr. Liveing prefers the precipitated to the sublimed sulphur, as being in a

tiper powder, and less irritating to the skin.

Instead of sulphur, an ointment may be used of liquid styrax (one part) and lard (two parts), or of powdered stavesacre and lard (Ji) to the ounce); but these are distinctly inferior to the sulphur. Ointments containing carbolic acid have also been made use of. It is advisable to well scald the underclothing of the patient, and after recovery to bake the outer garments, so as to insure the destruction of stray insects.

TINEA TONSURANS.

Tinea tonsurans is peculiarly a disease of early life. This affection is practically contined to children, and in the form of ringuorm of the scalp is one of the most obstinate and contagious of complaints. The disease is due to the presence of a fungus—the tricophyton tonsurans—which grows

in the internal root-sheath within the follicle, and the fine mycelium file ments penetrate into the hair between the fibres. These filaments are composed of cylindrical, tube-like bodies united in chains. At the surface of the hear the spores of the tricophyton are collected into little globular masses called condus, and in very old-standing cases these are also see to fill almost the whole thickness of the hair. As a consequence of the presence of the parasitic fungus the hairs are greatly thickened; the colour changes to a dull gray tint, and their brittleness causes them to break off short at a point immediately above the folliele out of which they issue. The fungus is seen not only in the substance of the hair, and coating their shifts, but also as a more or less continuous layer on the sm face of the scalp. Through this covering the free ends of the stubbly hair can be seen as black points. Later, as the parasitic matter accumulates the stumps of hair become completely ensheathed in the mycelium coat ing so that their situation is only shown by a projection of the surface of the layer. Bazin has compared the appearance thus produced to that of surface covered with hoar-frost.

In very old standing cases, acute inflammation may be set up in the hair-follules. This may lead to complete destruction of the hairs, so that

the part of the scalp affected remains partially bald.

Symptoms -On the scalp ringworm is seen in more or less circular patches. These in the earliest stage are slightly raised above the surface. and cause considerable itching. The hairs are not broken off, and have almost a natural appearance; but they will be found to be very brittle, so that they generally break if an attempt is made to extract them. As the disease proceeds the patches become distinctly circumscribed, and of pale fawn or slate-gray colour. Their surface is covered by a thick scurf formed of epithelial scales mixed with the fungoid growth. This scurgives a frested appearance to the patch, and adheres to the shafts of the hairs as these emerge from the follicles. The patches are not entirely covered by the short bristly hairs, for in many places these have faller out, leaving the surface bare. Those which remain are short and twisted They look as if cut off about a line or two above the surface of the scale and are thickened, dull in colour, and sometimes loose in their sockets. If the scurf has accumulated to a great thickness, the ends of the hair may be completely concealed from view.

The number of patches existing at the same time varies. Sometimes they are very numerous; indeed, in certain cases, the disease takes on diffuse form, in which little groups of scaly patches with bristly stumps of

hairs are seen scattered over the surface of the head.

When the tinea is scated on the skin of the body it is called times circulate. This is also a very common form of the disease, and is generally found on the face and neck, although it may occupy any part of the body or limbs. It is seen as a slightly clovated, roundish patch, of a light reaction, and of the size of a small pea. This begins to extend at its edges and as the circumference spreads, the central part fades and becomes less prominent, so that the circular patch is converted into a ring which continues to enlarge. With a lens the surface affected is seen to be covered with brainly scales; and fine vesicles are noticed at the margins. If two adjacent rings happen to touch one another, morbid action at the point of contact undergoes no further extension. In this way curiously irregular shapes are often produced. In the central part of the ring the skin although of comparatively healthy appearance, has yet a yellowish tint, and a roughened look from small scales. These spots cause a great deal

of irritation, and the fungus is no doubt often conveyed by the child's

mails from the hody to the scalp.

The general health of children affected with ringworm is often unsatisfactory; and the complaint seems to attack, by preference, weakly and scrofulous subjects. The latter, especially, have seemed to me to be pecu-

harly prope to the disorder.

Praynosis.—In cases of ringworm of the scalp the chief diagnostic point is the appearance of little rounded, scaly patches, on the surface of which the hours are thick, dull in colour, and broken short off just above the follicles. If one of these short hairs be removed with a pair of fine forceps, and placed with a drop of liq. potassis under the microscope, the characteristic masses of spores and mycelium filaments will be readily distinguished. If the hair-stump be allowed to soak in the drop of potash solution for an hour or two before inspection, the parasitic fungus will be

more readily detected.

At an earlier period than this the complaint is less easy to recognise, It is, however, of great importance to detect the affection in its early stage. It often happens that when one child of a family suffers from times tonsurans one of his brothers or sisters is brought for examination, because he has been noticed to have some irritation of the scalp. If, in such a case, rangworm be present, we shall find one or two small rounded patches, roughened with fine scales; and shall notice that although no stumpy hairs are to be seen, and the hairs have a natural appearance, they are yet them out with the forceps. From the first, therefore, in ringworm the hairs are brittle; and at an early period of the disease the circular shape of the patch on the scalp, and the brittleness of the hairs growing upon it, are the two points of chief diagnostic value.

An important question, and one upon which our opinion is often required, is that of whether in a given case the child is well. To settle this point correctly requires a very careful examination of the scalp. If any diseased stumps of hairs remain the complaint is not entirely eradicated. The child is therefore still a source of infection to others, and is himself hable to a relapse. Even a bald patch from which the hairs have been carefully extracted is not to be considered well. Often after an interval the stumps will shoot up again, the diseased bulb of the hair having been left in the follicle. It is not until the part lately the seat of the ringworm is seen to be covered with a line downy growth, in which no single stump of the old crop can be detected, that it can be said, confidently, to be free

from disease.

In some cases a difficulty is occasioned by the presence of eczema, which has invaded the scalp towards the end of an attack of ringworm. When this happens the evidences of ringworm may be quite concealed by the complication. We must therefore withhold a positive opinion until

the eczema has been cared.

The arremata is distinguished by its annular shape, and in cases of doubt by examination under the microscope of a scraping from the skin of the patch. The spot selected for this purpose should be a part of the ring towards the inner margin. This should be gently scraped, and the scaly matter removed is to be placed under the microscope, with a drop of hig. potasse. The jointed mycelium will then be recognised, and a few spores will usually be seen.

Treatment.—In cases of ringworm of the scalp, the measures to be adopted, and the probable efficacy of the treatment, vary considerably, ac-

cording as the disease is of recent or remote origin. Recent cases can usually be quickly cured, but chronic cases resist treatment with singular obstimacy.

Treatment will also vury according to the age of the patient. Ringworm can only be cured by local applications, and the measures to be adopted consist of the use of two classes of remedies, viz. those which irritate the skin and destroy the fungus, by exciting inflammation in the follicle, and those which kill the parasite without producing inflammation. Of these two classes the first is not suitable to very young patients. Blueters and violent caustics are dangerous remedies in the case of infants; and on account of the pain they excite are not to be used carclessly even on older subjects.

In injusts and young children it will be usually sufficient to wash the head thoroughly with soap and hot water every night, and after careful drying to paint the patch with tincture of iodine. After a few days the application can be changed to the unguentum hydrargyri ammonio-chloridi (P. B.) diluted with an equal proportion of lard; or equal parts of this salve and the unguentum sulphuris may be made use of. Either of these must be well rubbed into the affected parts of the scalp. Another useful application is the glycerine of carbohe acid diluted with a third part of glycerine. This may be painted on the patch with a stiff brush, or rubbed in with a piece of sponge tied to the end of a pencil.

In older children the treatment varies according to the acuteness or chromenty of the disease. In either case it is important to keep the harrout closely to the scalp in the neighbourhood of the patches. The disease is most infectious in its earlier stages, and becomes much less liable to be communicated when undergoing treatment. Of course care will be taken that towels, pillows, etc., used for the patient are not shared by the other children. As an additional precaution Dr. R. Liveing recommends that the carbolised glycerine, pure or diluted with an equal proportion of glycerine, should be well rubbed into the scalp every morning.

In a recent case, if the diseased patch be of small extent, it should be blistered by the liq. epispasticus. Afterwards, when the sore has healed, the cleate of mercury continent (five per cent.) should be well rubbed into the patch every night. It is useful to vary the application every week or ten days. Therefore, in addition to the preceding, a salve composed of sulphur continent (half an ounce) with white precipitate (twenty grains) may be used, or the continent 'recommended by Mr. Alder Smith, made by adding one parts of the unguentum sulphurs, may be employed. A favourite remedy in recent cases is the proparation known as "Coster's paste," made by adding two drachms of iodine to one conce of the colourless oil of tar. The application is to be painted thickly on the patch with a camel's-hair brush.

If under treatment the patches become very sore, so that the rubbing in of the cintments causes too great pain, Mr. Alder Smith recommends simply smearing the surface of the patch with the carbolic cintment during the day and poulticing with bread-and-water every night. These measures are often followed by a rapid cure. The penetration of the

¹ In mixing this continent no heat is to be applied. The two salves are first to be amalgamated and the carbolic acid is then to be rubbed in. The strength of this application can be varied according to the age of the child by increasing the proportion of carbolic soid and nitrate of mercury.

remedy into the hair-follicles is aided by previous removal of the hair-stumps. This epilation is done with a forceps made for the purpose. Care must, however, be taken in extracting the hair, as on account of its brittleness it is very apt to break off, leaving the bulb still in the follicle. It is also important to pick or wash off the fine crusts of scurf which, as long as they remain, are greatly in the way of efficient treatment. If the scah is difficult to remove it should be well greased with cold cream or exturated with olive-oil, and poulticed. It then becomes quite soft and

can be easily picked off.

In old-standing cases the above remedies are still of service, and careful epilation should be practised. Sometimes the long duration of the disorder seems to be due to ignorance or neglect; the remedies not having been applied effectually, or care not having been taken to remove the scurf before applying the salve. The energetic use of cleate of mercury cintment (five per cent.) is recommended by Mr. Alder Smith as a useful remedy even in chronic cases. After careful washing of the head the cleate, freshly made, is well rubbed into the whole scalp with a sponge mop. In the use of this application it is well to refrain from charging the mop too liberally with the remedy, lest the ointment run down the face and neck. At night, too, a linen cap should be worn on the head; and a thin towel is often necessary, applied as a turban, to prevent irritation of the face by the cleate. Any smearing of the skin elsewhere than on the scalp with the salve will produce a copious eruption of small pustules and much swelling. Every night the general application is to be repeated; in the morning the inunction is to be limited to the diseased patches. While this plan of treatment is being carried out the head must be washed only once a fortnight, but scabs or yellowish incrustations must be frequently removed by the forceps. If the cleate set up inflammation in the patch a speedy cure is usually effected.

The beneficial effects observed as a consequence of inflammation set up in the patch has led to the employment of special arritants with the express view of producing this result. Mr. Alder Smith, who has devoted much attention to this method of treatment, states that very long-standing cases can sometimes be cured by this means. He selects a small patch and applies to it croton-oil in moderate quantity with a small stiff camel's hair brush. After a few hours he applies a poultice and keeps it on the head all night. If severe inflammation has not ensued by the next day the process is repeated, and sometimes three or four applications may be needed. The object is to set up artificial "kerion," i.e., to produce a swollen, boggy, freely-discharging surface from inflammatory swelling and offusion in the tissues around the follicles. When kerion is produced no more croton-oil need be applied, but the part must be frequently fomented with warm water. After a few days the stumpy hairs become loose and fall out, and when the inflammation has subsided a smooth, shining, slightly-raised red surface is left "utterly destitute of all hairs and stumps and practically well." Eventually, the spot becomes again covered by new

healthy hairs.

This plan of treatment is only admissible in the older children, and the application should be confined to a limited surface if the patch is a large one. While in progress the carbolic glycerine or cleate should still be applied to other parts of the scalp. By this means Mr. Alder Smith states that he has had successful results in apparently incurable cases, and has never seen any internal irritation or crysipelas set up by the use of this powerful irritant.

In obstinate cases of ringworm of the scalp constitutional treatment is also required. Often the patients are analisis, scrofulous, or ill-nourished subjects, and cod-liver oil and tomes will be of service in improving their general health.

Ranguarm of the body (times circulate) is quickly cured by the application of a strong irritant. I am in the habit of painting the ring lightly with glacial acetic acid. This application causes some smarting for a short time, but usually cures the disorder at once. Sometimes a second application to parts of the ring is required after five or six days. Other applications which may be used are the strong tincture of iodine, and a solution of nitrate of silver (3 j. to the ounce).

TINKA PAVOSA.

Tinea favosa, or favus, is much less common in England than the preceding. Lake it it is a contagious disease, and is most frequently seen in scrofulous or neglected and badly-fed children. It is said to be common in some countries in mice and rats, and instances have been known in which the disease has been conveyed from these animals to the children of the family.

Favus is due to the presence of a cryptogam—the achorism Schoenleum. The mycelium and spores of this fungus may be seen without difficulty if a portion of the crust be put under the microscope, moistened with a drop of hig. potassa.

Symptoms.—Like tinea tonsurans, favus may occur on any part of the body, but is usually met with on the head. It begins in small scaly patches which cause much itching. In this early stage the disease bears a close resemblance to the ordinary ringworm, especially as the hairs growing on the diseased spot quickly lose their lustre and get duil in colour. They do not, however, as in ringworm, become brittle, so that there is no

difficulty in pulling them out with the forceps.

After a time small yellow crusts of about the size of a pin's head appear on the patch round the hairs. These crusts are at first convex, but afterwards as they enlarge become cup-shaped. They are of a sulphur-vellow colour, and vary from a split pea to a mass of the diameter of half an meh. Usually one or two hours pass through the centre. At first the favus crusts are placed singly, but they may afterwards become confluent, so as to form irregular-shaped masses, more or less extensive, and without the characteristic cup-shaped depression. The smell of the head covered by the cruster is very unpleasant and somewhat resembles that of mice. On the removal of a favus crust a depression is seen which is red and may be ulcerated. This, after a few days, disappears and the surface becomes again covered by a new crop of cup-shaped crusts. When the crusts become detached and fall off spontaneously the skin is merely seen to be stuned of a dark red or violet colour. As the disease goes on the hairs lose their natural tint. and grow loose in their sockets so as to be pulled out with ease. Their shafts are found on inspection to be irregular in their diameter at different points, and their roots are atrophied. They become fewer in number, and if the disease persists may disappear altogether, leaving the part completely hald.

On the body favus, like tinca tonsurans, forms rings, but these always remain small, seldom exceeding half an inch in dumeter, and have not the characteristics of tinea circinata. In other respects they bear a close re-

semblance to that disease. Afterwards, however, the characteristic crusts make their appearance at the edges and on the surface of the rings.

Diagnosis — When the disease is well developed on the scalp, the cupshaped crusts, and their sulphur-yellow colour are very characteristic. It is in the early stage before the crusts appear, and in the later stage when the crusts have lost their peculiar features, that the disease is liable to be mistaken. In the early stage the round, itching, scaly putches closely resemble common ringworm, but a distinction is supplied by the want of brittleness of the hairs in favos. In this disease the hairs can be pulled out of their follicles with ease, while in times tonsurans, if an attempt be made to extract the hair, it almost invariably snaps short off close to the scalp. In the later stage when the crusts have lost their distinctive character, especially if, as often happens, they have become complicated with a secondary eczematous eruption, the diagnosis is again less obvious, but the history of the case, and a careful microscopic examination of the crusts, which reveals the mycelium and spores of the cryptogam, will indicate the nature of the case.

Treatment. The crusts must be removed by saturating them with eliveoil, and then poulticing, or by constantly applying a strong sulphurous
acid lotion under a cap of ciled silk. When the scalp is quite denuded of
crusts and scabs the hair must be cut close to the skull, and steps can
then be taken to remove all the hairs from the diseased surface. This is a
work requiring much time, trouble, and patience; for each hair must be
carefully extracted by the forceps taking care to pull in the direction in
which the hair is growing. When this has been done, the special remedy
must be well rubbed into the scalp. Any of the applications recommended
for times tonsurans may be made use of, but one of the most effectual is
the cleate of mercury continent (five per cent.). This must be used carefully and with precaution that the continent does not run over the face.

fully and with precaution that the outment does not run over the face.

If the child be badly nourished or anomic, strengthening medicines and good nourishing food will be of service in aiding his recovery.

CHAPTER VI.

SCLEREMA.

Schreem, a disease which consists in a hardening of the cutaneous cellular tissue sometimes met with in young infants, is rarely observed in England, but appears to be less uncommon on the continent of Europe. The affection was first completely described by Underwood and Denman. Shortly afterwards Andry of Paris applied Underwood's description to a totally different lesion. This observer had frequently noticed at the Hospice des Enfants-Trouvés of Paris a condition in which the surface of the body be comes indurated as a consequence of subcutaneous adema. This disorder answered in many respects to Underwood's description, so that by a not unnatural confusion Andry adopted Underwood's term for his own account of adema of the new-born infant. After his time the error, thus begun, was perpetuated by successive writers until Parrot, to whose labours the pathology of infantile disease is so much indebted, showed clearly in his work on "Athrepsie" that two very different conditions had been hitherto confounded under the same title. In the present chapter the true sclerema will be first described; afterwards a short account will be given of "ædema of the new-born infant."

TRUE SCLEREMA.

True sclerema (induration of the cutaneous cellular tissue) is confined to new-born infants. This lesion is not to be confounded with the sclero-derma which attacks older children and adults. It occurs only, according to Parrot, in feeble infants and those wasted by bad feeding and unwhole-some conditions generally. According to Underwood it appears as a fea-

ture of the last stage of atrophy from digestive derangements.

Morbid Anatomy. The lesion consists in a curiously condensed state of the skin. This tissue is thinned as if from compression of the several The rete Malpighii and corium have sensibly lost thickness and the coils of the former layer can hardly be detected, so intimately are they amalgamated into a compact mass. In the adipose layer the fat-lobules are atrophied; their globules are wasted; and the connective-tissue bands are more numerous and thicker than in the normal state. According to Underwood, the induration of the cellular tissue may reach the sheaths of the muscles and even affect their fibres. There is never any subcutaneous cedema in the true disease. The blood-vessels, especially those of the papille, are so narrowed that their lumen is obliterated. These pathological changes form a very distinct condition—different on the one hand from cedema of the new-born, and on the other from scleroderms of older children and adults. They are the consequence, according to Parrot, of deaccation of the tegumentary tassnes owing to the draining away of fluid by the copious watery discharges from the bowels. There must, however, be some other cause for the pathological change, for in this country it is common enough to find young infants reduced by bad feeding and profuse watery diarrhops to a state of extreme emaciation; but selerema is a lesion

so rare that when discovered it is regarded as a clinical curiosity.

A form of sclerema called adipose sclerema is sometimes met with. This is different pathologically from the preceding. It is due to a solidification during life of the subcutaneous fat. According to Dr. Langer the melting point of infant's fat is 113° Fahr., or a higher point than the temperature of the body; while adult fat becomes perfectly fluid at a temperature of 96.8° Fahr. Hence, in the healthy child during life, a large proportion of its fat is not quite fluid but merely soft. If, from any reason, such as collapse, or the rapid withdrawal of heat which sometimes occurs in young infants as a consequence of depressing illness, the temperature of the body falls to 89.6°, this degree of cooling, according to Dr. Langer, is sufficient completely to solidify all the fat in the panniculus adiposus.

Symptoms.—The more special symptoms of sclerema are preceded by great impairment of nutrition and rapid wasting. The induration begins to be noticed at the end of the first week of life, or on the ninth or tenth day, or in some cases in the course of the second month. According to some writers it is especially in infants born fairly healthy and robust, and whose nutrition has become rapidly impaired that the cutaneous symptom

is most likely to occur.

The induration generally begins in the lower limbs and spreads thence to the long, the back, the chest, and eventually to the whole body, face included. In some cases the face is said to be attacked early, and the induration to spread from this part to the body. The affected skin, completely losing its natural softness and suppleness, becomes hard and unvielding, and pressure with the finger meets a resistance like that of horn or hardened leather. The folds and lines of the skin disappear, and partly from rigidity, partly from its close connection with the underlying tissues,

it can no longer be pinched up between the finger and thumb.

When the whole body is thus affected the induration prevents any bending of the joints, so that the limbs are stretched stifly out, and it is even said that the body may be supported in a horizontal position in the air by a hand placed under the lons. The rigidity of the face, especially of the lips and cheeks, makes sucking impossible, although the induration of this part is usually less advanced than that of other regions of the body. But for this, and for the little feeble respiratory movement of the abdomen and chest, the infant might be thought to be dead. Indeed, the tightly-compressed hps, the closed eyes, the mask-like face, the immobility of the frame, and the peculiar coldness of the surface, resemble death more nearly than life.

The lowness of the temperature is one of the striking features of this condition. The diminution of heat of the skin gives a marked sensation of coldness to the hand, and even in the rectum the temperature may fall far below the normal level. The body is not only cold, but seems incapable of being warmed; and even the occurrence of pneumonia has no appreciable effect in raising the temperature. The pulse and respiration fall in frequency. The former may be as low as sixty in the minute, the latter fourteen. The respiratory movements are hampered and feeble, and the

cry is weak and almost inaudible.

The course of the disease is very rapid. The induration proceeds apace. By the third day, according to Underwood, the skin has become intimately adherent to the tissues beneath. By the fourth the induration

has become general over the body. The child usually dies on the seventh day or soon afterwards,

GEDEMA OF NEW-BORN CHILDREN.

Edema of new-born children is also a very rare disease in this country. The subcutaneous tissue is infiltrated with yellowish scrosity which permeates between the adipose lobules, but never passes between the muscles or sinks below the level of the subcutaneous tissue. The fat is converted into a yellowish brown mass. In some cases there is congental attemptions.

Symptoms.—The disease begins, according to Valleix, before the third day of life, and the infants affected are almost always prematurely born or feeble. At first the child is noticed to be drowsy, and its skin is then found to be lived and very cold to the touch. The cedema is first noticed in the feet and thence spreads upwards to the thighs. The hands are next attacked, and later the ordenn appears in the genitals and the back. There are, however, exceptions to this order. Valleix states that he has known the ordena to appear first in the cheek; and sometimes the hands begin to swell directly after the feet have been attacked. The swelling is usually greater on one side than on the other, and tends always to sink to that on which the infant is lying. The affected parts pit with difficulty on pressure, but are swollen, and feel doughy and hard. The skin at first has a purple colour, especially at the extremities, and before death may have a jaundiced hue. It does not become adherent to the parts beneath as in the case of sclerems, and there is not the same stiffness of the joints. The temperature is low and may fall to 86°. It is little raised by the external application of warmth to the body. The child lies in a drow-y apathetic state, and scarcely attempts to cry. The pulse is small and very feeble; the breathing slow and interrupted; convulsions may come on, and the prostration may be increased by a watery diarrhua. Death may be hastened by intercurrent attacks of bronchitis, pneumonia, collapse of the lung, gastric or intestinal catarrh, etc. In some of the cases parenchymatous nephritis and albuminuris have been observed.

Diagnosis. The two diseases, selerema and ordems of the new-born, are very dissimilar, although they appear to be produced by much the same conditions, and certain symptoms are common to both. In each case we find a lowering of the temperature, a fall in the pulse and respiration, and a rigidity of the surface of the body. In each case the weakness is profound; and the infant lies motionless, refuses to suck, and more nearly resembles a dead child than a living one. There are, however, important differences in the two diseases. In sclerema the skin is tense and bard, and adheres firmly to the tissues beneath it; the joints are extended and stiff, and the whole body is rigid as if petrified or frozen. The firmness and rigidity increase day by day, and death occurs at the end of the first

or the beginning of the second week.

In ordenn the parts affected are firm and swollen, but can be made to pit on deep pressure. The swelling is partial and is most marked on the side upon which the child is lying. The skin can be moved over the parts beneath it; and the stiffness of the joints is but little pronounced, never prevailing, as in sclerema, to a sufficient degree to resist the force of gravity. The disease, also, is of longer duration than is the case with sclerema, and although very dangerous on account of the weakness of the

child, is not invariably fatal. The two diseases may exist together, or sclerema may succeed to cedema, as in a case reported by Parrot.

Treatment.—In cases of true sclerema little can be done. On account of the impossibility of sucking, the infant should be fed with white wine whey by means of the syringe feeder (see page 15). By this means a sufficient quantity of food can be introduced at intervals into the back of the throat when it is readily swallowed. In order to maintain the warmth of the body, the child should be wrapped in cotton-wool, and should be surrounded with hot water-bottles.

In the cedema of new-born infants the child, if he cannot suck, may be fed with the syringe as directed above. He should take white wine whey, milk and barley-water, and other varieties of food suitable to this period of life (see page 603). Warmth must be maintained as in the former case, and gentle frictions to the surface of the body are of service in helping to disperse the cedema.

INDEX.

Atrophy, progressive muscular, rare in Bowels aperients in danger of, 664 astrongent injectious in treatment of, childbood, as? Atropia in treatment of whooping-cough, constipation in, 661 Attitude, clinical value of, 8 Attitudes in spiral caries, 178 diagnosis of, 664 diarrhoea in, 002 Auscultation of chest, 403 diet in, 666 of skull in zickets, 138 bamerriage from 662 malted bread in treatment of, 666 BACILLUS of whooping-cough, 115 the tubercle, 191, 306, 510 morbid anatomy of, 660 natrition in, 662 Back, pain in, in caries of spine, 178 proguesis in, 665 raw meat treatment of, 666 in occebro spanni fever, 69 in small-pox, 56 stools in, 652 Back, staffness of, in caries of apine, 178 symptoms of, 661 Backward children, 395 temperature in, 663 Bacteria in umbilical phiobitis, 717 treatment of, 666 Balsam of Peru as an application for Brain, congestion of, 316 embies, 799 eausation of, 316 Barley-water in the hand-feeding of inconnection of, with convulsions, 317 diagnosa of, 319 fants, 604 Bath, the cold, 16 morbid anatomy of, 317 prognosis in, 320 the hot, 16 stup or m, 318 the mustard, 16 symptoms of, 318 Baths for eczema, 793 the therapeutic value of, 16 temperature in, 319 Belladonna rash, 783 tolerance of, in childhood, 19 treatment of, 391 Brain, hasmorrhage into (see Cerebral Bile-ducta, malformation of, 716 Ha morrhage i, 323 Bi.harria hematobia, 717 Brain, tumour of (see Cerebral Tumour), Bladder, atomy of, in enterte fever, 71 330 stone in, symptoms of, 767 tube realous of, 194 Breast-milk, analysis of, 597 Breath, offensive, in cases of constipation, diagnosis of, 199 633.9 symptoms of, 197 of fibroid induration of lung, 477 Blindness in cerebro-spinal fever, 71 of gaugrene of lung, 439 Blood, clotting of, in heart, 98, 550 of gangrenuos stematitus, fid8 extrav mations of, in sourcy, 254 of ulcerative stomatitis, 565 in anamia, 220, 232 Breathing, amphone, value of, 404 cavernous, value of, 404 Cheyne-Stokes type of, 264 in lene eythemia, 217 in lymphadenoma, 222 in purpura 24% hollow, in cases of enlarged bronchial in strols (see Melmas) glauds, 182 hollow, in cases of enlarged tonnis, possessing in diphtheria, 95 vomiting of (see Hæmatemesis) 244 Blotches, purpure, in cerebro-spanil fever, hollow, value of, 494 69, 70 irregular in tubercular meningitis, 359 in lymphadenoma, 224 Breathing stortorous, in membranous in purpora, 248 in scurvy, 258 croup, 95 In ordena of glottis, 408 in apostaneous gangrene, 168 in retro pharyngeal absects, 592 in scald of laryny, 107 Bone, arrest of growth of, in infantile spinal paralysis, 373 in stridulous laryngitis, 413 in rickets, 14) in suppuration about laryax, 420 Bones, perverted essification of, in rickets, in tubercular laryngitta 416 in warty growths on laryux, 417 scrofulous disease of, 178 syphilitic disease of, 206 Breathlessness (see Dyspness) in ausemia, 202 age most liable to, 208 in heart disease, 547 Bathriocephalus latus, 707 Breath sounds, conduction of, by chest-Bowel, perforation of, in enteric fover, 82 wall, 404 treatment of, 87 suppressed from impaction of foreign Bowel, prolapse of, from straining at stool, body in air-tubes, 528 weak, comeal value of, 404 Bowels, obstruction of, causes of, 668 Bright's disease, acute. 39 Bowels, niceration of, 660 convulsions in, 39

Bright's disease, acute, symptoms of, 39 Cancrum oris (see Stomatitis, Gangrentreatment of, 46 onsi, 567 Cardiac dropsy, 547 urine in, 30 Bright's downse, chronic, 752 amenius in 755 causation of, 753 diagnosis of, 759 stridulus, 269 dropsy in, 754 morbid anatomy of, 758 prognosis in, 760 symptoms of, 734 treatment of, 700 Bromide salts in convulsions, 284 in epilepsy, 202 in laryngismus striduina, 278 in whooping cough, 125, 284 mus, 261 rash, 292 in idiocy, 394 Bronchi, acute dilatation of, 485, 439 diagnosis of, 441 Bronchi, chronic dilatation of, 474 diagnos a of, 514 Bronchial glands, enlargement of, 178 asthmatic attacks in, 182, 523 diagnoses of, 185, 522 dyspaces in, 182, 523 earliest sign of, 158 opustance in 181 boarseness in, 182 cedema of face in, 191 Catarrhal), 434 physical aigms of, 182 prognosis in, 186 signs of pressure from, 181 stomatitis, 570 symptoms of, 180 terminations of, 181 treatment of, 148 veneus bum in, 182 Bronchiectasis, acute, 435, 439 obrone, 474 physical signs of, 476 Brouchitia, acute, 481 capillary, 4%3 causation of, 481 counter-irritation in, 486 diagnosis of, 485 expectorants in treatment of, 487 morbid anatomy of, 482 physical signs of, 486 prognosie in, 456 pulse in, 4%4 symptoms of, 483 temperature in, 483 treatment of, 486 Bronchitia, chronic, 484 symptoms of, 484 treatment of, 480 Bronchitas, tuberculous, 196 diagnosis of, 190 CALABAR bean, effect on pulse of, 312 in treatment of tetanus, 313 of tetany, 276 Calculi, renal, 263 Calculus impacted in urethra causing retention, 748 of kidney (see Kidney, Calculus of),

treatment of, 553 Carica of spine, symptoms of, 179 Carpo pedal contractions in laryngismus in stridulous laryngitis, 413 Cascation of giands, 173 Casciu of cow's milk, 507 of goat's milk 597 of human milk, 597 Castor oil in treatment of dysentery, 651 of inflammatory diarrhosa, 638 Cataract, congenital, a cause of nystag-Catarrh, gastrio (see Gastrie Catarrh), 801. intestinal (see lharrhers), 824 laryngeal see Laryngities, 406 proneness to, in nekets, 142 ra serofula, 176 Catarrh, pulmonary, 481 causation of, 481 in teething, 539 recurring attacks of, 488 symptoms of 483 treatment of, 486 Catarrbal pneumonia (see Pneumonia, Canterisation in treatment of gangrenous Cephalalgia (see Headache) Cerebellar tumour, symptoms of, 237 Corobral arteries, symbilitic degeneration of, 211 congestion (see Brain, Congestion of), flush in tubercular meningitis, 359 Cerebral hamorrhage, 322 diagnosis of, 328 from congestion of brain, 338 from municipatis 325 from tumour of brain, 328 from angurism of a cerebral artery, in a case of purpura harmorrhagica, 25% morbid anatomy of, 328 prognosis in, 320 symptoms of, 326 temperature in, 324 treatment of, 329 Cerebral embelism, case of, 548 murmur in rickets, 138 paralysis, diagnosis of, 377 pueumonia, 364 rhenmateam, 16tt, 159 Cerebral sinuses, thrombosis of, 351, 650 discression, 353 symptoms of, 351 Cerebral symptoms in croupous pneu-monia, 353, 364, 382 without cerebral discuss, 2 Cerebral tumour, 330 convulsions in, 833

Cerebral tumour, diagnosis of, 337 beadache in, 332 loss of special sense in, 833 morbid anatomy of, 330 nature of, 3d9 optic neuritis in, 338 paralysis in, 332 prognessa in, 339 symptoms of, 331 treatment of, 339 tremours in, 333 varieties of, 331 vomiting in, 332 Corebritis see Encephalitis), 351 Cerebro spanal fever, 68 blindness from, 71 cansation of, 68 coma in, 69 convulsions in, 70 deafness from, 71 diagnosis of, 72 duration of, 72 eruption in, 70 hadneinstions in, 70 in infants, 73 invasion of, 69 merbid anatomy of, 68 paralysis in, 70 prognosis of, 78 page in, 71 pupils in, 71 retinction of head in. 09 rigidity of joints in, 69 symptoms of, 69 temperature in, 70 treatment of, 73 urine in, 71 vemiling in, 70 Chest, auseu tation of, 403 defice to movement of, 401 distortion of, in rickets, 139 examination of, in children, 399 flattened, the, 490 infra mammary depression of, 400 movements of, in respiration, 400 pain in, from foreign body in zir-tubes, pain in, a sign of spinal caries, 178 percussion of, 402 pigeon-breasted, the, 400 pterygoid, the, 400 resonance of, in childhood, 409 Chest, retraction of, in cirrhosis of lung, in inspiration, 400 in pleurisy, 450 Chest, shape of, in chronic bronchitis, 485 in chronic tubercular phthiaia, 508 in congenital heart disease, 588 in emphysema, 193 Chest wall, resistance of, to percussion, Chieken-pox, diagnosis of, 49 daration of, 49 gangrenous, 49 symptoms of, 46

Chicken-pox, temperature in, 48 treatment of, 50 Childhood, convalescence in, 5 definition of, 5 diathetic tendencies in, 4 functional disorders in. 3 proneness to amenda in, 229 sudden death in, 5 270, 374 Children, forced feeding of, 15 Chilis, ausceptibility to, in early life, 4 in ricketa, 142 in acrofula, 176 ('hloral, in treatment of chronic albumin uria, 46 of convulsions, 284 of laryngismus stridulus, 273 Oblorate of potash in ulcerative atomatitie, 566 Chlorides, urinary, diminished in croupous pneumonia, 428 Chorea, 299 a cause of valvular disease of heart, 344 amenic in treatment of, 305 atro; by and contraction of muscle after, 363 causation of, 299 cold douche in treatment of, 303 connect, 304 death from, 304 diagnosis of, 304 ether spray in treatment of, 306 forced feeding in, 306 beart murmurs in, 303 massage in treatment of, 808 mental state in, 303 muscular weakness in, 303 pathology of, 300 prognosis in, 304 symptoms of, 301 temperature in, 309 treatment of, 305 urme in, 303 Circulation, changes in. at hirth, 536 fortal, at term, 535 in brain, 316 Circhosis of liver (see Liver, Circhosis of), 726 of lung (see Fibroid Induration of Lung), 473 Club-foot from infantile spinal paralysis, from intra-uterine convulsions, 277 Cod-liver oil, precautions in giving, 18 Cold douche in treatment of chores, 305 of malignant scarlet fever, 45 of rickets, 146 of serofula, 188 precautions in giving, 17 Cold spanging in enteric fever, 86 in inflammatory durrhosa, 637 in lagungiamus seridolus, 272 Cold water packing for animma, 235 Colic, cry of, 9 diagnosis of, 674 in dysentery, 047

Colic, in infants, 619 in purpura humorchagies, 240 in spontaneous gangrene, 166 repai, 766 treatment of simple, 623 Collapse, general, in intususception, 671 of lung (see Atelectusia), 461 Colon, sewere catarrh of, GH character of stools in, 635 symptoms of, #32 treatment of 6 9 Colour, bage, in Lyanosis, cause of, 539 Coma tree Stuport Complexion in amyloid disease of liver, 732 in anamile 232 in atrophic circhosis of liver, 727 in congenital atelectars, 462 heart disease, 538 in difficult digestion, 7 in empyems, 447 in gastric catarrh, 231, 611 in gastro intestina, hamorrhage, 656 in homophilis, 244 in harmorrhague purpura, 250 in healthy infants, in hypertrophicd spleen, 238 in inherited sypholic, 7, 210 in leacony themia, 217 in lymphadenoma, 234 in pleurisy, 446 in rickets, 141 in scurvy, 256 in tuberculosis scute, 195 pasty, from constipution, 619 Conduction of sounds in chest, 404 Congemual catamet, 261 rickets, 135 syphilis (see Syphilis, Inherited), 202 Conidia of trichephyton tonsurans, 800 Constitution, 817 after chronic dysentery, 650 after rhemmatism, 618 aperents for, 621 causation of, 617 diagnosts of, 620 diet for, 023 impaction of faces in, 620 in christic Bright's disease, 758 in entera fever, 77 in hamophilia, 246 in intussusception, 670 in porton ta, scute, 687 tuben ular, 600 in peri-typhilam, 680 in renal inadequaes, 758 in tubercular meningitis, 358 in typhlit s, 619 in alceration of bowels, 662 pepein in treatment of, 622 symptoms of, in infants, 610 in o ler children, 619 trentment of, 621 value of enemata in treatment of, 823 Consumption, palmonary (see Phthisis, Pulmonary), 502 Convalescence from scate disease, 5

Convalescence from chronic ducam, ? often slow in enteric faver, % Convulsions, 277 at onset of scate disease 3 bromides in treatment of, 234 canaston of, 277 chloral in treatment of 284 common in infance, 277 complicating lary agreenua, 208 consequences of, 350 description of, 279 diagnosis of 251 during destition, 278, 560 causes of, 560 from america of brain, 251, 278 from arachnoul ha morrhage 23 from blood possoning in marginal scarlet fever, 37 from cerebral disease 263 from cellapse of lung, 27c, 467 from carache, 278, 218 from lead given meannahr, 579 from peripheral irratation, 275 from ura mia, 282 treatment of, 46 imbeei sty after, 281 in scute tula re des a, 106 in cerebral ha mornings 324 in cerebro-spinal fever 69 in congenital malformation of huf-540 in encephalitia, 351 in enterio fever 79 in erympelas III in infantile spinal paralysis, 173 in intussuees prion, 631 in lone seythen in, 218 in lyn phaden ma, 227 in measles, 23, 25 in melana neonatorum, 656 in paralent meningitie, 349 in rickate, 142 in sensiet fever, 34 in spectameous gargrene, 170 in inhercular mening tie 3:0 in tumour of brack, 338 in un taleal phicture, 719 in whosping cough, 119 treatment of 121 internal .see Laryngisinus Stratt'est 267 nitrite of amyl in treatment of N paralyses after, 289 programms in, 253 rare as a consequ nee of indigest. rare in wasted infants 3, 277 reflex, frequent in rukete, 143 stupor after, 281 treatment of, 284 Cornes, ulceration of, in facial paralysis SHEET in small pox, 50 treatment of, 64 Coryan, mentiatinous, 38

Coryza, scarlatinous, treatment of, 64 Coryza, syphilitie 200 Cry in carnohe, 0 Cry in Infancy, absence of, 10 Cough, characters of, in bronchial asthma, significance of, 6 varieties of. in bronchitis, acuta, 483 Cry in a ferema, 807 chrome, 185 Cyanosis (see Heart Disease, Congenital), in catarrhal pueumonia, 437 5085 in chronic chargement of tonsile, 588 Cystitis, tubercular, 197 in chronic largegitis 48 in eirrh sets of lung, 176 DACTYLPIE, syphilitio, 207 ів стопрова рисимови, 424 diagnosis of, 212 in enlargement of bronchial glands, Deafness a cause of late talking, 395 from enlarged tonsile, 587 in follicular pharyngitis, 578 from followiar pharyagitis, 579 from quincy, 585 in fore go body in air-tubes, 528 in gangrene of lung, 408 in carries of petrous hone, 360 in measles, 24 in cerebro spinal fever, 71 in membranous croup, 95, 413 in enterio fever, 79 in inherited syphilis, 211 in measles, 23 in ordema of glottis, 409 in phthis s, neute, 506 chronic pur umonic, 509 in mumps, 66 tubercular, 311 in scrofula, 177 in retro-pharyngeal abscess, 592 Death, andden, in infancy, 5, 270, 374 in stridulous laryngitis 412 in pleurisy, 458 in tubercular lary ngitis, 416 Deformities in rickets, 137 in valvular disease of heart, 547 Deglutation in dightheria, 100 in warry growths on larynx, 417 Delirium, causes of, 263 early, with fever, in croupous pneu-monia, 262, 426, 420 evidence of, in infants, 363 in whooping-rough, 116 Counter-trutation, value of, 17 Cow pox. 51 Cramo tabes in inherited syphilis, 208 from debility, 203 in rickets, 138 from dimens nated embeli of brain, 158 Cretimison, 302 in acute infantile spinal paralysis, 373 absence of thyroid gland in, 393 peritonitis, 687 affinity of, with congenital rickets, 185 theumatism, 159 in cerebro-sp nal fever, 70 in chorea, 303 causation of, 392 defective sight in, 394 diagnosis of, 2003 in croopous pneamonia, 262, 425, 430 early ossitivation of skull in, 393 in debility, 262 in diphtheria, 95, 97 fatty masses above collar-bones in, 393 hearing normally acate in, 394 in dysentery a fatal sign, 651 in enterio fever, 77, 79 large size of head in, 394 in infants, 203 Vitchow's views of, 303 Crisis in croupous pneumonia, 429 in measles, 24 Croton chloral in treatment of whoopingin mumps, 66 cough, 126 in purulent meningitis, 350 in scarlet fever, 36, 43 in small pox, 60 Croup, fabre see Stridulous Laryngitis), 411 Croup, membranous, 95 apners in 90 in tubercular meningitis, 359 death in 94 significance of, 263 diagnosis of, 101 Dentition (see Teething), 555 diagnosis from foreign body in air-tubes, 101, 533 Desquamation in crysipelas, 112' in erythenia papulatum, 782 from odema of glottis, 490 in measter, 23 from retro pharyngeal abacess, Desquantation in scarlet fever, 36 earliest sign of, 43 postpooed, 36, 42 from stridulous laryngitis, 413 duration of 98 treatment of, 47 dyspicala in, 96 Diagnoses of ague, 146 nature of 89 of air-passages, foreign body in, 523 ргодиона ів. 102 of alopecta areats, 751 of anemia, 233 of asertes, 703 of asthma bronchial, 523 symptoms of, 95 trachectomy in, 105 treatment of, 105 Croupous pneumonia (see Pneumonia, of ateleptases, congenital, 468 Croupous), 423 post-natal, 469

Diagnosis of atrophy, infantile, 603 of bowels, ulceration of, 664 Diagnosis of harmorrhage into spinal coulof brain congestion of, 319 of heart, congenital disease of, 540 hemorrhage into, 328 valvular disease of, 550 tumout of, 837 of hydatid of liver, 740 of Bright's disease, chronic, 759 of hydreephalus, acute, 363 of bronchial asthma, 524 obsome, 345 of hydronephrosis, 703, 774 of hydrothorax, 455 giands, enlargement of, 185, 522 of brouchiestans, 514 of broughits, 4% of calculus of kidney, 767 of hysterical aphonia, 409 of ictorus neonatorum, 719 of cancrum oris, 560 of idiony, 395 of cardiac dyspines, 98 of infantile spinal paralysis, 377 of inherited syphilis 311 of cerebellar tumour, 337 of cerebral apoplexy, 328 of intussusception, 678 congestion, 319 of jannd ce, 719 embolium, 551 of kidney, calculus of, 767 paralysis, 377 tumour of, 773 amuses, thrombosis of, 858 of laryngiamna str dulus, 271 tumour, 337 of laryngitts, chropic, 409 of cerebro-spinal fever, 72 simple, 468 of chicken-pox, 49 of chores, 394 stridulous, 413 tubercular, 417 of club foot from infantile spinal paof larynx, absensa of, 420 ralysis, 377 of colic, 674 amercia of, 400 cederus of, 414 of congruital syphilis, 211 scald of, 409 malformation of heart, 540 warty growths of, 417 of construction, 620 of lencocythemia, 218 of liver, amyloid, 732 of contraction, tonic, of extremities, of liver, amyloid, cirrhosas ef, 729 275 of convulsions, 281 congestion of, 729 fatty, 736 hydated of, 740 of cretmism, 396 of croup, false, 413 membranous, 101 of lung, collapse of, 469 of cynnosis, 540 tibroid 478 of dentition, derangements of, 561 gazgrene of, 499 of diarrhusa, cholernie, 644 of lymptadenoma, 227 of measles, 26 inflammatory, 634 of megram, 296 of dilated bronchi, 514 of diphtheria, 100 of meningitis, purulent, 353 of dightheritic paralysis, 101 of dysentery, 650, 674 tubercular, 362 of molline um contagiosum, 797 of dyep upa, cardine, 98 of mumps, 67 paroxysinal, 521 of myelitis, acute generalised, 377 of eczema, 792 382 of emphysema, 494 of pertiernals, 788 of empyema, 454 of ordena of larynx, 414 594 of encephalitis, 353 of asiema of new born infanta, 808 of otitus, 352 of endocarditis, acute, 162 ulcerative, 162 of panelysis, cerebral, 377 of enterio fever, 63 diphtheritic, 101 of epidemic rescola, 31 facual, 3:0 of epilepsy, 200 infantile spinal, 377 of erysipelus, 112 pseudo hypertrophie, 387 of crythems simplex, 783 spassmodic spinal, 383 nodosum, 784 of pemphigus, 780 of facial paralysis, 869 of pericarditis, 161 of feecal masses in bowels, 186, 664 supporative, 103 of peritouitis, acute, 074, 689 tubercular, 697 of foreign body in air-tubes, 531 of gangrene of lung, 499 of perityphlitis, 683 of pharyugitis folicular, 579 herpetic, 580 spontaneous, 170 of gangrenous varietlin, 49 of generalised myrlitis, 877, 383 of hamophilia, 245 tuberenlar 589 of humorrhage, gustro-intestinal, 657 of phthisis, fibroid, 478

Diagnosis of phthisis, pulmonary, acute, 507
pulmonary, chronic, 513
Diagnosis of phthisis, pulmonary, acute, 514
rapid wasting in, 543
salicylate of lime in treatment of, 645 pulmonary, chronic, 513 of plennay, 453 stools in, 643 of pneumonia, catarrhal, 439 ceretral, 430 symptoms of, 642 temperature in, 643 стопровы, 480 treatment of, 644 of portio dura, paralysis of, 369 vomiting in, 643 of purpura hemorrhagica, 231 Diarrhea, chronic, 633 simplex, 251 diagnosts of, 034 of quinay, 588 of retro-pharyngeal abscess, 594 diet in, till) nstrate of silver in treatment of, 641 of rheumatism, acute, 161 of abdominal muscles, 161 prognosis in, 655 raw ment in treatment of, 640 of rickets, 148 symptoms of, 633 of ringworm, 801 of ringola, 787 of scables, 799 treatment of, 640 Diarrhuea from faccai accumulation in rectum, 619 diagnosis of, 621 of searlet fever, 41 of schreina, 808 in cases of ulceration of bowels, 662 of scurry, 257 Diarrhea, inflammatory, 629 astrongents in treatment of, 638 of small pox, 61 causation of, 129 of spasmodic spinal paralysis, 882 of spinal caries, 185 character of stools in, 630 cold bathing in treatment of, 687 diagnosis of, 684 of spleute tumour, 240 of spontaneous gangrene, 170 diet in, 636 of atomatitis, aphthous, 504 ipecacuanha in treatment of, 638 gangrenous, 569 ulcerative, 566 morbid anatomy of, 630 parenchymatous nephritis in, 683 of syphilis, inherited, 211, 602 prognosis in, 645 of teething, derangements of, 561 of tetanus, 312 of tetany, 275 rapid wasting in, 681 spurious hydrocephalus in, 632 symptoms of, 630 of thrush, 574 temperature in, 631 of timea circinata, 801 treatment of, 636 favora, 505 Diarrheea, benterie, 626 tonaurana, 801 treatment of, 628 of tuberculosis, 198 in infants 199 nocturnal, from lumbricus, 710 Diarrhron, simple, 624 causation of, 624 in infants from infantile atrophy, 6611 morbid anatomy of, 626 of tumour of brain, 38? relation of, to teething, 556 of kidney, 773 of typhhtm, 682 symptoms of, 625 treatment of, 626 of ulceration of bowels, 664 Diathesis, the scrofulous, 175 of urtienna, 780 of variou la, 49 two types of, 176 Diathetre diseases, the, 173 Diet in america, 234 of variola, fil of varioloid, 49 in ascites, 704 of variolous rescola, 61 in atelectoris, congenital, 464 of vulvitis, aphthous, 776 of whooping-cough, 123 post-natal, 4:3 in atrophy, infantile, 663 of worms, intestinal, 711 in Bright's disease, acute, 46 chronic, 761 in bronchitis, 487 in calculus of kidney, 768 Diaphragm, paralysis of, 100 diagnoids of, 102 Diaphragm, spasm of, 270 Diarrhua, choleraic, 642 in cancrum oria, 569 campation of, 642 in cerebral bemorrhage, 329 collapse in, 643 in chorea, 305 diagnosis of, 644 duration of 644 in congenital syphilis, 214 in constipation, 623 bypodermic injection of morphia in, in dentition, 502 in diarrhæa, choleraic, 644 koumiss in treatment of, 644 inflammatory, scute, 536 morbid anatomy of, 642 inflammatory, obronic, 640

Diet in urticaria, 786

Diet in diphtheria, 109 in dysentery, acute, 651 obrone, 653 in eczema, 793 in emphysems, 495 in empyema, 460 in enterio fever, 85 in epilepsy, 202 in erystpelas, 118 in erythema nodosum, 785 in extremittes, tomo contraction of, 226 in gangrene of lung, 501 spontaneous, 171 in gastrie entarch, 607, 615 in ha-mophilia, 246 in heart, valvular disease of, 553 in scterns neonatorum, 721 in sdiocy, 397 in intussusception, 677 in kidney, calculus of, 768 in laryngismus stridulus, 273 in laryngitis, 411 in laryux, suppuration about, 421 to liver, congration of, 724 cirrhoete of, 730 in lung, collapse of, 464, 472 fibroid, 480 gangrene of, 501 in measles, 29 in megrim, 298 in melena neonatorum, 659 та типора, 67 in night terrors, 569 in peritonitis, acute, 691 tubercular, 699 in pentyphlitis, 684 in pharynguis, herpetic, 581 tuberoular, 583 in phthinis, fibraid, 480 pulmonary, soute, 517 pulmenary, chronic, 517 in pleurisy 457 in pneumenia, catarrhal, 443 croupona, 452 in purpura, 253 in quinsy, 5×9 in rhenmatism, acute, 164 in rickets, 144 in sear et fever, 44 in selerema, 800 in acrofala 187 in scurvy, 258 in small pox, 63 in splenie tumour, 240 in spentaneous gangrens, 171 in stomatitis gangrenous, 563 nlocrative, 566 in syphile, infantile, 214 in teething, 502 in tetanus, 313 in tetany, 276 in thrush, 575 in tuberculesis, 201 in typhlitas, 484 in ulceration of bowels, 666

in whooping-cough, 124 Digitalis as a diuretic for chi dren, 47 value of, in heart disease, 553 Diphtherm, 89 albummera in, 95 and croup, identity of, 88 antiseptic sprays in, 104 cardine thrombosis in, 98 causation of, 90 complicating scarlatina, 38 complications of, 97 diagnesis of, 100 diet in, 103 failure of heart in, 99 false membrane of, 93 forced feeding in, 107 infection, duration of, m. 90 laryngcal (see Membranous Croup), 95 local remedies in, 104 malignant, 97 mild form of, 93 morbid anatomy of, 91 nasal, 98 paralytic lesions in, 90 proguests in, 102 secondary, 97 severe form of, 94 andden death in, 99 symptoms of, 93 temperature in, 95 treatment of, 108 urme in, 95 varieties of, 98 Douche, cold in treatment of chores, 305 of laryngumus steedulus, 272 of rickets, 146 of scrofula, 188 Doughe, cold precautions in giving, 17 therapeutic value of, 18 Dover's powder in treatment of dysentery, 652 of inflammatory diarrhom, 638 Drinking, mode of, aignationace of, 13 Dropey after searlet fever, 331 in acute Bright's disease, 39 in chrome Bright's disease, 754 in heart divease, 547 Drowstness after e nvulsions, 262, 280 ns a sign of cerebral disease, 262 from disturbed sleep, 320 in acquired hydrocephalus, 844 in ague, 149 in cerebral congestion, 318 in congenital atelectasis, 462 mulformation of heart, 540 in croupous parumoma, 425 in encephalitis, 351 in hypertrophic carrhosis of liver, 720 in lymphadenoma, 224 in malignant scarlet fever, 37 in purulent mesangitis, 349 in spasmodic stage of whooping-cough in spontaneous gangrene, 168 in tubercular meningitis, 359

Drowaineas in premia, 755 Ecseme, treatment of, 793 varieties of, 700 significance of, 263 Emboli of minute arteries as a cause of Ductus afternosus, time of closure of, 536 Dyspura, cardine, 98 causes of, 519 chorea, 300 Embolism, cerebral, case of, 548 of umbilical veins a cause of ligmor-rhage from navel, 654 definition of, 519 expiratory, 522 Embolisms, various, in cases of ulcerative endocard tis, 158, 547 from ascites, 701 from cletsing of blood in heart, 98 Emetics in treatment of bronchitis, 487 from congenital malformation of heart, 538, 541 of collapse of lung, 464, 471 from embarrassed pulmonary circulaof fibroid induration of lung, 480 ton, 427 of a ridulous laryngitis, 414 Emphysema, pulmonary, 491 from enlarged bronchial glands, 182, 323 enusation of, 491 diagnosis of, 494 from foreign body in air-tubes, 527 diet in, 495 morbid austomy of, 493 from interstitial cedema of lung, 39 from membranous laryngitia, 96 from orderen of glottis, 407 prognusis in, 495 from paralysis of diaphragm, 100 symptoms of, 493 from pressure on larynx, 420 on lung, 449, 519 treatment of, 495 Empyema, 477 from retro pharyngeal abscess, 592 clubbing of fingers in, 455 from sarcoma of kidney, 771 from scald of glotts, 407 diagnosis of, 454 diet in, 460 from softened ribs in makets, 519 symptoms of, 447 from stradulous larvagitis, 413 temperature in, 447 from supportation about larguz, 419 treatment of, 458 Encephalius, 347 in acute palmonary phthisis, 506 in bronchiel asthma, A21 convulsions in, 351 in expulsey bronchitis, 484 diagnosis of, 162 duration of, 351 in catarrhal pneumonia, 437 merbid anatomy of, 847 іп стопроик расписация, 427 in diphthema, 96 paralyais 121, 351 in peritonitia, 687 pulse in, 351 in pleurssy, 449 stupor in, 351 in palmonary gangrene, 498 symptoms of, 351 in valvular disease of heart, 547 temperature in, 351 inspiratory, 523 treatment of, 354 Dyspuces, paroxyamal, causes of, 519 Endocarditis, rheumatic, 155 definition of, 520 diagnosis of, 521 diagnosis of, 162 morbid anatomy of, 154 prognosta in, 163 EAR, hamorrhago from, in hamorrhagic purpura, 240 rest, importance of, in, 165 treatment of, 165 in mel saa neonatorum, 656 Endocarditis, alcerative, 154 in pertusus, 118 diagnosis of, 102, 552 morbid anatomy of, 154 symptoms of, 154, 547 Ear, inflammation of middle (see Otitis). malformation of, in the idiot, 896 Enemata, astringent, in diarrhosa, 639 position of, in the idiot, 396 in dysentery, 653 in nicoration of bowels, 667 Earnobe, convulsions from, 348 peculiar cry of, 9 Enemata, sedative, in prolapsus ani 639 signs of, in the infant, 348 value of, in treatment of cometipation, Eclampsia (see Convulsions), 277 Ecthyma, 780 033 Enterie fever, 74 Eczema, 789 causation of, 74 capitis, 790 cervical neuralgia in, 79 character of stools in, 77 camation of, 780 diagnosis of, 792 complications of, 81 dust in, 790 constipution in, 77 deafness in, 72 mfantale, 791 rubrum, 790 defective action of kidneys in, 82 simplex, 790 diagnosis of, 83 symptoms of, 790 from acute gastrio catarrh, 88 tarni, 791 from scute tubercular perstenitis, 808

Temperature in fasting infants, 10 in infantile atrophy, 602 Tenderiess, general, in scurvy, 256 in severe riokete, 137 Tenesinus in cases of colitis, 632 of col.tin, treatment of, 638 of dysentery, 649 of intessuspeption, 670 of polypus of rectum, 657 Terrore, night, 121 treatment of, 563 Tetanus, idropathic 308 calabar bean in treatment of, 313 causation of, Just committee of cry in, 310 chloral in treatment of, 313 diagnosis of, di2 duration of, 311 morb 1 anatomy of, 300 opisthotonos in, 310 prognosis in, 312 rapid westing in, 310 seds ives in treatment of, 813 apasma in, 310 stiffness of jawa in, 310 temperature in, 310 tome rigidity in, 310 trestment of, 313 Tetany (see Extransitios, Tonic Contraction of), 274 Thermometer, value of, 11 Thirst, intense, in choleraic diarrhora, 643 signs of, in the infant, 8 Throat, diseases of mouth and, 555 in fammation of (see Pharyngitis), 576 inspection of, 13 Thrombosis of heart, 98 treatment of, 108 of cerebral sinuses see Cerebral Sin-Thrush, 571 applications for, 575 causation of, 571 diagnosis of, 574 diet in 575 general atrophy in, 572 morbil anatomy of, 573 necessity of cleanliness in treatment of, 575 oidium albicans of, 579 prognosis in, 574 spurious hydrocephalus in, 573 symptoms of, 573 te aperature in, 573 treatment of, 574 Thymus gland, syphilitic disease of, 205 Thyroid body, absence of, in the cretin, 203 Tinea civinata 800 Tinea farma, 801 diagnosis of, 803 symptoms of, 804 Tinea tonsurans, 799 croton oil treatment of, 803 diagnosts of, will sympoms of, 800

Times tonsurans, treatment of, 802 Tongue, appearance of, in gustric catarrh, 611 in worms in the alimentary canal, 709 Tongue, ulceration of, in whooping-cough, Tomes, general value of, 18 Tonsils, chronic enlargement of, 584 alteration of features from, 587 causation of, 584 cough from, 588 deafness from, 587 effect of, on general health, 587 hellow breathing from, 583 morbid anatomy of, 585 nasal voice from, 587 symptoms of, 586 treatment of, 589 Tonsils, inflammation of (see Quinsy), 584 Tortreollis, rheumatic, 159 Traches, pressure on, causing stertor, 183 Tracheutomy, accidents after, 107 in membranons croup, 105 Tremours in cerebral tumour, 838 in enterte fever, 84 in tubercular maningitis, 360 significance of, 263 Tricophyton tonsurans, 799 Tube, stomach, for forced feeding, 15 Tubercular meningitia, 355 abdomen in, 359 auromalous cases of, 362 breathing in, 359 causation of, 355 cerebral flush in, 359 coma in, 360 constipation in, 359 convulsions in, 300 deceptive improvement in, 360 diagnosis of, 362 from acute gastric catarrh, 364 from cerebral paeumonia, 364 from enteric fever, 83 from mali utrition 1943 from simple meningitis, 365 from sparious hydrocephalus, 363 drowsin se in, 359 fontanelle, in, 350 hewlache in 359 inadious beginning of, 368 morbid anatomy of, 356 nystagmus in, 360 paralytic stage of, 360 premonitory stage of, 357 primary form of, 361 progress in, 365 pulse in, 358, 359, 361 pupils in, 359 retention of urine in, 859 rigidity of joints in, 360 secondary form of, 301 squinting in, 359 stage of invasion of, 358 of irritation of, 359 symptoms of, 357 temperature in, 358, 359, 361

Tubercular meningitis, tongue in, 358 fremia, convulsions in, 382 Uramic potsoning cruse of, 33 aymptoms of, 19, 282, 156 treatment of, 365 twitchings in, 360 vomiting in, 358 treatment of, 46 Urea, exerction of, increased in croupon Tuberculosis, acute, 190 pneumons, 4.6 in the child, 745, 758 bactlus of, 191 causation of, 190 diagnosis of, 198 Ureter, impaction of calculus in, 766 from acute gastric catarrh, 198 Uric acid, formation of, in the urina from infantile atrophy, 199 passages 783 from typhoid faver, 83 in regal ducts a cause of hematuris duration of, 198 in urine a cause of wetting of the bed, 748, 766, 765 forms of, 190 morbid anatomy of, 191 ordema of lega in, 195 pain in urethra from, 765 onset of, 194 Urinary calcult, 763 physical signs of, 196 Urinary casts in acute desquamntive na prognous in, 200 phritis, 39 reduction of pyrexia in, 200 symptoms of, 194 in chrome Bright's disease, 755 in passive congestion of kidney, 740 Urinary deposits, 757, 758 secondary to empyema, 453 Urine, albumen in see Albuminuria) blood in (see Hamaturia) temperature in, 195 treatment of, 200 Tumour of brain (see Cerebral Tumour), 330 characters of healthy, 745 flow of, a sign of rocovery in conver-sions, 283 Turpentine as an anthelmintic, 712 Tympanie membrane, rupture of, in whoopin ascites, 701 ing cough, 119 Tympanitis, treatment of, 692 Typhints, 618 in acute generalised myelitis, 377 phthisis, 506 rhoumatism, 154 tuterenlosis, 195 causation of, 678 diagnosis of, 683 diet in, 684 In ague, 149 prognosis in 693 in atrophic cirrhesis of liver, 727 in Bright's discare, acute, 39 symptoms of, 679 treatment of, 684 chronic, 756 in cerebro-spinal fever, 71 in chorea, 303 Typhoid fever (see Enterio Fever), 74 Utterration of bowels (see Bowels, Ulin congenital disease of heart, 589 ceration of), 660 in cystetes, tubercular, 197 Ulceration of mucous membrane in infanin dir htherm, 95 tile syphiles, 2 4 382 in dysentery 349 in lymphadenoma, 222 in enteric fever, 78 in gastric catarrh, 611 in ulcerative stomat tis, 563 in hamorrhagie purpura, 249 In hydroneplacus, 772 Ulceration of throat in diphtheria, 93 in searlet fever, 34 ... in hypertroplus carrhosis of liver in tubercular pharyngitis, 581 70% Ulceration of vocal cords in infantile apply ins, 3 4 in leterus neonatorum, 716 in tubercular laryogitis, 416 in infantile tetanus, 310 in inflaminatory dustributa, 683 Ulceration, sub-lingual, in whooping-cough, in lencocythenita, 224 Ulcerative endocorditis, 154 in meas es, 24 stomatitis (see Stomatitis, Ulcerative), in membranous croup, 89, 414 364 in preumonia croupous, 426 Umbilical artentis, 718 in rheumatism of abdominal muscles Umbilical phicbitis, 717 159 diagnosis of, 720 pathology of, 718 prognosis in, 720 in rickets, 134 in sarcoma of kidney, 770 in scarlet fever, 39 symptoms of, 719 treatment of, 720 in source 357 in spontaneous gangrene, 170 Umbilical vein, hamorrhage from, 654 in thrush, severe cases of, 574 Umbineus, hemorrhage from, 656, 717 in ulcerative endomiditis, 158 Unconsciousness in infante, test of, 262, in ambilical phichetes, 719 indienn in, test for, 6.35 milky, from urates, 745 Uramia, blood in urine in, 38

INDEX, 843

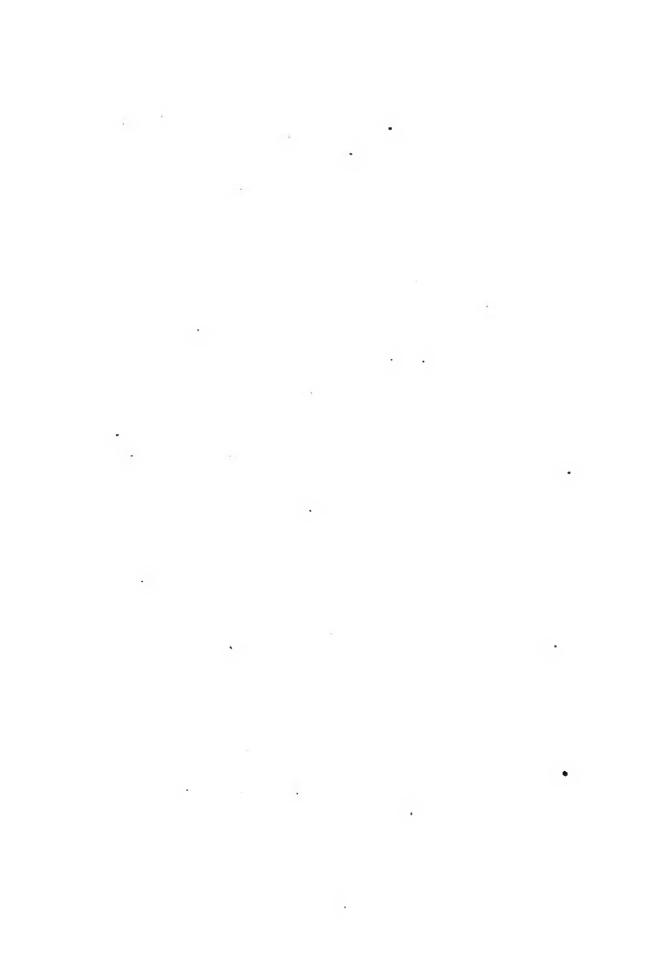

Urine, nocturnal incontinence of, 748	Voice, alteration of, in foreign body in air-
a symptom of epilepsy, 291	tubes, 530
of sand in water, 765	in infantile syphilia, 210
of small-pox, 61	in membranous croup, 95
causation of, 748	in scald of glottis, 407
pathology of, 749	in stridulous laryngitis, 412
treatment of, 750	in suppuration about 1 rnyx, 490
Urine, offensive, from catarrh of bladder,	in tubercular laryngitis, 416
746	in warty growths on larynx, 417
Urine, retention of, causes of, 748	Voice, nasal, in enlargement of tonsils, 587
from thread-worms, 748	in quinsy, 585
in dysentery, 649	in retro-pharyngeal abacess, 592
in enterio fever, 78	in tubercular pharyngitis, 582
in peritonitis, acute, 687	Vomiting a sign of cardiac failure, 99
in tubercular meningitis, 359	oerebral, 264, 558
in tumour of medulia oblongata, 337	chronic in infants, treatment of, 607
Urine, scanty secretion of, 744	clinical importance of, 2
in choleraic diarrhesa, 643	in amyloid liver, 732
Urine, yellow, from bile pigment, 746	in atrophic cirrhosis of liver, 728
Urticaria, 785	in capillary bronchitia, 464
diagnosis of, 786	in cerebral tumour, 832
in cases of purpura, 248	treatment of, 339
symptoms of, 785 treatment of, 786	in choleraic diarrhoea, 643
treatment of, 786	in chronic Bright's disease, 755
Urticaria pigmentosa, 786	in fibroid induration of lung, 477
Uvula, destruction of, in tubercular pha-	in gastrio catarrh, 611
ryugitis, 582	in idiopathic anemia, 233
cedematous in quinsy, 585	in infantile atrophy, 607
	in inflammatory diarrhosa, 631
VACCINATION, 51	in intussusception, 672
efficient, 58	in lymphadenoma, 224
in treatment of comma, 795	in malignant diphtheria, 97
mode of operating in, 58	in peritonitis, simple soute, 687
protective value of, 58	in peri-typhlitis, 679
sequelæ of, 53	in symmetrical gangrens, 168
temperature in, 52	in typhlitis, 679
Valvular disease of heart (see Heart,	in tubercular meningitis, 358
Chronic Valvular Disease of), 544	in umbilical phlebitis, 719
Varicella (see Chicken-pox), 48	in whooping cough a cause of danger,
Variola (see Small-pox), 55	118
Varioloid, 61	Vulva, gangrene of, 170
diagnosis of, from varicella, 49	treatment of, 171
Veins, fulness of superficial, in catarrhal	Vulvitis, aphthous, 776
pneumonia, 437	diagnosis of, 776
in cirrhosis of liver, 728	symptoms of, 776
of lung, 477	treatment of, 777
in enlarged brouchial glands, 181	Vulvitis, catarrhal, 775
in tubercular peritonitis, 695	symptoms of, 775
Venous hum from enlarged bronchial	treatment of, 776
glands, 182	, and the second
Ventilation of bed-rooms, importance of, 234	Walk, peculiarities of, in cerebellar tu- mour, 337
Vermiform appendix, ulceration of, 678	in pseudo-hypertrophic paralysis, 385
diagnosis of, 683	in spasmodio spinai paralysis, 382
peritonitis from, 682	Walking late in chronic bydrocophalus, 3-3
prognosis in, 683	in idiocy, 392
symptoms of, 682	in rickets, 143
Vibration, vocal, often absent in children,	Warty growths on vocal cords, case of, 417
401	Wasting, general, from deficient nourish-
Vision, disorders of, in megrim, 295	ment, 596
impaired, in cerebral tumour, 382, 388	Wasting of muscle in acute infantile spinal
Vocal cords, ulceration of, syphilitic, 204	paralysis, 375
tubercular, 416	in chorea, 303
Voice, alteration of, in ansemia of larynx,	in hamorrhage into spinal cord, 377
TOD	in pseudo-hypertrophic paralysis, 386
in chronic laryngitis, 408	in ricketa, 134

Wasting of third cerebral nerve from pressure, 875 Whooping-cough, diet in, 124 digestive derangements in, 116 rapid, in choleraic diarrhose, 643 Wetting the bed a symptom of epilepsy, 291 of sand in water, 785 of small-pox, 61 Wetting the bed (see Urine, Nocturnal Incontinence of), 748
White lead paint as an application for erysipelas, 118 White wine whey, 608 in treatment of gastric catarrh in infants, 608 in treatment of post-natal atelectasis, 464 in treatment of thrush, 575 Whoop, occasional absence of, in pertuasis, 117 Whooping-cough, 109
absence of whoop in, 117 antiseptic sprays in treatment of, 126 atropia in treatment of, 124 bacillus of, 115 bronchitis in, 120 catarrhal pneumonia in, 120 stage of, 116 causation of, 114 collapse of lung in, 119 complications of, 117 convulsions in, 119 diagnosis of, 128 treatment of, 127 croton chloral in treatment of, 126 diagnosis of, 122

duration of, 117 of infection in, 114 emphysema of lungs in, 120 epistaxis in, 117 fungus of, 115 hæmorrhages in, 116 morbid anatomy of, 114 mucous disease after, 121 nature of, 115 nervous accidents in, 118 agitation in, 115 paroxysms of, 116 pathology of, 114 physiognomony of, 7 prognosis in, 123 pulmonary lesions in, 119 quinine in treatment of, 125 rupture of tympanic membrane in, 18 sequelæ of, 120 spasm of larynx in, 118 treatment of, 127 spasmodic stage of, 116 sub-lingual niceration in, 117 symptoms of, 115 treatment of, 124 vomiting in, a cause of danger, 118
Worms, intestinal, 705
causation of, 707
diagnosis of, 711 symptoms of, 708 treatment of, 711 varieties of, 705
